Welcome

Welcome to the 24th Annual Congress of the ECSS

Welcome to Prague

Dear Colleagues,

On behalf of Charles University and ECSS, we would like to extend a warm welcome to join us at the 24th Annual Congress of the ECSS in Prague, Czech Republic, from 3-6 July, 2019. The congress will take place near the heart of the city at the newly rebuilt Prague Congress Centre (PCC), overlooking the Prague Castle and River Vltava, surrounded by all of the amenities this old and dynamic city has to offer.

The mission of the PCC is to create a warm and friendly atmosphere for inspiring scientific, medical, commercial and political meetings that will enable us in our work to make the world a better place.

Our conference topic "Uniting the World through Sport Science" reflects the role of sport and physical activity in the modern world. During the congress you will not only have the opportunity to expand your network, but also to be privy to presentations that incorporate a wide variety of topics connected with sport and physical activity. The congress will bring together international experts to provide the latest research in sportd and exercise science, and the experience and vision of professionals who are dedicated to one of the most fascinating areas of sport. Physical activity and sport represent important strategies used to alleviate chronic diseases and improve the quality of daily life in today's world.

If you would like to learn more about the Czech Republic, we recommend visiting the city which has more than a thousand years' worth of history.

Enjoy the congress, enjoy Prague!

Václav Bunc
Congress President

CP-PM01 Molecular signaling response

EFFECTS OF ORAL LACTATE ADMINISTRATION ON ENDURANCE TRAINING-INDUCED MITOCHONDRIAL ADAPTATIONS IN MICE

TAKAHASHI, K., KITAOKA, Y., YAMAMOTO, K., HATTA, H.

THE UNIVERSITY OF TOKYO, KANAGAWA UNIVERSITY

INTRODUCTION: Recent studies have revealed that lactate is not merely an intermediate metabolite, but also a signaling molecule which induces mitochondrial adaptations. However, effects of oral lactate administration on muscle mitochondria remain to be clarified. In this study, we tested the hypothesis that oral lactate administration results in enhanced mitochondrial biogenesis.
METHODS: [Chronic experiment] Eight-week-old male ICR mice were assigned to four groups as follows: saline-sedentary group (n=8), lactate-sedentary group (n=9), saline-training group (n=8), and lactate-training group (n=8). Mice were orally administrated either saline or sodium lactate (5 mg/g of body weight) 5 days a week for 4 weeks. Training group performed a treadmill running (speed: 20 m/min, duration: 30 min) 30 minutes after each administration. Tissues were harvested 24 hours after the last administration.
[Acute experiment] We investigated to seek lactate-activated signaling pathway. Mice were assigned to four groups same as the chronic experiment (n=8, respectively), and orally ingested saline or lactate, followed by a sedentary period or a treadmill running as described above. Tissues were quickly taken 60 minutes after the oral administration (i.e. immediately after the treadmill running).
RESULTS: [Chronic experiment] We confirmed that oral lactate administration increased blood lactate concentration with or without the endurance exercise (2.8 ± 0.3 mmol/L vs. 9.4 ± 0.7mmol/L, $p<0.01$). Following the experimental period, exercise training significantly increased maximal activity of citrate synthase and cytochrome c oxidase (COX), and COXIV protein content in both soleus ($p<0.05$) and plantaris muscle ($p<0.01$). In addition, main effect of oral lactate administration (i.e. positive effect) on maximal COX activity was observed in the soleus muscle ($p<0.05$), but not in the plantaris muscle. Given that murine soleus muscle has more oxidative muscle phenotype compared to plantaris muscle, we next examined heart muscle. Oral lactate administration, but not exercise training, significantly increased maximal COX activity in the heart ($p<0.05$).
[Acute experiment] We analyzed phosphorylation state of AMPK, ACC, p38 MAPK, and CaMKII, key kinases for mitochondrial adaptations, in the skeletal muscle. Endurance exercise significantly increased ACC and p38 MAPK phosphorylation in the soleus ($p<0.05$) and plantaris muscle ($p<0.05$), and AMPK and CaMKII phosphorylation in the plantaris muscle ($p<0.01$). However, there was no significant effect of oral lactate administration on phosphorylation state of these proteins.
CONCLUSION: Our results suggest that oral lactate intake enhances mitochondrial biogenesis, especially in oxidative muscles. These lactate-induced mitochondrial adaptations do not appear to be associated with the greater activation of AMPK, p38 MAPK, and CaMKII.

A NETWORK-DRIVEN APPROACH TO IDENTIFYING MECHANISMS OF CONTRACTION-INDUCED MUSCLE ADAPTATION AS A FUNCTION OF AGE

WILLIS, C.R.G., AMES, R.M., DEANE, C.S., PHILLIPS, B.E., WEEDON, M.N., BOEREBOOM, C., ABDULLA, H., BUKHARI, S., LUND, J.N., WILLIAMS, J.P., WILKINSON, D.J., SMITH, K., GALLAGHER, I.J., KADI, F.

UNIVERSITY OF EXETER, UNIVERSITY OF NOTTINGHAM, UNIVERSITY OF STIRLING, ÖREBRO UNIVERSITY.

INTRODUCTION: Optimisation of resistance exercise (RE) remains an important goal for muscle growth and maintenance across ages. However, the molecular pathways underpinning muscle adaptation to the two contractile components of RE (i.e. eccentric (ECC) and concentric (CON)) remain poorly defined in youth and older age. Here, we account for the complex and coordinated nature of interactions among genes by employing an advanced network-driven approach to further investigate the molecular signatures of contraction-specific muscle adaptation as a function of age.
METHODS: RNA-sequencing data was generated from vastus lateralis biopsies of eight young (18-30 y) and eight older (65-75 y) exercise-naïve volunteers collected at rest and 5 h following unilateral CON and contralateral ECC leg contractions. Weighted Gene Co-expression Network Analysis (WGCNA) was subsequently applied to identify distinct gene clusters (i.e. 'modules') as based on expression similarity. Network modules with an expression profile in some way influenced by contraction were: i) annotated for their gene function using the Gene Ontology, ii) associated with exercise-induced declines in maximal voluntary isometric contraction (MVC; % baseline) to decipher their potential relevance to the acute post-exercise functional response and, iii) subject to hub gene and predictive transcriptional regulator analyses in order to identify candidate targets of the contraction response.
RESULTS: WGCNA generated a network comprising 56 distinct modules across 12044 genes, of which 21 displayed an age/contraction-dependent expression pattern. These included 'mitochondrial'- (dysregulated post-CON with ageing), 'extracellular'- and 'nucleic'-related (largely displaying age/mode dependent contraction-induced upregulation and downregulation, respectively) modules, along with two modules of unknown function upregulated by contraction per-se. Candidate target identification lead to a vastly reduced subset of 273 hub genes across age/contraction-related modules, along with an even further refined number of putative transcriptional regulators (43 in total). Notably, only 2 modules were also linked to the acute post-exercise functional response in their respective age/contraction context. One such module was enriched with genes involved in cell adhesion, upregulated with ECC exercise per-se and positively related to the post-ECC decline in MVC. The other module was enriched with genes related to transcription factor activity, downregulated with contraction per-se and negatively associated with the % decline in MVC following contraction.
CONCLUSION: This work suggests predictive network-driven analysis as a powerful approach to systematically identify putative mechanistic targets of age / contraction mode (in)dependent muscle molecular and functional responses to contraction.

THE EFFECTS OF LOW-INTENSITY PULSED ULTRASOUND EXPOSURE ON THE AKT/MTOR SIGNALING PATHWAY AFTER CARDIOTOXIN-INDUCED MUSCLE INJURY IN A MOUSE MODEL.

SAKAMOTO, M.1, NAKAMURA, A.2, YONA, M.3, MURO, M.4, TADANO, C.4, MATSUNAGA, A.1

1: KITASATO UNIV., 2: ODAWARA MUNICIPAL HOSP., 3. TUPLS, 4. TOHO UNIV. MED.SCHOOL OF ALLIED HEALTH SCIENCES, KITASATO UNIVERSITY

INTRODUCTION: Skeletal muscle injuries occur at high frequency in sports injuries. Low-intensity pulsed ultrasound (LIPUS) is a common modality used for improving and enhancing connective tissue healing. LIPUS therapy has been shown to accelerate muscle repair from damage (Piedade et al., 2008, Nagata et al., 2013). However, the mechanism behind the effect of LIPUS on muscle repair remains unclear. LIPUS promotes the proliferation of cultured chondrocytes via the phosphatidylinositol 3 kinase/Akt (PI3K/Akt) signaling pathway (Takeuchi et al. 2008). The Akt/mammalian target of rapamycin (Akt/mTOR) pathway is also a regulator of skeletal muscle hypertrophy. This study examined whether LIPUS activates the Akt/mTOR signaling pathway using a mouse model.
METHODS: Female, 12-week-old ICR mice were divided into muscle injury (non-LIPUS, N=11) and LIPUS exposure after injury (LIPUS, N =13) groups. Cardiotoxin was injected into the left tibialis anterior (TA) muscle to induce muscle injury. LIPUS exposure was initiated 2 hours after injury to the left TA muscle and it was applied once daily on the following day until the day before sacrifice. LIPUS was performed for 10 min/day, at a frequency of 3 MHz, intensity of 0.5 W/cm², and 50 % duty cycle. The non-LIPUS group received sham LIPUS. TA muscles were removed at 3 days and 5 days after injury and made into frozen serial cross sections. Sections were stained with hematoxylin and eosin. The phosphorylation levels of mTOR, Akt and p70S6K were measured by immunoblotting analysis. Results were analyzed using an unpaired t-test with statistical significance set at $p < 0.05$.
RESULTS: HE staining revealed that necrotic muscle fibers were observed, and many mononuclear cells were infiltrated in the necrotic area at 3 days after injury. At 5 days, mononuclear cells infiltrated the necrotic area, however newly regenerated muscle fibers were also observed. Phosphorylated mTOR, Akt and p70S6K were detected at both 3 days and 5 days after injury. However, the phosphorylation levels of mTOR, Akt and p70S6K were not significantly different between the non-LIPUS group and the LIPUS group.
CONCLUSION: We examined the Akt/mTOR signaling pathway at 3 days and 5 days after injury. However, it seems that LIPUS exposure does not affect the Akt/mTOR signaling pathway. Previous studies reported that LIPUS promoted the ERK/ MAPK pathway, therefore, we need to clarify the role of other signaling pathways in future studies.

EFFECT OF RENALASE ON DEXAMETHASONE-INDUCED MUSCLE ATROPHY

TOKINOYA, K.1,2, SUGASAWA, T., YOSHIDA, Y.3, SEKINE, N.1, TAKEKOSHI, K.1

1: UNIVERSITY OF TSUKUBA, 2: RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, 3: TSUKUBA INTERNATIONAL UNIVERSITY

INTRODUCTION: Muscle atrophy is a major health concern in our society. Dexamethasone, commonly used to treat inflammation, induces muscle atrophy as a side effect.
It has been reported that renalase has cell survival and protective effect in skeletal muscles, thus promoting cell survival (1). Our previous studies suggested that the expression of serum renalase by skeletal muscles increases during exercise despite a decrease in kidney function (2, 3). Therefore, we proposed that renalase may have an effect on protein degradation in skeletal muscles.
In this study, we aimed to clarify whether renalase was related on muscle atrophy induced-dexamethasone in vitro.
METHODS: C2C12 myoblasts were cultured in Dulbecco's Modified Eagle's Medium (DMEM) with 10% fetal bovine serum and 1% penicillin and streptomycin at 37°C in 5% CO2. When the C2C12 myoblasts were 70-80% confluent, DMEM was replaced with 2% horse serum and changed every 2 days, in order to induce differentiation of the myotubes. On the 5th day, myotubes were treated with either dimethyl sulfoxide (DMSO) or dexamethasone (DEX). Renalase protein and mRNA expression were measured by western blotting and real time RT-PCR. Other factors related to muscle atrophy were also measured.
RESULTS: Observation of myotubes showed greater myogenin expression on day 5 of C2C12 differentiation as compared to before differentiation. We determined the concentrations of DEX, and time course of renalase expression. Renalase expression was significantly increased by 10μM DEX upon incubation for 48 hours with DEX as compared to DMSO. DEX caused a greater increase in atrogenes such as MuRF-1 and MAFbx as compared to DMSO.
CONCLUSION: In this study, increased atrogene expressions by DEX caused muscle atrophy. Moreover, dexamethasone also caused increased expression of renalase protein in C2C12 myotubes. This suggests that renalase expression increases to protect muscle cells, especially through the proteinkinase B (Akt) signaling pathway. However, DEX decreases Akt signaling due to the presence of factors such as atrogenes and myostatin.

THE INFLUENCE OF A COMBINATION OF AURANTIOCHYTRIUM INTAKE AND RESISTANCE EXERCISE ON AMPK AND MTORC1 SIGNALING IN MURINE SKELETAL MUSCLE

MORI, R.1, YOKOKAWA, T.2, KATAMOTO, Y.1, ISHIHARA, K.3, IWATA, O.4, ASAYAMA, Y.4, SUZUKI, K.4, FUJITA, S.1

1: RITSUMEIKAN UNIVERSITY, 2: KYOTO UNIVERSITY, 3: NATIONAL RESEARCH INSTITUTE OF FISHERIES SCIENCE, 4: EUGLENA CO., LTD

INTRODUCTION: Docosahexaenoic acid (DHA) activates AMP-activated protein kinase (AMPK) (1). Aurantiochytrium extracted oil (AT) contains various fatty acids such as palmitic acid, stearic acid, myristic acid, eicosapentaenoic acid (EPA) and abundant amount of DHA; therefore, it may also activate AMPK. Resistance exercise (RE) is one of the stimuli that activates mammalian target of rapamycin complex 1 (mTORC1) signaling and enhances protein synthesis in skeletal muscle (2). On the other hand, it has been reported that activated AMPK pathway suppresses mTORC1 activity (3). Therefore, present study was aimed to examine whether AT intake suppresses RE-induced mTORC1 signaling activation.

METHODS: Male C57BL/6J mice were fed either standard diet (AIN-93G) or AT diet, in which 4.36% of the soybean oil in standard diet was replaced with AT extracted oil, for 8 weeks. After 8 weeks of feeding, the right gastrocnemius muscles of the mice were exercised with isometric contraction via percutaneous electrical stimulation (3×10 sec, 5 sets). Blood and gastrocnemius muscle samples were obtained 1 and 6h after RE. The muscle samples were analyzed by using Western blot analysis in order to measure the phosphorylation level and total protein of AMPKα and p70S6 kinase (p70S6K) and S6 ribosomal protein (rpS6), both of which are makers of mTORC1 activity.
RESULTS: AT showed the tendency to increase the phosphorylation level of AMPKα at Thr172 (p=0.05). RE increased phosphorylation of p70S6K at Thr389 and rpS6 at Ser240/244 1 and 6h after RE (p<0.001). On the other hand, the main effect of AT on mTORC1 activity and statistical interaction was not detected, indicating that no significant suppression on exercise-induced mTORC1 activity by AT.
CONCLUSION: Activation of AMPK showed the slight tendency, but not significant, and subsequently mTORC1 inactivation was not detected. AT contains multiple kinds of fatty acid. Palmitic acid was reported to activate AMPK and Akt, an upstream signaling protein of mTORC1 pathway. Also, a significant increase of phosphorylation of AMPKα at Thr172 and p70S6K at Thr 389 by DHA has been reported previously. Hence, part of fatty acids including DHA and palmitic acid in AT may inhibit mTORC1 through the activation of AMPK, palmitic acid may also activate mTORC1. In conclusion, 8 weeks of AT feeding did not affect the acute RE-induced mTORC1 activity of skeletal muscle in mice.

EFFECT OF TWICE-A-DAY ENDURANCE TRAINING ON SKELETAL MUSCLE OXIDATIVE CAPACITY BASED ON ACUTE RESPONSES OF PGC-1A

TAKAKURA, H.1, UENO, D.2, KATO, H.1, HIEDA, M.3, IZAWA, T.1
1: DOSHISHA UNIVERSITY, 2: NARA INSTITUTE OF SCIENCE AND TECHNOLOGY, 3: TOYOHASHI UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Improvement of endurance performance by exercise training requires an increase in mitochondrial volume via upregulated peroxisome proliferator-activated receptor-γ coactivator-1α (PGC-1α) expression and activation. In a previous study, Pgc-1α transgenic mice exhibited enhanced performance during peak oxygen uptake exercise, which was supported by enhanced mitochondrial function such as increased mitochondrial gene expression and associated enzyme activity (Calvo et al., 2008). Because Pgc-1α expression increases as an acute response to endurance exercise, additional acute exercise effectively activates PGC-1α to promote mitochondrial genes, leading to overall enhancement of the increase in mitochondrial volume. Moreover, the timing of exercise induces a change in Pgc-1α mRNA expression levels after a few hours of acute exercise, leading to different training-induced adaptations in skeletal muscles. The aim of the present study was to determine whether training twice a day every second day could enhance the increase in mitochondrial proteins in the skeletal muscle via the acute response of Pgc-1α.
METHODS: Male Wistar rats were randomly assigned to the following training (TR) and control (C) groups. TR (5 days/week at ~30 m/min for ~90 min, slope: 5°) was conducted for 9 weeks at two time points: when Pgc-1α expression levels at rest, which showed circadian expression rhythm, were maximal (20T group) and minimal (6T group). The TR groups were divided into once-a-day training every day (3-h interval between exercise bouts) and twice-a-day training every second day (2×Tr@20T and 2×Tr@6T, respectively) groups. After the TR period, western blotting was performed to evaluate COXIV and cytochrome c expression levels in the deep portion of the gastrocnemius muscle.
RESULTS: COXIV and cytochrome c expression levels were higher in the 2×Tr@20T group than those in the 20T ($p < 0.05$ and $p = 0.09$, respectively) and 20C groups ($p < 0.05$ for both), and were also higher in the 2×Tr@6T group compared to those in the 6T ($p = 0.09$ and $p < 0.05$, respectively) and 6C groups ($p < 0.05$ for both).
CONCLUSION: Training twice a day every second day had different effects on skeletal muscle oxidative capacity than daily training twice a day, even though the overall training volume was equivalent. Further research is needed to determine the mechanism underlying these differences.

FIBRE-TYPE SPECIFICITY OF STATIN ASSOCIATED MYOPATHY

MALLINSON, J.E., CONSTANTIN-TEODOSIU, D., SIDAWAY, J., WESTWOOD, F.R., GREENHAFF, P.L.
UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Statins are associated with exercise intolerance (1) and muscle related pain (2), which could conceivably lower physical activity levels resulting in a reduction in muscle metabolic health status. Statin associated myopathy is also reported to be fibre type specific, with type IIB fibres being the most susceptible in both rodents (3) and humans (4). Using an in vivo model of statin myopathy we aimed to determine whether molecular markers of muscle proteolysis and altered fuel metabolism were differentially altered in muscles of differing fibre composition.
METHODS: Female Wistar rats were dosed daily with 80 mg.kg-1.d-1 simvastatin for 12 days (n=5) or with vehicle (0.5% w/v hydroxypropyl methylcellulose & 0.1% w/v polysorbate 80; control, n=6) for 12 days by oral gavage. Soleus (80% type I, 20% type IIA fibres), gastrocnemius (homogenous sample of the medial and lateral muscle) (10% type I, 8% type IIA, 22% type IIx, 60% type IIB) and biceps femoris (7% type IIA, 16% type IIX, 77% type IIB) muscles were harvested for quantification of targeted analysis of mRNAs and proteins known to induce changes in muscle proteolysis and fuel metabolism in this model (5). Statistical comparisons were performed using unpaired Students t-test and a significance level of $p<0.05$ was used (IBM SPSS 22).
RESULTS: Simvastatin administration decreased Akt (Ser473) and FOXO1 (Ser253) phosphorylation in the biceps femoris muscle when compared to control ($p<0.05$ and $p<0.05$, respectively), but no corresponding changes were evident in soleus or gastrocnemius muscle. These statin induced changes in the biceps femoris muscle were paralleled by increased expression of the proteolytic genes MAFbx (10.74 ± 4.1 fold, $p<0.05$) and MuRF-1 (8.79 ± 3.5 fold, $p<0.05$) compared to control, and PGC-1 alpha (3.65 ± 1.2 fold, $p<0.05$), PDK4 (13.6 ± 5.0 fold, $p<0.05$) and TNF alpha (9.1 ± 3.4 fold, $p<0.05$). No equivalent responses were observed in soleus or gastrocnemius muscle.
CONCLUSION: Muscles comprised primarily of type IIB fibres appear to be highly susceptible to statin induced changes to the Akt/FOXO signalling and upregulation of downstream gene targets thought to regulate muscle proteolysis and carbohydrate oxidation, which

aligns with the previously reported fibre type specificity of statin myopathy (3, 4). The significance of this to older people, who have the highest statin prescription rate, experience a fibre specific reduction in type II muscle fibre area with age (6) and are the least active remains to be elucidated.

MOLECULAR MECHANISMS INVOLVED IN REDUCED MTORC1 SIGNAL RESPONSES AFTER REPEATED BOUTS OF RESISTANCE EXERCISE

TAKEGAKI, J., SASE, K., FUJITA, S.

RITSUMEIKAN UNIVERSITY

INTRODUCTION: Resistance exercise promotes skeletal muscle protein synthesis through the activation of mammalian target of rapamycin complex 1 (mTORC1) signal, and the repetition of exercise leads to skeletal muscle hypertrophy. On the other hand, continuous resistance training gradually attenuates muscle hypertrophic responses (1). Inactivation of mTORC1 signal after resistance exercise may be involved in this process (2), but the detail mechanism is remains unclear. The present study aimed to investigate the bouts dependent changes in the 90kDa ribosomal S6 kinases (p90RSK) and insulin receptor substrate (IRS) responses, which are contributing factors for activation of mTORC1 signal in resistance exercise.

METHODS: Male Sprague-Dawley rats were resistance-exercised 10 bouts with intervals of 48h between bouts. The resistance exercise consisted of 50 repetitions of maximal isometric contractions of the gastrocnemius muscle, which were elicited by transcutaneous electrical stimulation under anesthesia. Muscle samples were collected immediately (0h post RE) and 3h (3h post RE) after the 1st (1B), 5th (5B), and 10th (10B) exercise bouts.

RESULTS: At 3h-post RE, resistance exercise phosphorylated p70S6K (Thr389, a marker of mTORC1 activity) in all groups, but the magnitude was decreased with increased repetition of bouts (1B > 10B, $P < 0.01$). Similarly, p90RSK (Thr573) was phosphorylated in all exercised groups at 0h-post RE but was markedly decreased with increased repetition of bouts (1B > 10B, $P < 0.01$). Additionally, extracellular signal-regulated kinase (ERK) 1/2, an upstream target of p90RSK showed similar results (1B > 10B, $P < 0.01$). On the other hand, the expression of IRS-1 was not changed with repeated bouts. Furthermore, resistance exercise phosphorylated IRS-1 significantly (at Ser636/639, Ser612, and Ser1101; exercise effect, $p < 0.01$ for each phosphorylation site), but the magnitudes were not modified with repeated bouts.

CONCLUSION: The present results suggest that blunted activation of p90RSK could contribute to the reduction of mTORC1 response induced by repetition of resistance exercise. Additionally, the suppressed ERK 1/2 activation may also be involved in the blunted p90RSK activation.

HIGH-INTENSITY CYCLING PERFORMED PRIOR TO RESISTANCE EXERCISE STIMULATES AUTOPHAGY SIGNALLING THROUGH ACTIVATION OF AMPKα2 IN HUMAN SKELETAL MUSCLE

APRO, W., MOBERG, M., EKBLOM, B., HOLMBERG, H.C., BLOMSTRAND, E.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

INTRODUCTION: High intensity interval cycling performed prior to resistance exercise potently increases AMPKα2 activity and mRNA expression of the muscle specific E3 ligases MuRF1 and MAFbx, suggesting a link between AMPK activation and muscle breakdown (1). Autophagy, another catabolic process, is initiated by AMPK-mediated phosphorylation of Unc-51 Like Autophagy Activating Kinase 1 (ULK1) at Ser317 and Ser555. Thus, AMPK-mediated activation of autophagy may represent a pathway by which training adaptations are modulated in response to various training modes. The aim of this study was therefore to examine if autophagy signalling is activated to a higher degree by concurrent exercise compared to resistance exercise alone.

METHODS: Eight male subjects performed two trials in a randomized order. In the ER trial, they performed five 4-min intervals at a work rate of 85% of each subject's maximal oxygen uptake. Fifteen minutes after the last interval, subjects performed 3 warm-up sets after which they performed 10 sets of heavy-resistance exercise; 4 sets of 8–10 repetitions at ~80% 1RM, 4 sets of 10–12 repetitions at ~70% 1RM, and 2 sets to fatigue at ~60% 1RM. In the R trial, the exercise was identical except that the cycling was replaced by rest. Muscle biopsies were sampled at rest before exercise, immediately after cycling in the ER trial and after rest at the corresponding time point in the R trial, immediately after resistance exercise and at 90 and 180 minutes during recovery in both trials. Using western blot methodology, muscle samples were analysed for the phosphorylation status of AMPKα2 at T172 and ULK1 at S317 and S555. As a readout of autophagic flux, total levels of LC3BI and LC3BII were also measured using western blot.

RESULTS: In the ER-trial, immediately after resistance exercise, phosphorylation of AMPKα2 at T172 increased compared to rest (+189 %, $p<0.05$). However, at the same time point in the R-trial, phosphorylation of AMPKα2 remained unchanged (+55 %, $p>0.05$). Phosphorylation of ULK1 at S317 increased following resistance exercise in both trials but was significantly more pronounced in the ER-trial (R-trial, +91 %, $p<0.05$; ER-trial, +219 %, $p<0.05$). Phosphorylation of ULK1 at S555 was only increased after resistance exercise in the ER-trial (+125 %, $p<0.05$).The LC3BII-to-LC3BI ratio decreased after resistance exercise (-40 %, $p<0.05$) in the R-trial as well as in the ER-trial (-65 %, $p<0.05$), however, the decrease was significantly larger in the ER-trial compared to the R-trial ($p<0.05$).

CONCLUSION: Endurance exercise-induced activation of AMPK increases phosphorylation of ULK1 at S317 and S555, resulting in increased autophagy in human skeletal muscle. These findings provide a novel mechanism by which concurrent exercise may alter training adaptations compared to single mode resistance exercise.

PROLONGED STRETCH DOES NOT IMPROVE INSULIN-STIMULATED GLUCOSE TRANSPORT IN INSULIN-RESISTANT RAT SOLEUS MUSCLE

HONDA, H.1, RA, S.G.1,2, IIZAWA, H.1, TOMIGA, Y.2, HIGAKI, Y.1,2, KAWANAKA, K.1,2

FUKUOKA UNIVERSITY

INTRODUCTION: An acute bout of prolonged exercise stimulates glucose transport independently of insulin action and also increases susceptibility of glucose transport to insulin in skeletal muscles with normal insulin sensitivity. In addition, acute exercise can improve insulin-stimulated glucose transport in insulin-resistant skeletal muscles. On the other hand, although mechanical stress, which is an integrated part of exercise stimulus, is known to stimulate muscle glucose transport independently of insulin action, it is unclear whether stretch increases susceptibility of muscle glucose transport to insulin and improves insulin resistance in skeletal muscles. Therefore, we examined whether an acute bout of prolonged stretch improves insulin-stimulated glucose transport in rat soleus muscle with insulin resistance.
METHODS: Male Wistar rats were divided into conscious control or unconscious immobilized group. In one hindlimb of unconscious immobilized rats, soleus muscles were shortened for 6 h under anesthesia by plantarflexion of the ankle joint and this position was fixed with kinesio tape. In contralateral hindlimb of unconscious immobilized rats, soleus muscles were stretched for 3 h following 3 h of shortening by dorsiflexion of the ankle joint. We measured basal and insulin (50μU/ml) stimulated glucose transport rate in isolated soleus muscles by using 2-deoxyglucose.
RESULTS: Insulin (50μU/ml) increased glucose transport by 2-fold in soleus muscle of conscious control rats ($P<0.05$). On the other hand, insulin (50μU/ml) did not significantly increase glucose transport in shortened soleus muscle of unconscious immobilized rats, showing that insulin resistance is induced in this muscle. Insulin (50μU/ml) also did not significantly increase glucose transport in stretched soleus muscle of unconscious immobilized rats. Therefore, 3 h of prolonged stretch did not increase susceptibility of glucose transport to insulin in insulin resistant soleus muscle of unconscious immobilized rats.
CONCLUSION: An acute bout of 3 h prolonged stretch does not improve insulin-stimulated glucose transport in rat soleus muscle with immobilization-induced insulin resistance.

COMPARABLE MUSCLE ATROPHY WITH 2 WEEKS OF IMMOBILIZATION (IMB) AS HYPERTROPHY WITH 10 WEEKS OF RESISTANCE EXERCISE TRAINING (RET): IMPLICATIONS FOR MECHANISMS OF PROTEIN TURNOVER

STOKES, T.

MCMASTER UNIVERSITY

INTRODUCTION: Skeletal muscle is a plastic tissue capable of responding to changes in the contractile load. Resistance exercise training (RET) stimulates the accretion of new muscle proteins whereas immobilization (IMB) results in muscle atrophy within days of unloading. There is, however, significant heterogeneity in the magnitudes of muscle hypertrophy following RET and atrophy following IMB between individuals. It is not known whether high(er) responders to RET are also more susceptible to muscle atrophy during disuse. Thus, we investigated the phenotypic and protein turnover changes using a within-subject design using RET and IMB in contralateral limbs.
METHODS: Twelve healthy young men (20±3 yr) were recruited from McMaster University to participate in 10 weeks of unilateral RET consisting of leg extension and leg press exercise at ~80% of 1RM. During the last 2 weeks, their contralateral limb was subjected to IMB by knee-bracing at a 60 degree angle of flexion to prevent weight bearing. In both limbs, vastus lateralis cross-sectional area (VLCSA) was quantified at 50% of thigh length using magnetic resonance imaging (MRI) at week 0 and week 10. A muscle biopsy was obtained at week 0 with contralateral biopsies obtained at weeks 8 and 10 for the assessment of integrated muscle protein synthesis (iMPS) using orally-ingested deuterated water in conjunction with serial skeletal muscle biopsies.
RESULTS: VLCSA increased by 8.1±4.2% after 10 weeks of RET and decreased by 9.0±6.5% after 2 weeks of IMB, suggesting a greatly accelerated rate of muscle loss relative to gain. iMPS increased by 12.6±4.8% in the RET leg and decreased by 9.5±5.1% in the IMB leg, mirroring closely the phenotypic changes observed in VLCSA. However, further analyses revealed a significant correlation between the change in iMPS and VLCSA only in the IMB leg ($r=0.8$).
CONCLUSION: RET-induced muscle hypertrophic gain in VLCSA took five times longer than comparable IMB-induced VLCSA atrophy; hence, we propose that differences in muscle protein turnover, driven predominantly by changes in MPS, were discordant between the legs.

POST-EXERCISE COOLING IMPAIRS DAILY MUSCLE PROTEIN SYNTHESIS RATES DURING 2 WEEKS OF RESISTANCE-TYPE EXERCISE TRAINING IN HEALTHY YOUNG MALES

FUCHS, C.J., KOUW, I.W.K., CHURCHWARD-VENNE, T.A., SMEETS, J.S.J., SENDEN, J.M., VAN MARKEN LICHTENBELT, W.D., VERDIJK, L.B., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY MEDICAL CENTRE+

INTRODUCTION: Post-exercise cooling is a frequently applied strategy by athletes to improve post-exercise recovery and, as such, to facilitate muscle reconditioning following exercise. We have observed that cold-water immersion during recovery from an acute bout of resistance-type exercise impairs postprandial myofibrillar protein synthesis rates (unpublished observations). However, whether repeated post-exercise cooling affects daily myofibrillar protein synthesis rates when assessed over a more prolonged period of resistance-type exercise training has never been studied. Therefore, the aim of this study was to assess the impact of post-exercise cooling on daily myofibrillar protein synthesis rates during 2 weeks of resistance-type exercise training.
METHODS: Twelve healthy, male adults (age: 21±1 y) performed seven sessions of resistance-type exercise training over a 2-week period. Each exercise session was followed by water immersion of both legs for 20 min. One leg was immersed in cold water (8°C: CWI) while the other leg was immersed in thermoneutral water (30°C: CON). After water immersion, a beverage was ingested containing 20 g milk protein with 45 g carbohydrate. Maximal strength of each leg was assessed by 1-repetition maximum (1-RM) strength testing before and

after the 2-week training period. Deuterated water (2H2O) was applied with the collection of saliva, blood, and muscle biopsies over 2 weeks to assess myofibrillar protein synthesis rates. A two-factor (treatment x time) repeated-measures ANOVA was performed for the analysis of 1-RM strength. A paired samples t-test was used to determine differences in myofibrillar protein synthesis rates between treatments (i.e., CWI vs CON leg). Data represent means±SEM.
RESULTS: Leg extension 1-RM increased in both legs (CWI: 68±5 to 76±5 kg; CON: 66±4 to 74±5 kg; time effect, P<0.01), with no differences between legs (treatment effect, P=0.230; time x treatment interaction, P=0.689). Myofibrillar protein synthesis rates assessed over 2 weeks were significantly lower in the CWI when compared to the CON leg (1.48±0.05 vs 1.67±0.11%·d-1, respectively; P=0.042).
CONCLUSION: Cold-water immersion during post-exercise recovery lowers myofibrillar protein synthesis rates during prolonged resistance-type exercise training.

EFFECTS OF COMBINED BLOOD-FLOW RESTRICTED TRAINING AND HEAVY-LOAD RESISTANCE TRAINING ON MYOFIBER MORPHOLOGY AND MECHANICAL MUSCLE FUNCTION

HANSEN, S.K., RATZER, J., NIELSEN, J.L., SUETTA, C., KVORNING, T., FRANDSEN, U., AAGAARD, P.

1 UNIVERSITY OF SOUTHERN DENMARK, 2 BISPEBJERG & HERLEV HOSPITALS, UNIVERSITY OF COPENHAGEN, 3 DANISH ELITE SPORT INSTITUTION

INTRODUCTION: Heavy-load conventional resistance training (HRT) is traditionally the preferred training modality to gain improvements in mechanical muscle function and myocellular hypertrophy. However, HRT results in high stress forces on muscles, tendons and joints. Consequently, low-load resistance training (LRT) is often applied during de-loading (rehabilitation) or tapering periods, despite evidence that both mechanical muscle function and myocellular properties remains largely unaffected with this type of training. Notably, recent evidence suggest that low-load resistance training combined with restriction of blood-flow to the working muscle (BFR-RT) can mediate upregulation of myogenic stem cell (satellite cells, SC) content and myonuclei density in skeletal muscle leading to increases in muscle size and improved mechanical muscle function.
Thus, the purpose of this study was to investigate if a block-structured training program consisting of alternating weeks of BFR-RT and HRT would induce enhanced adaptations in mechanical muscle function, myofiber size and SC and myonuclear content compared to HRT alone.
METHODS: Eighteen active males and females (23±1.2yrs) were randomized to 6-weeks of progressive HRT (HRT, n= 9) or block-structured training alternating weekly between HRT and BFR-RT (BFR-HRT, n= 9). HRT and BFR-HRT were matched for total training time (4 sessions per week, 4 sets of knee extension and leg press exercise). Maximal isometric knee extensor strength (MVC) and rate of force development (RFD) were measured pre and post training. Muscle biopsies were obtained to examine changes in quadriceps (VL) myofiber cross-sectional area (CSA), myonuclei number and satellite cell content.
RESULTS: Both training protocols led to increased (p<0.05) type II myofiber CSA (BFR-HRT: +16%, HRT: +16%) whilst type I myofiber CSA increased following HRT only (+12%, p=0.05). Myonuclei number remained unchanged in both groups, whereas SC content increased in type I myofibers following HRT (p<0.05). MVC increased in both groups (BFR-HRT: +12%, HRT: +7%; p<0.05) accompanied by a tendency for elevated RFD100ms following BFR-HRT (+12%; p=0.067).
CONCLUSION: In conclusion, alternating weekly blocks of HRT and BFR-RT were not superior to HRT in producing gains in muscle strength, RFD and myofiber size. On the other hand, conventional HRT appeared to be periodically replaceable by BFR-RT without compromising training-induced gains in muscle strength and type II myofiber size. The present regime of low-frequency block-structured BFR-RT combined with HRT did not result in elevated SC content or increased myonuclei number. Nevertheless, BFR-RT may be used periodically to unload muscles, tendons and joints while improving mechanical muscle function and increasing muscle mass.

ALTERED RESPONSE TO MONO-ARTICULAR EXERCISE IN THE SKELETAL MUSCLE OF PATIENTS WITH HOMOZYGOUS SICKLE CELL DISEASE

GOURAUD, E., CANNAS, G., FAES, C., GAUTHIER-VASSEROT, A., POUTREL, S., RENOUX, C., JOLY, P., HOT, A., CASSIRAME, J., CONNES, P., HAUTIER, C.

CLAUDE BERNARD UNIVERSITY LYON 1

INTRODUCTION: Homozygous sickle cell disease is a genetic red blood cell disorder characterized by the presence of abnormal hemoglobin, which under deoxygenation, polymerizes and causes red blood sickling. Sickle cell patients (HbSS) are anemic and have poorly deformable red blood cells. Recent works also reported muscle abnormalities in HbSS patients such as a profound remodeling of skeletal muscle microvasculature, amyotrophy and decreased oxidative capacity. However, the functional impacts of these modifications are currently unknown. The aim of this study was to characterize the muscle function of HbSS patients during an acute mono-articular exercise.
METHODS: Sixteen HbSS patients at steady-state and 14 healthy subjects (HbAA) were included in this study. They performed 4 bouts of 20 dynamic extensions of the quadriceps (tEnd) at 25% of maximal isometric strength (Smax). Smax was measured before and immediately after tEnd. EMG activities of the Vastus Lateralis (VL) and Vastus Medialis (VM) were recorded.
RESULTS: Smax decreased in HbSS patients after tEnd (-15.83 ± 23.29 %, $p < 0.05$) while it remained unchanged in HbAA (-1.09 ± 30.38 %). The magnitude of Smax reduction in HbSS patients was not related to the level of anemia (i.e., hemoglobin level). The root mean square value (RMS) decreased in HbSS for both VL (-10.48 ± 28.91, $p = 0.066$) and VM (-20.07 ± 24.13, $p < 0.05$) after tEnd but not in HbAA. During tEnd, movement speed was reduced ($p < 0.05$) and power tended to be lower ($p = 0.064$) in HbSS compared to HbAA but there was no significant change during tEnd in the two groups. RMS/RMSmax, and median power frequency (MPF) were not affected by tEnd in the two groups. We then analyzed the changes of EMG markers within each of the 4 bouts for the two groups. RMS/RMSmax in the VL continually increased over the repetitions of each bout in HbSS patients while we noted a change in RMS/RMSmax over the repetition for only one of the 4 bouts (the second one) in HbAA. MPF significantly decreased over the repeated contractions in 3 of the 4 bouts in HbSS and in the 4 bouts in HbAA.
CONCLUSION: Altogether, these results suggest that repeated sub-maximal mono-articular contractions may induce peripheral muscle fatigue in HbSS patients and not in HbAA individuals. These muscular perturbations could trigger inhibitory feedbacks resulting in a decrease in central drive and muscle force during maximal contractions.

LOW GLYCOGEN AVAILABILITY INCREASES AUTOPHAGY SIGNALLING FOLLOWING RESISTANCE EXERCISE

HORWATH, O., GRANBERG, J., APRO, W.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES, GIH

INTRODUCTION: It is well known that nutrients and energy availability influence exercise-induced adaptations in skeletal muscle. Recently, effort have been aimed at examining the impact of low glycogen availability and studies have shown that manipulation of glycogen content can modulate molecular pathways regulating exercise adaptations. However, available studies have primarily focused on endurance exercise and little is known about glycogen availability and resistance exercise (RE) adaptations. As the molecular pathways regulating muscle protein balance are highly influenced by nutrient availability, it is hypothesized that resistance exercise with low glycogen levels may activate autophagy, a process responsible for degrading and recycling cellular proteins. Autophagy is largely activated by the energy sensing protein AMPK which in turn is activated by high-intensity exercise and low glycogen availability. Activation of this pathway may therefore have negative effects on muscle protein balance. Therefore, the aim of the present study was to compare the effect of performing RE with high or low glycogen availability on molecular pathways regulating autophagy in skeletal muscle.
METHODS: Participants recruited to the present study were considered resistance-trained (≥3 times/week). Employing a unilateral exercise-model (depleted vs loaded leg), differences in glycogen availability were obtained through a preceding phase of carbohydrate loading (10 g/kg bodyweight/day) and a one-legged depleting exercise session, completed in the evening prior to the experimental trial. Reporting to the laboratory in a fasted state, participants performed unilateral leg extension exercise (10 sets at 10RM) interspersed by 3 minutes of rest. Exercise volume was matched between legs with the depleted leg performing the exercise first, followed by the loaded leg. Muscle biopsies from the vastus lateralis were collected before and immediately after exercise. Muscle glycogen content was measured through spectrophotometric detection following enzymatic digestion, and phosphorylation status of proteins involved in autophagy were measured using western blot.
RESULTS: Unilateral glycogen depletion resulted in 67 % lower glycogen levels in the depleted leg compared to the loaded leg (618 vs 202 mmol/kg dry wt) prior to RE. Immediately after RE, AMPK phosphorylation at T172 was elevated 4.5-fold in the depleted leg but remained completely unchanged in the loaded leg. Phosphorylation of ACC at S79 increase after RE in both legs but more so in the depleted leg (5.4-fold vs 2-fold). Similarly, ULK1-phosphorylation of the AMPK-specific site S555 increased in both legs, but this increase was more pronounced in the depleted leg (3-fold vs 1.6-fold).
CONCLUSION: In this study, we found that RE performed with low glycogen-availability increases autophagy signalling through elevated AMPK phosphorylation in human skeletal muscle.

EFFECT OF SCIATIC DENERVATION ON MITOCHONDRIAL STRUCTURE IN SINGLE MUSCLE FIBER

TAKEDA, K.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Skeletal muscle mitochondria are highly dynamic organelles controlled by cellular conditions. For example, sciatic denervation is an experimental model for muscle atrophy which accelerates mitochondrial fission and degradation in mouse hindlimb skeletal muscles (1). The purpose of this study is to verify the changes of mitochondrial structure in single muscle fibers after denervation surgery using 3D images.
METHODS: C57BL/6J mice (male/6-7 weeks old) underwent sciatic nerve transection or sham-operation surgery. Skeletal muscle samples were collected on 4, 7, and 14 days after surgery. Extensor digitorum longus (EDL) muscles were digested by collagenase 1 and stained with Mito Tracker Red and anti-α-actinin antibody. Images of single fibers were recorded under a confocal microscope and deconvolved by computer software. Image processing and 3D projections were conducted by ImageJ software.
RESULTS: In sham-operated skeletal muscle fibers, Mito Tracker Red signals were observed in transverse and longitudinal directions. Transverse mitochondria were localized along z-discs stained with α-actinin. Four days after surgery, transverse Mito Tracker Red signals were eliminated despite longitudinal mitochondria remained. This observation lasted for 7 and 14 days after denervation surgery.
CONCLUSION: Our study revealed that highly-organized longitudinal and transverse mitochondria were observed in sham operated muscle fibers. Disorganized mitochondria were observed 4 days after sciatic denervation surgery.

STRENGTH IMPROVEMENTS THROUGH OCCLUSAL SPLINTS? THE EFFECTS OF DIFFERENT LOWER JAW POSITIONS ON MAXIMAL ISOMETRIC FORCE PRODUCTION AND PERFORMANCE IN DIFFERENT JUMPING TYPES

OHLENDORF, D., MAURER, C., WANKE, E.M., MICKEL, C., HELLER, S., SURE, J., FUCHS, D., GRONEBERG, D.A.

GOETHE UNIVERSITY, OCCUPATIONAL, SOCIAL AND ENVIRONMENTAL MEDICINE

INTRODUCTION: The influence of the jaw position on postural control, body posture, walking and running pattern has been reported in the literature. All these movements have in common that a relatively small, but well controlled muscle activation is required. The induced effects on motor output through changed jaw positions have been small. Therefore, it has been questioned if it could still be observed in maximal muscle activation.
METHODS: Twenty-three healthy, mid age recreational runners (mean age = 34.0 ± 10.3 years) participated in this study. Three different jump tests (squat jump, counter movement jump, and drop jumps from four different heights) and three maximal strength tests (trunk flexion and extension, leg press of the right and left leg) were conducted. Four different dental occlusion conditions and an additional familiarization condition were tested. Subjects performed the tests on different days for which the four occlusion conditions were randomly changed.
RESULTS: No familiarization effect was found. Occlusion conditions with a relaxation position and with a myocentric condylar position showed significantly higher values for several tests compared to the neutral condition and the maximal occlusion position. Significance was found in the squat jump, countermovement jump, the drop jump from 32cm and 40cm, trunk extension, leg press force and rate of force development. The effect due to the splint conditions is an improvement between 3% and 12% (min and max). No influence of the jaw position on symmetry or balance between extension and flexion muscle was found.
CONCLUSION: An influence of occlusion splints on rate of force development (RFD) and maximal strength tests could be confirmed. A small, but consistent increase in the performance parameters could be measured. The influence of the occlusion condition is most likely small compared to other influences as for example training status, age, gender and circadian rhythm.

EFFECTS OF ACUTE STATIC AND BALLISTIC STRETCHING EXERCISES ON MUSCLE STRENGTH AND BALANCE: A PILOT STUDY

MANI, E., KIRMIZIGIL, B., OBUZ, T., ANGIN, E.

EASTERN MEDITERRANEAN UNIVERSITY

INTRODUCTION: Stretching exercises are performed to prevent injuries and improve sportive performance (1). Static and dynamic stretching are most preferred stretching techniques in physical activities (2,3). The aim of this study was to investigate the effect of 60 second static and ballistic stretching exercise to dynamic balance and muscle strength.
METHODS: Eleven healthy young people completed this study conducted in a randomized cross over study design, involving ballistic and static stretching conditions with a 72 hours interval between trials. Stretching exercises were applied to gastrocnemius, quadriceps and hamstring muscles for 30 seconds and 2 sets. The dynamic balance of individuals were measured with the Y-Balance test and the quadriceps and hamstring isokinetic peak torque with the isokinetic dynamometer (Concentric-concentric, 60º/s). Mann Whitney U test was used to perform Inter-group comparisons and Wilcoxon test was used for Intra-group results.
RESULTS: Their mean age was 23.82±1.9 years and the mean body mass index was 23.35±3.9 kg/m2. There was no statistically significant difference between the groups of muscular strength (hamstring and quadriceps) and dynamic balance test results ($p>0.05$). There was a statistically significant difference in the dynamic balance and quadriceps muscle strength in the static balance group according to intra-group comparisons. (p values, respectively, $p=0.01$, $p=0.04$). Also there were significant difference in ballistic stretching group ($p=0.01$). For both conditions, there was no significant difference in any other parameters in intragroup comparisons ($p>0.05$).
CONCLUSION: According to our study, it is recommended to apply the static and ballistic stretching exercises for 60 s duration where dynamic balance is required. Although our study is a pilot study, it is seen that acute static stretching exercises decrease the quadriceps muscle strength and could be more careful in the use of static stretching exercises in the activities that require the quadriceps muscle strength.

RELATIONSHIP BETWEEN BROWN ADIPOSE TISSUE AND MUSCLE TISSUE AND INTRAMUSCULAR ADIPOSE TISSUE IN YOUNG AND MIDDLE-AGED PEOPLE

OGAWA, M., KOSKENSALO, K., LAURILA, S., LAHESMAA, M., AKIMA, H., NUUTILA, P.

NAGOYA UNIVERSITY, JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, TURKU PET CENTRE, UNIVERSITY OF TURKU

INTRODUCTION: Brown/beige adipose tissue (BAT) is prevalent in humans until adolescence, but it's prevalence gradually decreases with age. However, it has been confirmed that even adults have BAT, its volume and activity varying between individuals. Previous studies have reported that muscle volume of infants, children and adolescents are factors predicting BAT volume. Therefore, muscle volume may be a useful indicator to predict BAT volume also in young and middle-aged people. Previous studies have reported that BAT volume and activity positively correlates with visceral adipose tissue volume. Since there is also a high positive correlation between visceral adipose tissue volume and intramuscular adipose tissue volume, intramuscular adipose tissue may be related with BAT, but its relationship has not been clarified. Recent studies have been clarified BAT fat fraction by magnetic resonance imaging (MRI) reflects BAT volume and activity. The purpose of this study is to examine the relationships between BAT fat fraction by MRI and muscle volume and intramuscular adipose tissue content in young and middle-aged people.
METHODS: The subjects were 25 young and middle-aged men (mean age 36.5 ± 12.8 years). Modified 2-point Dixon (mDixon) images in the neck, supraclavicular, trunk (L4 to L5) and lower leg were used for calculating of signal-fat-fraction maps. BAT fat fraction was determined from volumes of interest which were set in the cervical and supraclavicular fat depot. High BAT fat fraction shows less BAT volume. Muscle volumes and intramuscular adipose tissue contents of tibialis anterior (TA) and multifidus muscle (MM) were measured using mDixon images and signal-fat-fraction maps.
RESULTS: There was a significant correlation between BAT fat fraction and whole-body fat content ($r = 0.534$, $P = 0.006$), body mass index ($r = 0.516$, $P = 0.008$), intramuscular adipose tissue content in TA ($n = 14$, $r = 0.661$, $P = 0.010$) and MM ($n = 21$, $r = 0.524$, $P = 0.018$). On the other hand, there was no correlation between BAT fat fraction and muscle volume in both muscles (TA; $n = 14$, $r = 0.053$, MM; $n = 21$, $r = -0.043$, n.s.), age ($r = 0.294$, n.s.). Stepwise linear regression analysis showed that only intramuscular adipose tissue content in TA was associated with BAT fat fraction.
CONCLUSION: Intramuscular adipose tissue content of lower leg is a predictor of BAT fat fraction in young and middle-aged people.

CP-PM05 Training and testing

EFFECTS OF REPEATED SPRINT TRAINING IN HYPOXIA ON REPEATED WINGATE SPRINT ABILITY AND LACTATE METABOLISM.

TAKEI, N.

THE UNIVERSITY OF TOKYO

INTRODUCTION: Recently, it has been reported that repeated sprint training in hypoxia (RSH) has greater effects on molecular adaptations and repeated sprint ability (10-s repeated sprints) (1). However, the effects of RSH on repeated Wingate sprint ability (30-s repeated sprints), and on lactate metabolism are unclear. We investigated the effects of RSH on single and repeated Wingate sprint ability, and on lactate metabolism during the exercise.
METHODS: Ten trained track sprinters performed 6 sessions of repeated sprint training (3×30-sec maximal sprint with 4.5-min recovery) in hypoxia (RSH, 14.5%O2) or normoxia (RSN, 20.9%O2) over 2 weeks in a single-blinded manner. Two days before (pre-) and 7-9 days after (post-) the training intervention, subjects performed 3 repetitions of Wingate sprints with 4.5-min recovery as performance tests. According to pre-test's Wingate sprints performance, subjects were divided into performance-matched 2 groups, RSH or RSN. RSH subjects were exposed to hypoxia during the repeated sprint training and its warm-up (≈ 26.5 min/session). Three minutes after each Wingate sprint, blood samples were taken from finger tips to evaluate blood lactate concentrations. Differences were analyzed using paired or unpaired t-test. Statistical significance was set at $p<0.05$. The magnitude of changes in variables were expressed as standardized effect size (ES, Cohen's d).

RESULTS: The improvement of single sprint performance (mean power of the 1st Wingate sprint) was close to significant in RSH (p=0.08, ES=0.35) but not in RSN (p=0.15, ES=0.10). Total work by 3 repetitions of Wingate sprints were significantly increased in both RSH (p<0.05, ES=1.35) and RSN (p<0.05, ES=0.58). Percentage of the power-drop between the 1st and 3rd Wingate sprint's mean power was significantly decreased (improved) in RSH (p=0.05, ES=1.10) but not in RSN (p=0.99, ES=0.01). Peak blood lactate concentration was significantly decreased in RSH (p<0.05, ES=1.21) but not in RSN (p=0.16, ES=0.50).
CONCLUSION: RSH dramatically improved the total work and the percentage power-drop of 3 repetitions of Wingate sprints (ES: "very-large" and "large"). In contrast, RSN significantly improved only total work and its effect size was smaller than that of RSH (ES 0.58 v.s. 1.35). Interestingly, RSH reduced peak blood lactate concentration in this study. It is possible that RSH reduced glycogen breakdown (glycogen sparing) and/or increased lactate oxidation by mitochondria. Glycogen sparing and increase in lactate oxidation provide competitive advantage for athletes who need to repeat sprints during competitions. Moreover, RSH provided favorable training effects and evoked physiological adaptations using only brief hypoxic exposures (≈ 26.5 min/session). In conclusion, RSH in this study would be an effective and time-efficient training strategy to enhance repeated Wingate sprint ability and evoke physiological adaptations.

NEUROMUSCULAR, METABOLIC AND PERCEPTUAL RESPONSE TO CONCURRENT TRAINING.

CROSS, R., MARSHALL, P., SIEGLER, J., LOVELL, R.
WESTERN SYDNEY UNIVERSITY - CAMPBELLTOWN CAMPUS

INTRODUCTION: The high frequency of matches during the competitive phase of the professional team sport season often results in the administration of concurrent training (CT), yet this prescription may compromise strength and power adaptations1. However, the studies suggesting that CT promotes an interference phenomenon via residual fatigue are limited in scope and lack ecological validity. Therefore, we aimed to a) determine the impact of prior intermittent aerobic activity on the performance of an ecologically valid lower limb resistance training (RT) session and b) investigate the fatigue and recovery mechanisms from CT.
METHODS: 9 team sport athletes with a history of RT participated in a randomised cross-over study involving an intermittent sprint protocol (ISP), lower limb RT and CT (ISP + RT separated by 1h). Prior to (PRE), immediately post (IP), 24 h and 48 h following each exercise condition functional measures (countermovement jump; CMJ) as well as central motor output (quadriceps muscle activation, voluntary activation), muscle contractility (evoked twitch responses), creatine kinase, muscle soreness and perceived fatigue were recorded.
RESULTS: RT performance was unaffected by prior intermittent exercise (ISP) in CT. CMJ height was reduced IP in RT (8.4%; 90% confidence intervals [CI]: 5.4%-11.4%) and CT (10.1%; CI: 7.7%-12.5%; $p \leq 0.015$) but not ISP, with jump height returning to PRE values in 24 h for RT and 48 h for CT. Contractile function was hampered in all conditions, with a significantly greater decline observed IP in RT (56%; CI: 47.6%-70.9%) and CT (55.6%; CI: 50.2%-60.9%) versus ISP (36.7%; CI: 29.9%-43.5%; $p \leq 0.036$), leading to an extended recovery time (RT & CT 48 h vs. ISP 24 h). Perceptual fatigue ratings increased IP in all conditions (RT Δ5, CI: 2.8-7.2; ISP Δ8, CI: 5.3-10.7; CT Δ10, CI: 8.9-11.1; $p \leq 0.025$) and were recovered 24 h post. Quadriceps muscle soreness remained elevated from PRE 24 h post. No changes were observed in voluntary activation, EMG and creatine kinase in any condition.
CONCLUSION: Prior intermittent aerobic exercise does not negatively impact the performance of lower limb strength and power RT. Both RT and ISP elicit contractile fatigue, which is not exacerbated in CT. Contractile function following RT and CT display the same recovery profile (48 h) while a shorter recovery time is observed when ISP is performed in isolation (24 h).

THE EFFECT OF WEATHER ON IAAF AND OLYMPIC TRACK AND FIELD PERFORMANCES FROM 1983 - 2017

GUY, J.H.1, IHSAN, M.2, GRUNDSTEIN, A.3, ALONSO, J.M.2, RACINAIS, S.2
1CENTRAL QUEENSLAND UNIVERSITY, 2ATHLETE HEALTH AND PERFORMANCE RESEARCH CENTRE ASPETAR, 3UNIVERSITY OF GEORGIA

INTRODUCTION: It is well documented that hot weather can negatively impact performance in endurance running events (1,2), and limited data has shown the opposite for sprint events (1). However, a systematic longitudinal approach to consider these effects on elite athlete performance is yet to be performed. It is the aim of this study to determine which weather variables are most strongly associated with performance in International Association of Athletics Federations (IAAF) and Olympic track and field events from 1983 – 2017.
METHODS: We collated and analysed the top eight performances relative to the world record at the time of the event for males and females in the 100 m, 200 m, 400 m, 800 m, 1500 m, 3000 m (females: 1983 to 1993), 3000 m steeplechase (females: 2005 onwards), 5000 m (females: 1995 onwards), 10000 m (females: 1987 onwards) , Marathon, 20 km racewalk (females: 1999 onwards), 50 km racewalk (females: 2017), 110 m hurdles, 400 m hurdles, long jump, triple jump, Heptathlon (Female) and Decathlon (Male) from 16 consecutive IAAF World Athletics Championships (1983 to 2017), and from 9 consecutive Olympic Games (1984 to 2016) (https://www.iaaf.org). For each event, corresponding weather conditions such as environmental temperature (°C), relative humidity (%), wind speed ($m \cdot s^{-1}$), and dew point (°C) were obtained from the nearest meteorological station relative to the event venue. Data was analysed by event and gender by multiple linear regression with weather data as the independent variables and top eight performances as the dependent variable.
RESULTS: Significant effects on performance due to temperature were seen in the male 1500 m ($p = 0.015$, adjusted R square = 0.391), female 400 m hurdles ($p = 0.025$, adjusted R square = 0.298), and female Marathon ($p = 0.050$, adjusted R square = 0.426). Significant effects on performance due to RH were seen in male 1500 m ($p = 0.04$), and male 800 m ($p = 0.016$, adjusted R square = 0.153). Significant effects on performance due to wind speed and dew point were seen in male 1500 m ($p = 0.031$, and $p = 0.007$, respectively).
CONCLUSION: Finishing times for top eight competitors was affected in four of the 32 events analysed. These findings show there may not be a linear relationship between selected weather variables and race performance when compared to the world record at the time of the event. Comparison of top eight finishing times for each event has previously shown large detriments in performance for endurance events, and large improvements in performance for sprint events in hot weather (1). However, our findings have shown that over a longer time scale, and taking into account all IAAF and Olympic events, that there is no consistent pattern for slower times in endurance based events, and faster times or improved performance in short duration or sprint events.

EXERCISE DURATION IS AN INDEPENDENT MARKER OF WORKLOAD IN ENDURANCE TYPE CONSTANT-LOAD EXERCISE

WEINER, L., HANDL, T., TSCHAKERT, G., BIRNBAUMER, P., MÜLLER, A., HOFMANN, P.

UNIVERSITY OF GRAZ

INTRODUCTION: Platonov (1) and Viru (2) showed that fatigue only occurs after a certain duration during endurance loads with a given intensity, indicating duration beside intensity as an independent marker of workload (3). In this pilot study, effects of continuous cycle ergometer exercise tests (CE) with different durations at the same intensity on recovery were tested.
METHODS: The lactate turn points (LTP1, LTP2) of six trained subjects (age: 26.6±2.2yrs) were determined by an incremental exercise test. After a maximal duration (Dmax) CE at a defined intensity (10% of maximal Power below PLTP2) three randomized CE were performed for 70%Dmax, 40%Dmax and 20%Dmax applying the same intensity. Tests were separated by at least one week. Immediately before (Pre), 4 (Rec4), 24 (Rec24) and 48 (Rec48) hours after each CE, a submaximal incremental test up to LTP2 workload was performed. Heart rate (HR), blood lactate (La) and blood glucose (Glu) concentration were measured during the tests and the individual Physical Working Capacity (PWCi) defined as the power output at 90% of the individual HRmax was determined to monitor changes in performance.
RESULTS: Significant changes over time were found for peak HR, La, Glu and PWCi in Dmax and 70%Dmax, but not 40%Dmax and 20%Dmax. In Dmax a higher peak HR ($p<.05$) was observed in Rec4 (165.3±8.9) compared to Pre (158.7±12.4), Rec24 (156.5±9.5) and Rec48 (155.7±9.4). Peak La was lower ($p<.05$) in Rec4 (2.9±0.7) compared to Pre (3.9±0.6) and Rec48 (3.8±0.9) and peak Glu was lower in Rec4 (3.2±0.2) ($p<.05$) compared to Rec24 (4.0±0.4) and Rec48 (3.9±0.3). PWCi values were significantly lower in Rec4 (207.5±36.3) ($p<.05$) than in Pre (225.8±38.8), Rec24 (226.8±39.3) and Rec48 (233.1±33.7)
CONCLUSION: The time course of changes of peak HR, La, Glu and specifically PWCi confirmed the theoretical approach by Platonov (1) and Viru (2) showing greater changes with longer CE at the same intensity. The results indicate an independent relevance of the marker "duration" with regard to fatigue, recovery time and adaptation for constant-load endurance type exercise (3). These findings allow building up a framework to prescribe specific types of microcycles by intensity and duration on an individual basis. However, both incremental and duration tests need to be further developed and applied accordingly.

THE UTILITY OF A SELF-PACED SUBMAXIMAL RUNNING TEST TO MONITOR FATIGUE IN ULTRA-MARATHON RUNNERS.

SANGAN, H., HOPKER, J.G., DAVISON, G.

UNIVERSITY OF KENT

INTRODUCTION: The purpose of this study was to assess whether a self-paced submaximal running test was able to monitor fatigue in runners. Specifically, this study used ultra-marathon running as high dose of acute exercise induced stress in order investigate the ability of parameters derived from a novel self-paced running test to quantify athlete fatigue and performance status.
METHODS: Eleven competitive runners (3 Female, 8 Male; 40±9 years; VO2max 50±7 ml.kg-1.min-1) completed a self-paced submaximal running test (SRT) on a synthetic track at the same time of day, 1 week prior to a 6-hour ultra-marathon running race (PRE), and ~48 hours following completion (48h). The SRT comprised of three self-paced intervals anchored by the participant's rating of perceived exertion (RPE). Participants completed 3 submaximal intervals, each of 3 minutes duration anchored at an RPE 10, 13 and 17. Exercising heart rate (ExHR; b.min-1) and selected run speed (RS; km.h-1) were recorded throughout. In addition, symptoms of stress experienced by participants were analysed via the Daily Analysis of Life Demands of Athletes (DALDA) Questionnaire which was completed 24 hours pre-event, and 24hr, 48hr, 72hrs and 1 week after the event.
RESULTS: Participants completed an average distance of 50±5km and time of 333±54 mins during the ultra-marathon. Repeated measures ANOVA suggested there was no significant change in SRT RS (PRE vs 48h) corresponding to RPE 10 (10.3±2.1 vs. 10.1±2.0 km.h-1, $P=0.40$) and RPE 13 (12.9±2.3 vs. 12.4±1.7 km.h-1, $P=0.72$), however a significant decrease in selected RS was evident at RPE 17 at 48h (14.8±2.3 vs. 14.1±2.4 km.h-1, $P<0.001$). There was no significant change in ExHR comparing PRE to 48h at RPE 10 (131±17 vs. 133±15 b.min-1, $P=0.37$), RPE 13 (157±13 vs. 152±8 b.min-1) or RPE 17 (170±10 vs. 167±9 b.min-1). However, magnitude-based inference suggests that the mean depression in ExHR recorded during RPE 13 and RPE 17 was very likely clinically relevant (96% and 100% chance, respectively). Reported symptoms of stress increased 24 hrs following ultra-running when compared to PRE (6.1±1.4 and 1.6±0.5; PRE vs 24h, respectively; $P=0.006$), which had decreased but not returned to baseline by 48h (3.0±0.8, $P=0.143$). Of the 11 participants, 6 demonstrated a clinically relevant depression in ExHR in at least 2 of the RPE based intensities at 48h, with the remaining 5 showing no change. Sub-analysis demonstrated those with a depression of ExHR had a significantly greater length of running time (372.4±30.0 vs. 289±42.80 mins respectively, $P=0.001$), and distance covered (53.6±4.3 km and 46.6±3.5 km respectively, $P=0.042$) during the ultra-marathon.
CONCLUSION: The results show that the SRT was able to reflect signs of acute fatigue in runners following ultra-marathon running. A reduction in submaximal running performance and heart rate, with increased symptoms of stress suggest increased fatigue status among runners after the ultra-marathon.

SPRINT INTERVAL TRAINING VERSUS HIGH INTENSITY INTERVAL TRAINING IN UNTRAINED UNIVERSITY STUDENTS

BOER, P.

NORTH WEST UNIVERSITY

INTRODUCTION: Sprint interval training (SIT) involves repeated bouts of high intensity training ("all-out" activity of 10-30 seconds) with successive periods of low intensity activity or rest. High intensity interval training (HIIT) also involves high intensity training (90% of VO2 max), usually one to four minutes, interspersed with recovery intervals of low intensity activity or rest. Purpose: The purpose of this study was to directly compare various physiological and performance parameters of SIT and HIIT with a non-exercise control group amongst untrained college students.
METHODS: Sixty-three untrained (37 men and 26 women) participants (22±1.7 yrs) volunteered for the study and were randomly allocated to SIT, HIIT and control group. Maximal oxygen uptake, the Yo-Yo intermittent recovery test (YYIRT), 20-meter speed, agility T-test, vertical jump and Wingate-test was assessed before and after 7-weeks of training.

RESULTS: Both interval groups improved significantly compared to control for VO2 max, peak treadmill speed, YYIRT and 20-meter speed ($p<0.05$) with no significant differences between SIT and HIIT (effect sizes small to large). Regarding power output associated with the Wingate test, significant improvements compared to control were realised for SIT only ($p<0.05$).
CONCLUSION: Both methods of interval training are feasible to improve exercise capacity in untrained university students.

EFFECTS OF MODERATE-INTENSITY ENDURANCE AND HIGH-INTENSITY INTERVAL TRAINING UNDER HYPOXIC CONDITIONS ON BODY COMPOSITION AND GLUCOSE TOLERANCE

OGITA, F.1, YAMATOYA, K.1, YOTANI, K.1, TAMAKI, H.2

1: NATIONAL INSTITUTE OF FITNESS AND SPORTS, 2: NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: We have reported that moderate-intensity endurance training (MIET) under hypoxic conditions improves risk factors of metabolic syndrome over the last decade (Ogita 2013, Ogita 2017). Several studies have also demonstrated that high-intensity interval training (HIIT) has positive effects on metabolic disease. Taken together, we hypothesized that HIIT under hypoxic conditions would improve metabolic risk factors even more effectively. The present study therefore examined the effects of HIIT under hypoxic conditions on body composition and glucose tolerance, compared with the effects of MIET.
METHODS: Fifteen healthy male subjects (mean age, 22±1 years) who were matched for baseline measurements were randomized into two groups: an MIET group (n=8); and a HIIT group (n=7). The MIET group underwent a 30-min endurance exercise at 50%VO2max, and the HIIT group underwent ten 1-min bouts at 100%VO2max with 1 min rest between each bout. Both groups performed the training under hypobaric hypoxic conditions corresponding to 2000 m above sea level 4 days/week, for 4 weeks. Before and after training, body mass, percentage body fat, and preperitoneal fat thickness were measured. In addition, a 3-h oral glucose tolerance test (OGTT) was conducted.
RESULTS: After the 4 weeks of training, body mass, percentage body fat, and preperitoneal fat thickness were significantly decreased in the MIET group ($P<0.05$). Furthermore, insulin sensitivity was also improved, showing a significant decrease in the area under the curve of both glucose and insulin concentration during OGTT ($P<0.05$). On the other hand, the HIIT group showed significant decreases in body mass and preperitoneal fat thickness ($P<0.05$), but not in percentage body fat. Furthermore, neither area under the curve of blood glucose concentrations nor insulin concentrations during OGTT changed significantly.
CONCLUSION: Our results demonstrated that HIIT under hypoxic conditions as used in this study does not necessarily bring evident improvements on metabolic risk markers, when compared with the effects of MIET, which did not support our hypothesis. Further studies are required to clarify the effects of HIIT under hypoxic conditions on metabolic risk markers.

CARDIORESPIRATORY FITNESS AND LOWER LIMB MAXIMAL POWER IN HIGH INTENSITY FUNCTIONAL TRAINING ATHLETES

ADAMI, P.E., ROCCHI, J.E., MELKE, N., MACALUSO, A.

UNIVERSITÀ DI ROMA FORO ITALICO

INTRODUCTION: High Intensity Functional Training (HIFT) is one of the fastest growing training modalities, which incorporates elements of Olympic weightlifting, gymnastics, plyometrics and calisthenics exercises. Among the most successful methods of HIFT there is CrossFit©. Few researches have investigated the physiological characteristics of elite athletes. The purpose of the present study was to define lower limb maximal power and maximal aerobic fitness, in a laboratory setting, and VO2 during an on-field training session of a group of HIFT athletes.
METHODS: Physiological assessments were performed on group of 10 male and 10 female individuals, aged 18 to 40 years, who practiced CrossFit© for at least 3 years and competed at national level for a minimum of 1 year. Vertical ground reaction force was measured on a force platform (model 9281 B; KISTLER Instrumente GmbH, Sindelfingen, Germany) during the performance of a countermovement jump on both legs. Maximal power, optimal force and optimal velocity of the lower limbs were then calculated. Cardiorespiratory fitness was assessed through a ramp maximal incremental exercise test on a treadmill in a laboratory setting and during a benchmark test on the field called "Nancy", which consisted of 5 rounds for time of 400 m run and 15 overhead squats with 42.5 kg for men and 30 kg for women. Oxygen uptake (VO2) and carbon dioxide production (VCO2) were measured by means of a portable metabolimeter (K4b2, COSMED, Italy).
RESULTS: Men reached greater values for maximal power output (4500±450 vs. 2700±320 W; p=<.05), optimal velocity (2.8±0.18 vs. 2.4±0.17 ms-1; p=<.05), optimal force (2100±280 vs. 1500±220 N; p=<.05), and jump height (39±4.9 vs. 28±8.5 cm; p=<.05) compared to women. Values normalized for body mass were also statistically significant (p=<.05) except for the optimal force. Men showed higher absolute values of VO2peak on the treadmill (4414±535 vs. 3257±393 ml·min-1; p=<.05) and on field tests (4224 ±478 vs. 3219 ±356 ml·min-1; p=<.05). When values were normalized for body weight these did not show any significant difference between men and women (53±5,6 vs. 52±6,1 ml·kg-1 min-1 on the treadmill, p=0.8; 50±3,8 vs. 52±5,7 ml·kg-1 min-1 on-field tests, p=0.5). There were no differences between men and women in VO2mean maintained during the on-field training session (85.4±10.37% vs 87.4±9.58% of VO2peak reached at the maximal aerobic test; p=0.7).
CONCLUSION: This study confirms the authors' hypothesis that HIFT athletes have high levels of cardiorespiratory fitness and lower limb maximal power due to the high intensity and very specific type of training that these athletes perform. Such high levels of cardiorespiratory fitness are confirmed from VO2peak and VO2mean values recorded during the on field recorded training sessions. Differences between men and women, although significant in absolute terms, showed no significant differences when normalised per body mass, thus showing that both genders adapt similarly to this training program.

SESSION-RPE METHOD FOR QUANTIFYING AND RELATING TRAINING LOAD TO SWIMMING PERFORMANCE IN ADOLESCENTS

PIND, R., MÄESTU, E., PURGE, P., JÜRGENSON, J., AREND, M., MÄESTU, J.
UNIVERSITY OF TARTU

INTRODUCTION: In competitive swimming, different types of training regimen (low and high intensity, interval or maximal speed) are used to improve performance. Therefore, swimmers have to develop their performance using training programs manipulating their training load to correspond to their race distance and time (Wakayoshi et al. 1992). Training session-based rating of perceived exertion (sRPE) (Foster et al., 2001) reflects an individual's response to training. The aim of this study was to investigate the effect of accumulated training load from low, moderate or hard effort sessions to changes in swimming performance.
METHODS: Twelve national level swimmers (16.4±2.1 yrs; VO2max 50.0±4.0 ml/min/kg) participated in a 10-week period preceding the National Winter Championships. Pre- and post-training physiological parameters (minute ventilation, aerobic and anaerobic threshold) and swimming performance variables (100m freestyle, 100m leg-kicks only) were measured. All training bouts and corresponding rating of perceived exertion (RPE) data were recorded. Based on the athletes RPE values, trainings were categorized to either light, moderate or hard, categorized by the methods from previous literature (Wallace et al., 2009; Seiler & Kjerland, 2006). Corresponding internal training load (ITL) accumulated in each zone was calculated by multiplying the zone specific RPE value with the total duration.
RESULTS: Small improvements in 100-m freestyle swimming time (-3.1%; $p<0.05$) and 100-m freestyle with leg-kicks only (-4.0%; $p<0.05$) were observed following the intensified period before the National Winter Championships. The overall ITL using the sRPE method was associated to changes in anaerobic threshold Watt/kg ($p<0.05$) during the training period. Also, sRPE from moderate sessions of Seiler & Kjerland (2006) based categorization was significantly related to changes in anaerobic threshold Watt/kg ($p<0.05$). Wallace et al. (2009) based categorization method did not have any associations with changes in performance variables.
CONCLUSION: ITL categorization could help coaches to estimate and quantify training load based on the difficulty of the workout to give further feedback from the training process and the adaptation of the athlete.

CHANGES IN THE COMMON SYNAPTIC DRIVE TO THE ANKLE DORSIFLEXOR MUSCLE DURING SPLIT-BELT WALKING IN HUMANS

OSHIMA, A., MURAI, H., TSUJIUCHI, N., KAMIBAYASHI, K.
DOSHISHA UNIVERSITY

INTRODUCTION: Humans can walk stably in varied environments by reactive and predictive motor adaptations (1-2). Herein, we focused on a common synaptic drive to the ankle dorsiflexor muscle to investigate the mechanisms of motor adaptation under a novel walking environment using the split-belt treadmill. Changes in the common synaptic drive to the muscle during walking at different speeds on the right and left legs were investigated using an intramuscular coherence analysis between a pair of surface electromyography (EMG) signals.
METHODS: Seven adult subjects participated in this study. They walked on a split-belt treadmill with two belts controlled separately. The treadmill was operated moving together "tied" or at difference speeds "split." The walking speeds were 0.5 and 1.25 m/s for the slow and fast conditions, respectively. The experimental paradigm consisted of three baseline phases ("tied" slow, "tied" fast, and then "tied" slow speeds for 2 min each) for 6 min, an adaptation phase ("split" condition of slow and fast speed) for 10 min, and a washout phase ("tied" slow speed) for 6 min. Each leg on the fast or slow belt speed during the adaptation phase was defined as the "fast leg" or "slow leg," respectively. A wireless surface EMG measurement system was used to investigate the coherence. EMG electrodes were placed on the distal and proximal ends of the tibialis anterior (TA-d and TA-p), soleus, medial gastrocnemius, rectus femoris, and biceps femoris muscles. The ground reaction force signals were recorded using force plates mounted underneath each treadmill belt. From the vertical component of the ground reaction force, the moments of heel contact and toe off were identified. The coherence in the swing phase of walking was evaluated at the TA-d and TA-p pair. For the index of coherence strength, values were calculated by frequency and time domain analyses at the first minute (0.5–1.5 min) of each baseline phase; in the first and last minutes of the adaptation phase as early and late adaptations, respectively; and in the first and last minutes of the washout phase as early and late washouts, respectively.
RESULTS: During the adaptation phase, the amount of TA-TA coherence in the beta (15–35 Hz) and gamma bands (35–60 Hz) in the slow leg decreased at late adaptation as compared with early adaptation. In the result of the cumulant density for the time domain analysis, the central peak in the slow leg at early adaptation was higher than that at late adaptation. However, the central peak at early adaptation was lower than that at late adaptation in the fast leg of the adaptation phase.
CONCLUSION: These results suggest that the common synaptic drive to the ankle dorsiflexor muscle during the adaptation phase of split-belt walking might be changed.

HIGHER ELECTROMYOGRAPHIC ACTIVITY IN THE DISTAL THAN IN THE PROXIMAL REGION OF THE BICEPS FEMORIS LONG HEAD AND SEMIMEMBRANOSUS DURING HIP-DOMINANT EXERCISE

RAKI, K., KATSUKI, T., TAKU, W.

GRADUATE SCHOOL OF COMPREHENSIVE HUMAN SCIENCES, UNIVERSITY OF TSUKUBA., GRADUATE SCHOOL OF HEALTH AND SPORTS SCIENCE, DOSHISHA UNIVERSITY., FACULTY OF HEALTH AND SPORTS SCIENCE, DOSHISHA UNIVERSITY.

INTRODUCTION: Each of the biceps femoris long head (BFlh), semitendinosus (ST), and semimembranosus (SM) is divided into the proximal and distal regions by their multiple nerve branches (1). These neuroanatomical properties appear to be associated with the previous findings of non-uniform activity levels within BFlh and ST during knee- and hip-dominant exercises (2, 3). Similar to BFlh and ST, the activity level of SM may also be non-uniform within the muscle, possibly because of the neuroanatomical property (1). However, no study has investigated the activity of different regions within SM during knee- and hip-dominant exercises. The purpose of the current study was to examine the activity level of regions within the individual hamstring muscles during Nordic hamstring (NH) and hip extension (HE) as knee- and hip-dominant exercises, respectively.
METHODS: Fourteen male collegiate sprinters performed two sets of two repetitions of NH and HE. They started NH from a kneeling position with the legs fixed, and lowered the upper body as far as possible. In HE, they lay prone on a bed, with the trunk flexed over the end of the bed and the legs fixed. They raised the upper body as high as possible, and then lowered the upper body. Electromyographic (EMG) activity of the individual hamstring muscles was measured during the exercises. After the borders of the individual hamstring muscles were carefully identified with an ultrasonic apparatus, surface electrodes were placed on the proximal and distal regions of the muscles. The root mean square values of EMG data (RMS-EMG) were calculated for the eccentric phase of NH and each of the concentric and eccentric phases of HE. The RMS-EMG values were normalized by RMS-EMG during maximal voluntary contraction (MVC) of knee flexion as %MVC.
RESULTS: The activity level during the eccentric phase of HE was significantly higher in the distal region than in the proximal region within BFlh ($P = 0.043$, Cohen's $d = 0.660$) and SM ($P = 0.014$, Cohen's $d = 0.686$). However, ST showed no significant regional difference in the activity level during the eccentric phase of HE. There was no significant regional difference in activity level of the individual hamstring muscles during the eccentric phase of NH or concentric phase of HE.
CONCLUSION: The results suggest that the distal region of BFlh and SM may greatly contribute to producing hip extension torque in the eccentric phase of HE. The neuroanatomical property of multiple nerve branches dividing BFlh and SM into the proximal and distal regions might be related to the region-specific activity within the muscles. These findings would be useful for designing resistance training and rehabilitation programs aimed at selectively strengthening specific regions of BFlh and SM.

GLUTEUS MEDIUS, QUADRATUS LUMBROUM, AND ERECTOR SPINAE MUSCLE ACTIVITY DURING VERTICAL JUMP WITH VARIOUS LOADS

VADÁSZ, K., NYISZTORNÉ MAYER, P., VASS, L., VARGA, M., SEBESI, B., MESZLER, B., ATLASZ, T., VÁCZI, M.

UNIVERSITY OS PÉCS FACULTY OF SCIENCES INSTITUTE OF SPORT SCIENCE AND PHYSICAL E

INTRODUCTION: Jump performance is not only influenced by lower extremity muscle activation but also pelvic and lumbal muscle activation. Less information is available how gluteus medius (GM), quadratus lumborum (QL), and erector spinae lumbal part (ES) muscles are activated during unilateral jumps when the load is increased. We hypothesized that activation of these muscles are different in three load conditions.
METHODS: Twenty-five subjects performed maximal voluntary hip abduction and trunk lateral flexion to obtain EMG signals from GM, QL, and ES muscles. Then subjects executed bilateral and unilateral countermovement jumps, and unilateral depth jumps, while EMG was measured in the same muscles. EMG values obtained during jumps were normalized to EMG values measured during maximal voluntary contractions.
RESULTS: There was a main effect of muscle in all jump condition, showing that the most and the least activated muscles were the ES, and the GM, respectively, regardless of the jump condition. Though the mean values of EMG activities increased with greater load, the differences were not significant.
CONCLUSION: We conclude that activation of the examined muscles were high but the magnitude of load did not affect the activation.

ABDOMINAL OBLIQUE MUSCLE ACTIVATION PATTERNS DURING THE CRICKET PACE BOWLING ACTION

FORREST, M.R.L., SCOTT, B.R., HEBERT, J.J., DEMPSEY, A.R.

MURDOCH UNIVERSITY

INTRODUCTION: Cricket pace bowlers are ten times more likely to sustain a side strain injury than other cricketers (1). Side strain injuries affect the external oblique (EO) and internal oblique (IO) muscles on the side opposite the bowling arm and cause approximately one month of missed cricket (2). Anecdotal evidence suggest these injuries occur when the non-bowling shoulder is rapidly pulled down form a position of near-maximal shoulder flexion while the trunk laterally flexes away from the bowling arm (2). The exact moment of injury within this phase, however, is not known. To better understand this potential mechanism, the current study employed surface electromyography to measure the activity of the EO and IO during the bowling action.
METHODS: Twenty-eight adolescent pace bowlers delivered six balls while surface electromyography data were recorded from the EO and IO muscles on the non-bowling side. Data were full-wave rectified and low-pass filtered at 6 Hz using a fourth-order Butterworth filter to create linear envelopes. The mean activation of the EO and IO was then examined during four phases of the bowling action, between the following events; 50ms prior to back-foot contact, back-foot contact, front-foot contact, ball-release, and 50ms post ball-release. Muscle activation data were expressed as percentage of maximal voluntary contraction (MVC). The MVC was recorded while the participants were in maximal isometric trunk flexion. Two separate one-way repeated ANOVAs with pairwise comparisons were used to detect differences in muscle activation between phases for each muscle.
RESULTS: The greatest levels of EO activation occurred during phase 1 (60 ± 18%) and phase 2 (62 ± 17%). The activation of the EO in phases 1 and 2 was significantly higher ($p<0.001$) than that seen in phase 3 (31 ± 14%) and phase 4 (23 ± 15%). Compared to the other phases,

IO activation was significantly higher during phase 2 (64 ± 16%, p<0.05). There were no differences in IO activation (p>0.05) when comparing phase 1 (49 ± 20%), phase 3 (51 ± 17%), and phase 4 (45 ± 17%).
CONCLUSION: The greatest levels of EO and IO activation occurred early in the bowling action. It is possible that these muscles were activating in relation to movements of the non-bowling shoulder, the ground reaction forces experienced at back-foot contact, or the rotational movements of the trunk between back-foot contact and front-foot contact. Future research is needed in this area and should consider the influence of these specific biomechanical factors on muscle activation. Calculating joint powers to determine contraction type (concentric or eccentric) may also provide insight into the mechanism of side strain injury in the cricket pace bowler.

CORE STABILITY NEUROMUSCULAR CONTROL DURING PERTURBED STANDING POSTURE

MORNIEUX, G., DUCHENE, Y., PETEL, A., PERRIN, P.P., GAUCHARD, G.C.
UNIVERSITÉ DE LORRAINE

INTRODUCTION: Core Stability (CS) is defined as the ability to control trunk positioning and movement over the pelvis (1). Although CS has been mainly studied during athletic tasks, it might play an important role during standing posture as well, due to the relative high mass and inertia of the trunk. This might be even more relevant when posture is perturbed (2). The aim of the study was to determine CS neuromuscular strategies during perturbed standing posture.
METHODS: Seventeen male handball players (22 ± 4 years, 82.9 ± 11.6 kg, 1.86 ± 0.08 m), performed two different perturbed standing postural tasks on a moveable platform. During the first task, participants stood on both feet and experienced a 6cm backward perturbation (PERTback). The second task consisted in a 6cm medial perturbation while subjects stood on their left leg (PERTmed). Inertial Motion Units (Captiv T-Sens Motion, TEA, Vandoeuvre-lès-Nancy, Fance) recorded hip and trunk joint angles, while electromyography (EMG) sensors (Delsys, Natick, MA, USA) were placed on the Rectus Abdominis (RA), External Oblique (EO), Erector Spinae (ES), Gluteus Maximus (GMax) and Gluteus Medius (GMed) muscles to evaluate trunk and pelvis neuromuscular control. Trunk and hip joints range of motion following the perturbation (RoM), EMG Root Mean Square (RMS) values during the perturbation as well as the time of muscles peak activation after perturbation were determined. The ratio between the amount of EMG activity (RMS) and the duration of the neuromuscular response (Time) was further evaluated. Kinematics and RMS/Time ratios were averaged over 6 trials. Linear regression analyses between kinematics and neuromuscular parameters were conducted (P<0.05).
RESULTS: Trunk and hip flexion/extension RoM during PERTback were 3.6 ± 1.1° and 2.7 ± 1.4°, respectively. During PERTmed, greater trunk and hip joint abduction RoM were observed (16.1 ± 6.6° and 14.2 ± 6.8°, respectively). None of the RMS/Time ratios was correlated to trunk flexion/extension RoM. Both GMax and GMed RMS/Time ratios were significantly associated with hip flexion/extension RoM (R^2=0.24 and R^2=0.32, respectively). RMS/Time ratio of the left ES was correlated to trunk abduction RoM (R^2=0.42), while no further relationship between neuromuscular parameters and hip joint was found.
CONCLUSION: Backward perturbation during standing posture elicited relatively low trunk and hip flexion/extension (<4°). Neuromuscular stabilization of these joints appeared to be mainly done at the pelvis level thanks to the glutei muscles. Medial perturbation during one leg standing involved larger trunk and hip joints abduction (>14°). However, only the contralateral Erector Spinae muscle activity was correlated to trunk lateral lean. Neuromuscular Core Stability strategies during standing might be difficult to further tease out without recording deep muscles activity.

TENSIOMYOGRAPHY INDICATES DIFFERENT LEVELS OF POST-EXERCISE CONTRACTILE FATIGUE BETWEEN TRADITIONAL SETS AND REST REDISTRIBUTION SETS AT DIFFERENT VELOCITIES

OMCIRK, D., MALECEK, J., PISZ, A., HALAJ, M., TUFANO, J.J.
CHARLES UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Compared to fatiguing traditional sets where repetitions are completed consecutively followed by long inter-set rest intervals, redistributing the total rest time to create shorter but more frequent sets results in a better maintenance of acute exercise performance. However, few studies have investigated the effects of rest redistribution on performance at the neuromuscular level, and no studies have investigated the lasting effects of such protocols on neuromuscular fatigue and contractile properties. Therefore, the purpose of this study was to determine the effects of traditional sets (TS) and rest-redistribution (RR) on contractile ability immediately following maximal-effort concentric exercise.
METHODS: 16 healthy males (23.7 ± 2.8 y, 81.1 ± 8.8 kg, 181.3 ± 7.3 kg) performed a familiarization visit and 4 quasi-randomized testing visits on an isokinetic dynamometer: RR60 and TS60 (60°•s-1) and RR360 and TS360 (360°•s-1). During each protocol, subjects performed 40 maximal effort concentric knee extensions with the dominant leg. The TS protocols included 4 sets of 10 repetitions with 95 s of inter-set rest, and the RR protocols included 20 sets of 2 repetitions with 15 s of inter-set rest. Before each experimental visit, baseline tensiomyography (TMG) measurements were taken to measure the involuntary electro-stimulated contraction time in milliseconds (Tc). Then, TMG was assed 2, 5, and 10 min post-exercise, all of which were calculated relative to that condition's baseline Tc value. For each velocity, a two-way repeated measures ANOVA was conducted to determine differences between the protocols, while effect sizes (g) were calculated to assess the magnitude of the difference between the protocols in all variables.
RESULTS: There were no protocol*time interactions for 60°•s-1 (P = .118) or 360°•s-1 (P = .054). There were no main effects for protocol at either speed (60°•s-1, g = 0.56; 360°•s-1, g = 0.73). However, there was a main effect for time at 60°•s-1 (P < 0.001) and 360°•s-1 (P < 0.001). For 60°•s-1, Tc never returned to baseline values. At 360°•s-1, Tc also decreased, but returned to baseline at 10 min post-exercise. At 360°•s-1, effect sizes favored RR at 2 (g = 0.54), 5 (g = 0.75), and 10 min (g = 0.79) post-exercise. At 60°•s-1, effect sizes favored RR at 2 (g = 0.31), 5 (g = 0.63), and 10 min (g = 0.69) post-exercise.
CONCLUSION: Although there were no protocol*time interactions, Tc recovered better after RR when considering the larger effect sizes at 60°•s-1 and 360°•s-1. Also, regardless of the set structure, Tc recovered quicker after 360°•s-1 compared to 60°•s-1, indicating that 60°•s-1 resulted in more accumulated fatigue than 360°•s-1. Therefore, when aiming to avoid acute fatigue from accumulating and carrying over into a subsequent exercise during a single training session, RR protocols may be a better option than TS.

CHANGES IN THE RATE OF FORCE DEVELOPMENT-SCALING FACTOR FOLLOWING ISOMETRIC ELECTROMYOSTIMULATION TRAINING PROGRAM

MIRKOV, D.M.1, KNEZEVIC, O.M.2, GARCIA-RAMOS, A.3, SARABON, N.4, MILANOVIC, S.2, FILIPOVIC, S.R.2

UNIVERSITY OF BELGRADE FACULTY OF SPORT AND PHYSICAL EDUCATION 2: UNIVERSITY OF BELGRADE INSTITUTE FOR MEDICAL RESEARCH 3: UNI OF GRANADA FACULTY OF SPORT SCIENCES 4: UNI OF PRIMORSKA FACULTY OF HEA

INTRODUCTION: The quality of movement initiation and the quickness of force production could be assessed using rate of force development–scaling factor (RFD-SF; the slope of the relationship of peak force of rapid force pulses and the corresponding RFD) (1). It has been suggested that both, maximum power and high speed-low resistance training, would improve the quickness of isometric muscular force production in young and older adults, mainly due to neural adaptations. The aim of this study was to determine whether unilateral electromyostimulation training (EMS) would improve maximum and explosive strength and quickness of isometric muscular force production in both, trained and non-trained quadriceps.
METHODS: 13 (7 female and 6 male) healthy and physically active subjects (age: 21.9 ± 2.3 years) completed a unilateral isometric EMS training protocol (3 times/week; 18 sessions; pulse frequency 75 Hz; intensity evoking 60-80% of knee extension torque of maximal voluntary contraction (MVC)). The same test protocol was carried out before and after the 6-week training period. After assessing MVC and RFD, participants were instructed to produce isometrics pulses as quickly as possible and then relax instantly. Participants completed five trials consisting of five pulses to each of four amplitudes (20, 40, 60, 80 %MVC).
RESULTS: Significant increases in the trained quadriceps were recorded in both MVC (12% and 28%) and RFD (15% and 21%) after 3 and 6 weeks, respectively. Gradual increase was also observed in the non-trained quadriceps (4% and 13% for MVC and 9% and 12% for RFD). RFD-SF decreased with time and after 6 weeks of EMS it was significantly lower compared to baseline, both in trained (5.99±0.58 vs. 5.08±0.67) and non-trained quadriceps (5.92±0.52 vs. 5.21±0.55). 3 weeks post-exercise MVC, RFD and RFD-SF were still significantly different from baseline values.
CONCLUSION: EMS training induced significant changes in neuromuscular function of both trained and non-trained quadriceps, indicating that the applied protocol could induce central adaptation. Although EMS led to increase in RFD similar to increase in MVC, it led to decrease in RFD-SF i.e., quality of movement initiation and the quickness of force production. This finding could be of particular importance for better understanding of neurophysiological mechanisms and adaptations behind EMS in training and particularly rehabilitation.

HISTORY DEPENDENCE OF MUSCLE EXCITATION AND OXYGENATION

SONG, J., PARK, J.

SEOUL NATIONAL UNIVERSITY

INTRODUCTION: The relationship between the end-effector force and physiological demands has been extensively investigated. However, there are controversial results regarding the linearity of muscle force to physiological demands such as muscle excitation and its oxygenation. We assume that the time history of performance might partially affect the nonlinearity of the behavior of physiological variables. Therefore, the current study attempts to address the issue of history dependence on muscle excitation and oxygenation by using surface electromyography (EMG) and near-infrared spectroscopy (NIRS).
METHODS: Eight male subjects performed the isometric force production with knee extension effort. A force transducer on the position of the ankle was used to measure the knee extension force. The EMG and NIRS were used to quantify the excitation and oxygenation levels of the vastus lateralis muscle. In order to induce a difference in history of muscle contraction, all subjects conducted force transition tasks which started steady force production at four force levels (initial phase: 30, 40, 60, 70% of maximal voluntary contraction, MVC) and commonly converges to 50% of MVC (terminal phase) by increasing or decreasing forces. We computed the integrated EMG (iEMG), total hemoglobin (tHb), and the desaturation rate of muscle tissue (TSIslope) in the initial and terminal phase to identify the effect of the history of contraction.
RESULTS: In the initial phase, all the variables (e.g., iEMG, tHb, and TSIslope) showed significant linear relationships with outcome forces ($r > 0.8$, $p<0.01$). In the terminal phase, however, the magnitudes of the variables were varied depending on the time history of forces. The iEMG in terminal phase was lower after condition of decreasing force (from 60, 70 to 50% MVC) than after increasing force (from 30, 40 to 50%). Further, it was varied according to the magnitude of changing force (30>40>60>70% MVC, $p<0.01$). The tHb and TSIslope showed significant differences according to the increase and decrease of force, but they did not depend on the magnitude of the changing force (tHb: 30=40<60=70, $p<0.001$; TSIslope:30=40>60=70, $p<0.01$).
CONCLUSION: We observed 1) the linear changes of the iEMG and NIRS indices concerning the magnitudes of the force, and 2) non-monotonic changes in these variables depending on whether the previous history of muscle contraction for the same magnitudes of force. The present result provides convincing evidence for the history dependence of the changes in physiological demands. The history dependence of muscle excitation could be associated with features of mechanical and neural hysteresis that describes different tension development along with the changes in muscle length (1). The oxygen deficit is affected by the initial level of muscle tension. Thus, it is highly probable that the time history of outcome forces may have an influence on muscle hemodynamics.

A NEW METHOD OF SPLITTING NEUROMUSCULAR ELECTRICAL STIMULATION CURRENT OVER SEVERAL SMALLER ELECTRODES

ALDAYEL, A.

KING SAUD UNIVERSITY

INTRODUCTION: The location and the size of electrodes are an essential factor that affects force generation during neuromuscular electrical stimulation (NMES). Discomfort or unpleasant feeling is considered a major limitation of using NMES in healthy individuals. Varying NMES parameters have been investigated to perceive the ideal NMES protocols for maximizing force generation and minimizing discom-

fort level. The aim of this study was to examine a new method of splitting the cathode electrode into several smaller electrodes which are connected in parallel and overlay multiple locations on the muscle.
METHODS: Torque output and maximal current tolerance were compared using a conventional method (one anode and one cathode, E1-1) and a new method of current distributing using one anode and five cathode electrodes (E1-5). Knee extensors of six healthy men (age range 19-46 years) were stimulated using NMES pulsed current (frequency: 50Hz, pulse duration: 400µs). Subjects were seated on Biodex dynamometer at the knee joint angle of 100° (0°: full extension) and the trunk angle of 110°. In E1-1 method, two rectangle self-adhesive electrodes (10cm x 5cm) were placed on quadriceps muscle, while in E1-5 method, one rectangle self-adhesive electrode (10cm x 5cm) was placed on the proximal portion of the quadriceps muscle and five round self-adhesive electrode (5cm diameter) were distributed on the muscle belly. Maximal isometric voluntary contraction (MVC) was determined then NMES was delivered to induce about 20 isometric contractions (on-off ratio 5-5 s) for each method in a counterbalanced trial order among subjects.
RESULTS: Results showed a greater torque output (MVC 233 ± 28 N.m) through E1-5 (33% of MVC) compared with E1-1 (22% of MVC) at the same current intensity. Furthermore, subjects tolerated more current amplitude during E1-5 (74 ± 15 mA) than E1-1 (57 ± 9 mA).
CONCLUSION: Distributing current over a number of electrodes can enhance force generating and ease the discomfort associated with high current intensity. In E1-5 method, more motor nerves are speculated to be induced and lower current amplitude is driven through each electrode, which may explain the advantage of this new method. Further investigation is needed to calculate the flow of current (mA) across each electrode and the effect of skin impedance on them.

CP-MI01 Strength and power

A NEW APPROACH TO EVALUATE THE FORCE-VELOCITY PROFILE: THE SIT TO STAND TEST.

BALTASAR-FERNANDEZ, I.1,2, RODRIGUEZ-LOPEZ, C.1,2, ALCAZAR, J.1,2, NAVARRO-CRUZ, R.1,2, CSAPO, R.3, GARCIA-TERCERO, E.4, LEAL, J.1,2, ARA, I.1,2, ALEGRE, L.M.1,2

1. GENUD TOLEDO RESEARCH GROUP, UNIVERSIDAD DE CASTILLA-LA MANCHA, TOLEDO, SPAIN.

INTRODUCTION: Power production capability is critical for the maintenance of physical function at older age. The F-V profile provides information on either force or velocity deficits, which would limit power production and have been related to negative health outcomes (1). Therefore, resistance training based on individual force-velocity (F-V) profiles might be an effective way to develop muscle power in elderly subjects (2). Our main goal was to evaluate the validity of the sit to stand (STS) test to assess the F-V profile in older people and its relation with functional measures.
METHODS: Fourteen older subjects (5 women; 73.6±3.8 years) participated in this study. Habitual (HGS) and maximum gait speed (MGS) and the timed up-and-go test (TUG) were measured. The F-V profile was evaluated during the STS test using a weighted vest (loads: 1.0×body weight (BW), 1.1×BW and 1.2×BW) and a previously validated equation (3), and compared with the F-V profile obtained during leg press (LP) exercise using a linear position transducer (Chronojump, Spain) and a force platform (Kistler, Switzerland). Paired t-tests, equivalence (two one-sided tests of means (TOST)) and Pearson's correlations were used to compare variables obtained from the F-V profile (force-intercept (F0), velocity-intercept (V0) and maximum power (Pmax)) and assess their association with functional performance, respectively.
RESULTS: No significant differences were found between STS- and LP-based values for F0 (1878.6±811.2 vs 1835.1±631.8 N), V0 (0.93±0.31 vs 0.84±0.36 m/s), and Pmax (407.0±151.0 vs 373.9±187.6 W) (all $p>0.05$). There was a significant correlation between STS and LP Pmax ($r=0.811$; $p<0.001$), while no significant associations were found for F0 or V0 ($p>0.05$). TOST showed no equivalence between tests in any of the variables. STS Pmax, but not LP Pmax, was associated with HGS ($r=0.56$; $p<0.05$) and tended to decrease with increasing TUG time ($r=-0.48$; $p=0.085$). By contrast, LP Pmax, but not STS Pmax, was associated with MGS ($r=0.58$; $p<0.05$).
CONCLUSION: Although not equivalent to leg press F-V testing, the STS test performed against different loads proved to be a valid tool to assess Pmax from the F-V profile in older people, yielding similar results as conventional F-V tests using resistance training devices. The limited time, space and material requirements (chair, stopwatch and weighted vest) of this test facilitate the evaluation of F-V profiles in large cohort studies and clinical routine.

THE EFFECT OF TRADITIONAL SETS AND REST-REDISTRIBUTION ON TOTAL WORK DURING CONCENTRIC ISOKINETIC KNEE EXTENSIONS AT TWO DIFFERENT SPEEDS

MALECEK, J., OMCIRK, D., PISZ, A., HALAJ, M., TUFANO, J.J.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY, PRAGUE, CZECH REPUBLIC

INTRODUCTION: Traditionally, repetitions in each set are performed in sequence with no rest between repetitions, which is highly fatiguing. Previous research has shown that redistributing long inter-set rest periods into shorter but more frequent inter-set rest periods can reduce acute fatigue in a multi-joint free weight movements. However, the absolute effectiveness of rest redistribution largely varies among these studies, likely due to a variety of exercises performed with different loads, an uncontrolled number of repetitions performed, or unintentional changes in load or displacement. Therefore, the purpose of this study was to determine the effect of rest redistribution on maximal effort concentric isokinetic actions at slow and fast speeds to determine whether rest redistribution may be more advantageous for maintaining total work during heavy explosive concentric movements or light explosive concentric movements.
METHODS: Sixteen resistance-trained men (23.7 ± 2.8 years; 81.1 ± 8.8 kg; 181.3 ± 7.3 cm) performed a familiarization visit and then four counterbalanced, randomized visits on an isokinetic dynamometer. Slow (STS; 60°s-1) and fast traditional sets (FTS; 360°s-1) included 4 sets of 10 concentric knee extensions with 95 s of inter-set rest, whereas the slow (SRR; 60°s-1) and fast rest-redistribution (FRR; 360°s-1)

sets included 20 sets of 2 with 15 s inter-set rest. Later, the 20 sets of 2 were grouped into 10-repetition sets to be compared to TS. Each session occurred around the same time of day and was separated by 48-96 hours. For each velocity, a two-way repeated measures ANOVA was conducted to determine differences in total work (TW) per repetition between TS and RR, while effect sizes (Hedge's g) were calculated to assess the magnitude of the difference between the set structures.
RESULTS: There were no protocol x set interactions between STS (208.91 ± 35.79 J) and SRR (216.33 ± 42.53 J) ($p = .428$) or between FTS (65.58 ± 7.88 J) and FRR (70.35 ± 9.85 J) ($p = .393$). For STS and SRR, there was not a main effect for protocol ($g = 0.18$), but there was a main effect for set when collapsed together ($p = .047$), with TW being greater in the 1st set of 10 repetitions (216.65 ± 41.09 J) than the 2nd (212.75 ± 42.04 J; $p = 0.023$), 3rd (211.01 ± 39.48 J; $p = 0.046$), and 4th (210.09 ± 38.19 J; $p = 0.040$) set of 10 repetitions. For FTS and FRR, there were no main effects for protocol ($g = 0.52$) or set when collapsed together.
CONCLUSION: Although there were no significant differences in TW between protocols at either speed, effect sizes indicated that there were small to moderate effects on TW, in favour of the RR protocols. As the range of motion and velocity were equal between protocols at each speed, it is possible that RR allows for greater force or torque to be applied throughout an entire range of motion, possibly affecting TW. Therefore, coaches may wish to prescribe RR when aiming to maximize TW, especially with faster movements.

THE EFFECT OF AN UNILATERAL SHORT-TERM STRENGTH TRAINING ON NEUROMUSCULAR EFFICIENCY

BASSAN, N.M., DE LIMA, L.C.R., BARRETO, R.V., CARITÁ, R.A.C., ABDALLA, L.H.P., CARDOZO, A.C., DENADAI, B.S., GRECO, C.C.

SÃO PAULO STATE UNIVERSITY

INTRODUCTION: Unilateral strength training promotes significant increases in muscle strength not only in the trained limb but also in the untrained contralateral limb (1). This phenomenon is known as "cross-training" and occurs due an improvement in recruitment and / or firing frequency of the motor unit in both limbs (2). Some studies have demonstrated that neuromuscular efficiency (MVC.iEMG-1) of the trained limb can also be improved after a strength training period (3,4), however, what happens in the contralateral untrained member remains unknown. Thus, the aim of this study was to analyze the effect of an unilateral short-term isometric strength training on neuromuscular efficiency on both members.
METHODS: Thirty-nine male subjects were randomly assigned in experimental group (EG - N = 25. 25 ± 3 years, 72.5 ± 10 kg e 175 ± 6 cm) and control group (CG - N = 14. 23 ± 4 years, 72.7 ± 19.5 kg, 178 ± 8 cm). They performed the following procedures, before and after a 3-week period: 1) familiarization with the isokinetic dynamometer and anthropometry, and; 2) maximum isometric contraction test for both dominant (DL) and non-dominant limbs (NDL), to determine maximal voluntary contraction (MVC) and surface EMG in the vastus lateralis muscle. The EG performed six unilateral knee extensors resistance-training sessions over 3 weeks. The subjects were instructed to ramp up to 100% of MVC over 1 s, hold it for 3 s, and relax. Each repetition had a 2-s interval (10); each set, a 2-min interval (3). The comparison of the variables between groups, member and time was analyzed by anova three way, complemented by the Bonferroni test.
RESULTS: There was a similar increase of MVC (DL = 14% and NDL = 11%) and iEMG (DL = 20% and NDL = 21%) in DL and NDL of the EG after the strength training period ($p < 0.05$). Additionally, there was a similar decrease in neuromuscular efficiency (DL = -5.5% and NDL = -11%) for both limbs of the EG ($p < 0.05$). There was no significant change for all variables of the CG ($p > 0.05$).
CONCLUSION: The changes in neuromuscular efficiency were similar on both members such as happened to MVC and iEMG after unilateral short-term strength training (5) However, this kind of training was not effective to increase neuromuscular efficiency, probably because strength training was accomplished in a short period of weeks and with high intensity which main adaptation are in neural drive (5). Besides that, training was done with joint stabilized, and this requires more neural activation of agonist muscle to increase the strength (3). So, it can be concluded that short-term isometric strength training induces similar changes on neuromuscular efficiency for trained and untrained limb, but this kind of training does not seems to be effective to increase this parameter.

EFFECTS OF PASSIVE ISOKINETIC HIP EXTENSION-FLEXION TRAINING WITH ELECTROMYOSTIMULATION ON HIP JOINT TORQUE AND SPRINT PERFORMANCE

MIKI, S.1, OGISO, K.2

1:KOGAKKAN UNIVERSITY, 2:AOYAMA GAKUIN UNIVERSITY

INTRODUCTION: This study was designed to investigate the effects of passive isokinetic hip extension-flexion training with electromyostimulation (EMS) of the hip extensors and flexors on hip extension and flexion torque. The effect on sprint performance was also investigated because the muscles of the hip joint play an important role in performance.
METHODS: Participants were randomly divided into 4 training groups: passive isokinetic hip extension-flexion training (ISOK), EMS training of the hip extensors and flexors (EMS), ISOK+EMS training, and no training as a control. Training was performed 3 times a week for 5 weeks. In the ISOK group, isokinetic hip-extension and flexion was passively repeated 50 times (90°/s). The ISOK+EMS group performed the same training as the ISOK group while applying EMS to the hamstrings and gluteus maximus. In the EMS group, EMS was applied to the same muscles for the same duration as the ISOK+EMS training at hip joint angles of 30°, 45°, and 60°. To evaluate the effects of the training, the following measurements were recorded 1 week before training, every week during training, and immediately after as well as 1 week following the end of training: maximum voluntary isometric hip-extension and flexion torque at hip joint angles of 30°, 45°, and 60°, maximum voluntary isokinetic hip-extension and flexion torque at 90°/s, and 50-m sprint time.
RESULTS: EMS applied to the hip extensors significantly increased maximum voluntary isometric hip-extension torque. However, the maximum voluntary isokinetic torque and 50-m sprint time improved significantly in only the ISOK+EMS group. No significant changes in torque or sprint time were observed in the control and ISOK groups.
CONCLUSION: The results of this study showed that the combination of EMS and passively stretching and shortening the muscles improved muscular strength and motor performance without any effort to generate force. EMS applied to relaxed muscle increased static

muscular strength but not dynamic muscular strength or sprint performance. Therefore, passive isokinetic muscle contraction training with EMS is an effective training method that can easily and efficiently improve muscular strength and athletic ability.

NEUROMUSCULAR RESPONSE TO DIFFERENT PERIODISATION STRATEGIES WITHIN RESISTANCE TRAINING: A PILOT STUDY

MALONE, J.J., MCMAHON, J., ANGELL, P.

LIVERPOOL HOPE UNIVERSITY

INTRODUCTION: Resistance training (RT) has been shown to be the most effective method for developing and/or maintaining muscular strength, hypertrophy and power (1). The development of these qualities requires careful planning through periodisation strategies in order to maximise the response to RT (2). The systematic variation in the load across a training microcycle provides a method of altering training volume and intensity to ensure optimal recovery time for athlete adaptation. Recent research (3) has examined the time-course response to different types of a single RT session. However, limited information is available investigating the response to consecutive days of periodised RT. Therefore, the purpose of this study was to assess the time course neuromuscular recovery following three different periodisation conditions across consecutive days of training.
METHODS: Five resistance trained males (23.4±2.7 yrs; 81.7±11.0 kg; 180.0±1.2 cm) completed three bouts of RT across consecutive days followed by two recovery days. Participants completed three separate periodisation strategies (Undulating; UND, Constant; CON, Tapered; TAP) in a randomised, cross-over design. RT sessions were made up of four exercises: back squat, bench press, deadlift and bent over row. Each exercise was performed at 85% 1RM for 5 repetitions, with the number of sets per exercise varying across the three days: UND = 2-5-2; CON: 3-3-3; TAP: 5-2-2. The neuromuscular response to each condition was assessed at pre-post each RT day and also during recovery (+24h and +48h). Countermovement jump (CMJ), drop jump (DJ), isometric (ISOM) and isokinetic (ISOK) variables were measured at each time point.
RESULTS: There were no significant differences observed across the three different periodisation conditions ($P > 0.05$). Despite significant main effects for CMJ height, DJ height, ISOM peak quadriceps and hamstring measures, post-hoc analyses revealed no significant difference for time point across each condition ($P > 0.05$).
CONCLUSION: Overall, these data suggest that neuromuscular recovery remains unaffected by the periodisation structure across a microcycle when total overall load is matched. Practically, the present findings would suggest that practitioners may adopt different periodisation strategies without potentially compromising recovery for athletes.

PERFORMING EXPERIENCE AND STABILITY OF RANGE OF MOTION IN BOTTOM POSITION OF SQUAT

OLIVA, V., KESZEGH, P., CHUDÝ, J., HALAJ, M., NOVOSÁD, A., BUZGÓ, G.

FACULTY OF PHYSICAL EDUCATION AND SPORTS, UNIVERSITY OF COMENIUS

INTRODUCTION: Conflicting opinions about the activation of primary muscles with a change in the depth of squat (1, 2) indicates the possible influence of the movement execution (3) and performing experience (4). The aim of research is to compare the stability of range of motion (ROM) and efficiency of the bottom position of squat among athletes with varying performing experience.
METHODS: Two groups of athletes with varying performing experience with the squat: non-squatters (NSG; n=9; age 21,1±2,4 y.; height 179,2±8,2 cm; body weight (BW) 70,0±7,4 kg) and squatters (SG; n=10; age 23,9±1,0 y.; height 182,3±3,9 cm; BW 81,0±4,1 kg) performed a progressive loading diagnostic test in the deep squat via the linear position transducer (FitroDyne Premium) and the dynamometric force plate (FitroForce Plate). The load was derived from the BW of athlete (ranging from 0 to 100% of BW). We chose the eccentric phase of motion (ROMECC = squat depth) and the ROMECC variation coefficient (CVECC) for the entire diagnostic set (10 reps) to measure the stability of ROM. Effectiveness of the bottom position of squat was measured by ratio of the force of athlete and barbell (FW) and value of the force peak in the bottom position of squat (FMAX). The significance of differences was evaluated by non-parametric test and effect size.
RESULTS: When compared mean squat depth between the NSG group (67,6±6,56 cm) and the SG group (74,8±4,76 cm), we found significant differences ($p = 0.022$; $r = 0.524$). Validity of difference was also confirmed by significant percentage differences in the squat depth in relation to body height (NSG - 37.7±2.81 %, SG - 41.0±2.37 %, $p = 0.028$, $r = 0.506$). We compared the CVECC of the NSG group (5.7±2.38 %) with the SG group (3.1±1.22 %) with a significant difference ($p = 0.002$; $r = 0.674$) in favour of SG. The average FW and FMAX ratio for SG was 1.93 (± 0.26) in favour of FMAX. In both groups, we note decreasing trend of the ratio with increasing external load. At the same time, we noted among groups a significant difference of ratio: +25% of BW ($p = 0.028$; $r = 0.506$); +50% of BW ($p = 0.043$; $r = 0.468$); + 75% of BW ($p = 0.002$; $r = 0.674$); +100% of BW ($p = 0.010$; $r = 0.581$) between the groups, except for the load at + 0% of BW ($p = 0.400$; $r = 0.206$).
CONCLUSION: The SG group achieved larger ROMECC, higher percentage of ROMECC from the body height and better squat stability for the diagnostic set (lower CVECC value) compared to NSG. We found significant between-group differences in efficiency of the bottom position of squat from resistance +25% of BW. The between-group differences highlight the impact of performing experience on stability of ROM and effectiveness of the bottom position of squat.

SHORT- VERSUS FULL RANGE OF MOTION EXPLOSIVE TRAINING TO ENHANCE LOWER LIMB POWER PRODUCTION

SOLBERG, C., PAULSEN, G., WERKHAUSEN, A., BOJSEN-MØLLER, J., SEYNNES, O.R.

NORWEGIAN SCHOOL OF SPORT SCIENCE

INTRODUCTION: Resistance training for sports requiring explosive movements is often performed over the full range of motion (ROM). Interestingly, training with either ballistic full ROM or explosive isometric contractions of the plantar flexors have resulted in similar increase in peak torque at high velocity and rate of torque development (RTD;1), although the functional transferability of such adaptations

remains untested. The purpose of this study was to test the hypothesis that explosive full ROM or very short ROM knee extensions would result in similar functional improvements in full ROM knee-extensions and leg press.
METHODS: Sixteen volunteers underwent a 10-week resistance training program using a leg press machine. Starting leg joint configuration was set at 90˚ of knee flexion and 80˚ of hip flexion. Training was performed unilaterally, with each leg assigned to very short (~10˚) or full ROM, explosive movements. Training load was matched between legs and monitored weekly and all sessions were supervised. Testing included vastus lateralis thickness, voluntary and electrically induced RTD of knee extensor muscles, and isokinetic knee extension torque at 30˚/s, 60˚/s, 180˚/s and 300˚/s. In addition, peak power, velocity and force were measured during full ROM leg press (80-180˚ knee angle).
RESULTS: Muscle thickness remained unaltered in both legs. Both training methods resulted in a similar increase in voluntary and electrically evoked RTD (P<0.01). Both legs produced a greater isokinetic knee extension torque at 180˚/s (P=0.01) and 300˚/s (P=0.02), but not at lower velocities. Peak power and force measured during leg press were improved with either training methods (P<0.01), while peak velocity did not change.
CONCLUSION: These results extend previous findings on the plantar flexor muscles by showing that explosive resistance training of the knee extensors leads to similar adaptions, irrespective of the ROM and the work performed during exercise. Collectively, the greater RTD and knee-extension torque at higher velocities is ascribed to neural and muscular adaptations improving rapid force production in the first part of the ROM, when most of the muscle force and work can be produced. Such adaptions may equally enhance elastic energy storage with both training modalities and enhance full ROM power output similarly. Hence, owing to the greater work produced by the muscle fibers in the first part of the joint excursion, explosive training with very short ROM contractions may be just as effective as full ROM contractions to improve power production over full ROM.

EXERCISE-INDUCED ENERGY EXPENDITURE DURING STRENGTH TRAINING – COMPARISON BETWEEN A MACHINE-BASED AND A BODYWEIGHT STRENGTH TRAINING PROGRAM

SCHIERBAUER, J., WACHSMUTH, N., SCHMIDT, W.

UNIVERSITY OF BAYREUTH

INTRODUCTION: It is well known that aerobic endurance exercise elicits a greater absolute rise in the exercise-induced energy expenditure (EEE) than resistance exercise. However, resistance exercise offers a considerable deal of health benefits which makes it a useful training component, e.g. to modulate long-term resting metabolic rate. Many studies have been conducted in terms of changes following endurance training, but almost no information is available regarding the EEE during strength training programs, particularly when comparing different workout regimens. Hence, the aim of this study was to determine the EEE during resistance exercise and whether there are measurable differences in EEE when performing either a machine-based (MB) or a bodyweight (BW) strength training program.
METHODS: Nine young healthy males (age: 23.4±0.9yrs, height: 1.81±0.1m, weight: 76.3±9.0kg) performed both a 30-minute MB and BW strength training program. Each workout consisted of eight exercises for all major muscle groups with a break of at least one week between the workouts. For the MB training 1-Repetition Maximum (RM) testing was used to determine the training load that was set as 60% of 1RM. For the BW group, training exercises were modified to the effect that they led to complete exhaustion of the subject at the end of an exercise. In both groups, every exercise had to be performed for 1 minute. Metabolic and cardiorespiratory data was measured before, during and after the workout using spirometry (Metamax 3B, Cortex Biophysik GmbH, Germany). Resting metabolic rate was determined for 30 min directly before starting the workout. Additionally, heart rate and capillary lactate concentrations were measured at stated intervals. Test-re-tests of MB were performed to evaluate the reliability of the measurement. The typical error of EEE in this study was 10.5kcal.
RESULTS: No significant difference in EEE (MB: 215.5±35.7kcal, BW: 223.8±22.7kcal, p=0.16) was found. Furthermore maximum heart rate (MB: 169±18.1bpm, BW: 165±12.5bpm, p=0.36) and maximum lactate concentrations (MB: 15.81±2.0mmol/l, BW: 13.9±2.9mmol/l, p=0.09) did not differ between the training workouts. Excess post-exercise oxygen consumption was still elevated after 30 minutes to the same extend after both workouts.
CONCLUSION: There were no significant differences in EEE, maximum heart rate and maximum lactate concentration between a machine-based or a bodyweight strength training program, indicating similar metabolic demands in both training regimens. Although we found the performance parameters to be in a range as expected during aerobic endurance training, EEE is by far less elevated. In addition, the typical error of the test-re-test analysis shows that a spirometry can be used as a reliable tool to determine energy expenditure during strength training programs in healthy young men.

ACUTE AND SHORT-TERM RESPONSE TO DIFFERENT LEVELS OF EFFORT DURING RESISTANCE TRAINING

CORNEJO-DAZA, P., VILLALBA-FERNÁNDEZ, A., GONZÁLEZ-BADILLO, J.J., PAREJA-BLANCO, F.

PABLO DE OLAVIDE UNIVERSITY

INTRODUCTION: Previous works have analysed the effect of resistance exercise protocols with different levels of effort (relationship between the repetitions completed in a set and those that could be performed) on time course of recovery (1-3). However, these studies prescribed the same number of repetitions for all participants with the same relative load (%1RM) (1-3). Since the maximal number of repetitions against a given %1RM shows great variability (4) it is possible that the level of effort induced for each participant was different. However, to our knowledge, no study has analysed the effect of resistance exercises with different levels of effort individualizing these levels of fatigue through the velocity loss induced during the set. Therefore, the objective of this study was to analyse the acute (Post) and short-term (6h-Post) response to four resistance exercise protocols (REP) of full squat exercise with 70% 1RM that differ in the velocity loss achieved in the set: 20% (70-20) vs. 20% cluster (70-20CLU) vs. 30% (70-30) vs. 40% (70-40).
METHODS: Sixteen physically active sport sciences students (age 22.1 ± 3.2 years, height 1.75 ± 0.04 m, body mass 70.7 ± 8.1 kg) performed four different REP in full squat exercise. All protocols consisted of three sets with 70% 1RM but differed in the velocity loss induced in the set: 70-20 vs. 70-20CLU vs. 70-30 vs. 70-40. All repetitions were recorded with a linear velocity transducer. In order to analyse the changes produced in the physical performance following the four REP, movement velocity against the load that elicited a 1 m·s−1 velocity at baseline measurements (V1-load), countermovement jump (CMJ) height and sprint time in 20 m (T20) were assessed at Pre, Post and 6 h-Post.
RESULTS: The 70-20 protocol resulted in less completed repetitions per set than the other REP, without significant differences between the other REP. All REP showed a significant decrease (P<0.001) in all mechanical indicators of fatigue (T20, CMJ and V1-load) at Post. The REP of greater velocity loss (70-30 and 70-40) showed impairments in performance (P< 0.05) at 6h-Post for all variables. However, 70-20 REP

only showed a significant worsening at 6h-Post for CMJ, whereas 70-20CLU did not show any significant performance impairment at 6h-Post.
CONCLUSION: A greater velocity loss in the set (70-30 and 70-40) produces greater decreases in physical performance in the following hours than smaller velocity loss magnitudes (70-20 and 70-20CLU), despite the fact that 70-20CLU performed similar number of repetitions than the REP with greater velocity loss. This deterioration in performance could persist over time, affecting the ability to apply force, interfering with other physical qualities or competitions.

EXPRESSION OF INFLAMMATORY MEDIATORS AT PATELLAR BONE-TENDON JUNCTION DURING THE ACCUMULATION OF JUMP LOAD

CHEN, X., WANG, L., LIANG, X., LIU, H., WANG, B., ZHANG, N., QU, Y.

BEIJING SPORT UNIVERSITY, UNIVERSITY OF LEEDS

INTRODUCTION: Patella tendinopathy as a common sports injury often occurs in sports that require repeated jumping. And it often happens in tendon and bone-tendon junction. The role of inflammation in the adaptation of load in tendinopathy still not clear. There are many studies focus on the role of inflammation during adaptation to load in tendon, but there are few focus on bone-tendon junction. However, the complex structure of the bone-tendon junction leads to a poor regenerative capacity. The aim of this study was to investigate the expression of inflammation cytokines at patellar bone-tendon junction during adaptation of jump load.
METHODS: Patellar bone-tendon junction was obtained from 32 female New Zealand white rabbits, both the hind limbs were used as experimental subjects（n=64）. Rabbits were randomly divided into blank control group (CON, n = 32), and jumping group (JUM, n = 32). The tissues were obtained at 2 weeks, 4 weeks, 6 weeks and 8 weeks. According to their sacrifice time, CON was divided into CON2W, CON4W, CON6W and CON8W group; JUM was divided into JUM2W, JUM4W, JUM6W and JUM8W group, each group contain 4 animals (n=8). The tissues after fixed, dehydrated, embedded, and then fabricated into tissue sections for immunohistochemical staining. IL-1β, TNFα, COX2, and PTGESE2 were used to evaluate the expression of inflammation mediator. One-way ANOVA was used to evaluate the changes of IL-1β, TNFα, COX2, and PTGESE2 in CON groups and JUM groups and use the Independent sample T test to analysis the difference between JUM and CON groups.
RESULTS: Compared to their counterpart CON group, the expression of TNF-α in the JUM2W and JUM4W group were significantly increased（all $p < 0.05$).Compared to their counterpart CON group, the expression of IL-1β in the JUM2W, JUM4W,JUM6Wand JUM8W group (all $p < 0.01$)was significantly increased. The IL-1β expression in the JUM6W group (all $p < 0.05$) was significantly decreased, compared to the JUM2W, JUM4W group.Compared to their counterpart CON group , the expression of COX-2 in JUM2W, JUM4W , JUM6W group (all $p < 0.01$) were significantly increased. The expression of PTGESE2 in JUM2W, JUM4W, JUM8W(all $p < 0.01$) group were significantly increased when compared with their counterpart CON group. In JUM group, the expression of PTGESE2 was significantly decreased in JUM4W when compared to JUM2W($p < 0.05$), and compared to JUM4W group, the expression of PTGESE2 was significantly decreased in JUM6W group($p < 0.05$).
CONCLUSION: During the adaptation to the jumping load, the expression of inflammatory cytokines in the patellar bone-tendon junction showed a temporal characteristic. The expression of TNFα, IL-1β, COX2 and PTGESE2 peaked at two weeks of jumping load, and then TNFα expression gradually decreased, and returned to the control level at the sixth week.COX2 continued to be highly expressed in the first 6 weeks, returned to the control level at the 8th week, IL-1β and PTGESE2 continued to be highly expressed during the first 8 weeks of load accumulation.

THE EFFECTS OF DYNAMIC TAPE APPLICATION ON THE FRONTAL PLANE KNEE PROJECTION ANGLE DURING DROP LANDING AND JUMPING IN FEMALE VOLLEYBALL ATHLETES

LIN, C.F., WANG, S.C., HE, C.S.

NATIONAL CHUNG CHENG UNIVERSITY

INTRODUCTION: Knee injuries are one of the most common injuries of volleyball athletes, which are related to repeated jumps, spike and block (1). In particular, anterior cruciate ligament injuries are the significant problem among female athletes. Two-dimensional frontal plane knee projection angle has been used to screen athletes who are at risk for anterior cruciate ligament injury. Recently, it has been showed that the dynamic taping could be applied in motor control training to decrease load of lower limbs muscles. The study found that there was a significant decrease in the frontal plane knee projection angle of single leg squat after the application of dynamic taping (2). Furthermore, the drop vertical jump was a task routinely used to assess athletic injury risk and performance potential. Therefore, the aim of this study was to determine the differences of two-dimensional frontal plane knee projection angle in female volleyball athletes with the application of dynamic taping or placebo taping during drop landing and jumping.
METHODS: Thirteen female volleyball athletes from National Chung Cheng University participated in the study. In the counterbalanced design, all participants were randomly given with no taping, placebo taping or dynamic taping. Before taping, participants warmed up for 1 minute. A spiral taping technique was placed with the hip in 40° abduction, 20° extension and full available external rotation (2). Participants performed drop landing and drop jumping from a 40-cm-tall box. The differences of standing, single leg squat, drop landing with single leg, drop landing with double leg and drop jumping in the frontal plane knee angle were analyzed with Image J. All participants were allowed to practice twice before the formal test. Data was analyzed by repeated measures one way ANOVA. The significant level is $\alpha = 0.05$.

RESULTS: The result showed that there was a significant difference in the frontal plane knee projection angle of drop landing with double leg ($p < 0.05$). Dynamic tape group (9.01° ± 5.87°) was lower than no tape group (12.03° ± 6.80°) and placebo tape group (12.57° ± 8.72°). In addition, there was also a significant difference in the frontal plane knee projection angle of drop jumping ($p < 0.05$). Dynamic tape group (10.73° ± 4.40°) was lower than no tape group (15.19° ± 4.02°) and placebo tape group (15.69° ± 9.41°).
CONCLUSION: The application of dynamic taping had a profound influence on decreasing frontal plane knee projection angle during drop landing and drop jumping. The effects might have contributions on reducing the risk of sports injuries in the lower limbs of volleyball athletes.

ILIOTIBIAL BAND STIFFNESS IN RUNNERS' KNEE – AN IMAGING- BASED INVESTIGATION

FRIEDE, M., KLAUSER, A., FINK, C., CSAPO, R.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Iliotibial band (ITB) syndrome is the most common cause of lateral knee pain in runners and one of the most frequent knee overuse syndromes in active populations. The etiology of ITBS is believed to be associated with excessive tone in the iliotibial tract leading to chronic compression of underlying tissues and, consequently, to inflammation and pain. However, currently there is no direct evidence to support this hypothesis (1). The primary aim of this study was to test the hypothesis that ITB syndrome would be caused by excessive ITB tension.
METHODS: 14 runners with ITB syndrome and 14 healthy controls were recruited. Ultrasound shear-wave-elastography was used to measure the stiffness in the ITB as well as the gluteus maximus and tensor fasciae latae muscles of both legs. In addition, hip muscle strength, VAS pain and subjective lower extremity function were assessed. To determine the efficacy of current treatment approaches, patients underwent 6 weeks of standard physiotherapy and data were collected pre- and post-intervention.
RESULTS: Preliminary results from 13 patients showed no statistical differences in ITB or muscle tension between the symptomatic and non-symptomatic leg [symptomatic leg ITB: 11.93 ± 3.62 vs. non-symptomatic leg ITB: 13.44 ± 2.72 (m/s), $p = 0.249$]. Further, no strength deficits were detected (all $p > 0.05$). Following 6 weeks of physiotherapy hip external rotator strength [pre: 116.82 ± 28.80 to post: 136.86 ± 35.88, $p = 0.042$], pain (pre: 78.62 ± 15.15 to post: 19.85 ± 29.23, $p= 0.002$) and lower extremity function (pre: 65.00 ± 6.66 to post: 75.62 ± 5.55, $p = 0.002$) were significantly improved without changes in ITB or muscle tension.
CONCLUSION: Data suggest that ITB tension is neither significantly different between patients' affected and non-affected leg nor sensitive to standard physiotherapy interventions. Comparisons with the control group (currently tested) will allow for conclusions regarding the etiology of ITB syndrome.

LOW-GRADE INFLAMMATION AND ITS RELATION TO MUSCLE MASS

KAMPER, R.S., ALCAZAR, J., GUDMUNDSSON, M., ANDERSEN, L.L., HADDOCK, B., JOERGENSEN, N.R., HOVIND, P., SUETTA, C.

1. BISPEBJERG-FREDERIKSBERG HOSPITAL, 2. RIGSHOSPITALET GLOSTRUP, 3. UNIVERSITY OF CASTILLA-LA MANCHA, SPAIN, 4. HERLEV-GENTOFTE HOSPITAL, 5. THE NATIONAL RESEARCH CENTRE FOR THE WORKING ENVIRONMENT

INTRODUCTION: Chronic low-grade inflammation has been associated with chronic age-related diseases including sarcopenia (1,2). However, results regarding the role of systemic low-grade inflammation on muscle mass are inconsistent, and lack unequivocal evidence as to whether systemic levels of inflammatory markers could represent biomarkers of sarcopenia. The aim of this study was to investigate the potential association between inflammatory biomarkers and appendicular lean mass in home-dwelling older individuals.
METHODS: 1206 healthy men and women (range: 22-93 years) were included in the present study. Appendicular lean mass (kg/h2) was assessed by DEXA (iDXA, GE Lunar). Plasma samples were analysed for IL-1beta, IL-4, IL-6, IL-10, IL-13, IL-15, IFN-gamma and TNF-alpha using commercially available multiplex bead-based immunoassay kits (Bio-Rad).
RESULTS: There was no association between biomarkers and muscle mass in subjects under 80 years. In subjects over 80 years, IL-13 was negatively associated with muscle mass in men ($P<0.01$) and women ($p<0.05$), while IL-6 was positively associated with muscle mass in women only ($P<0.05$). In men only, muscle mass was negatively associated with IL-4 ($P<0.05$) and IFN-gamma ($P<0.01$).
To assess the role of high cytokine levels on lower muscle mass (lowest 20%), data was analysed stratified by gender and in subjects > 60 years only using a logistic regression model controlling for age and relative fat mass. TNF-a was divided into tertiles with equal numbers across categories. The remaining cytokines were coded into 3 categories with levels below the lower limit of quantification as reference. Higher levels were divided into 2 groups, based on the gender-specific median. Women over 60 years with high levels of IL-13 (>0.74 pg/ml) had more than 3-fold greater odds of having lower muscle mass (Odds ratio [OR] 3.6, 95% confidence interval [CI] 1.42-8.94, $P<0.01$) compared to women with low levels (<0.28 pg/ml). Men over 60 years with intermediate levels of IFN-gamma (0.28-0.69 pg/ml) had more than 2-fold greater odds of having lower muscle mass (OR 2.5, 95% CI 1.00-6.07, $P<0.05$) compared to men with low levels (<0.28 pg/ml).
CONCLUSION: Overall, these data suggest that an association between muscle mass and biomarkers of inflammation is not evident until the 9th decade of life. A novel finding was the negative association of IL-13 with muscle mass in both men and women over 80 years, and the increased risk for women over 60 years of having lower muscle mass when having higher levels of IL-13.

REPEATED BOUT EFFECT ON MYOFIBER PERMEABILITY AND MUSCLE FUNCTION THAT IS DEPENDENT ON THE INTERVALS BETWEEN INITIAL AND SECOND BOUTS OF ECCENTRIC CONTRACTIONS IN RAT SKELETAL MUSCLE

HAYAO, K.1,2, TAMAKI, H.1, NAKAGAWA, K.1, YOTANI, K.3, OGITA, F.3, TAMAKOSHI, K.1, TAKAHASHI, H.1, ONISHI, H.1, YAMAMOTO, N.4

1: NIIGATA UNIVERSITY OF HEALTH AND WELFARE, 2: SOUTHERN TOHOKU GENERAL HOSPITAL, 3: NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA, 4: NIIGATA REHABILITATION HOSPITAL

INTRODUCTION: Eccentric contractions (ECC) often induce muscle damage with accompanying transient muscle strength reduction and morphological changes, in both animals and humans (Beaton 2002, Hayao 2018). Repeated bouts of eccentric contractions performed within several weeks or months result in less severe myofiber damage than the first intervention. The aim of this study was to investigate the effect of repeated bouts on membrane permeability and muscle force production associated with the intervals between the initial and second bouts of eccentric contractions in the tibialis anterior (TA) muscle in rats.
METHODS: Sixty-four male Fischer 344 rats (12-16 weeks of age) were divided into eight groups: (1) Control, (2) Post 1st bout, (3) Pre 2nd bout_1w, (4) Post 2nd bout_1w, (5) Pre 2nd bout_2w, (6) Post 2nd bout_2w, (7) Pre 2nd bout_4w, (8) Post 2nd bout_4w. For the ECC groups, ECC of first bout and second bouts were set to the same load strength. The left TA muscle was subjected to first or second eccentric contraction bouts consisting of 80 eccentric contractions (200 deg/sec) induced by direct electrical muscle stimulation (ES), separated by each week (2nd bout_1w, 2w, 4w). Evans blue dye (EB), used as a marker for myofiber damage, was injected intraperitoneally twenty-four hours before muscle collection. Maximum isometric contraction force (Fmax) evoked by the ES was measured before muscle collection. The TA muscle was excised two days after the last ECC session. We performed immunohistochemical staining against dystrophin and developmental myosin heavy chains (dMHC) on frozen transverse sections of the TA.
RESULTS: In each second bout group, the EB-positive fibers were lower in the Post 2nd bout_1w, Post 2nd bout_2w, and Post 2nd bout_4w groups than in the Post 1st bout ($P < 0.05$). In addition, EB fibers increased with the extension of the second bout execution interval. The Fmax was significantly higher in the Post 2nd bout_1w, Post 2nd bout_2w, and Post 2nd bout_4w than in the Post 1st bout ($P < 0.05$). dMHC-immunopositive reaction(ir)/dystrophin-ir was significantly higher in the Pre 2nd bout_1w and Post 2nd bout_1w than in the Post 1st bout ($P < 0.05$).
CONCLUSION: These findings suggest that repeated bout effects decreased with the extension of intervals between bouts. In addition, it was suggested that there was a difference between the functional effect and the histologic effect in terms of membrane permeability.

UNLOADING STRESS RETARDS SATELLITE CELL MIGRATION BY DELAYED MACROPHAGE RECRUITMENT AFTER SKELETAL MUSCLE INJURY IN RATS

KAWASHIMA, M.1, SUGIYAMA, M.1, MIYAKAWA, M.1, TANIGUCHI, K.2, ARAKAWA, T.1

1: KOBE UNIVERSITY GRADUATE SCHOOL OF HEALTH SCIENCES, 2: KOBE UNIVERSITY SCHOOL OF MEDICINE

INTRODUCTION: Unloading stress induced by the tail suspension of the rats could cause not only the atrophy of the skeletal muscle and increase the fast muscle, but also impairment of the muscle regeneration. Unloading stress during the muscle repair process perturbs the recruitment of macrophages (MPs) into the injured site and inhibits activation of satellite cells (SCs) (1). Skeletal muscle regeneration process is tightly regulated by differentially polarized MPs. In the early phase of normal muscle regeneration, leucocytes, especially proinflammatory MPs, the primarily invading phenotype of MPs, accumulate into the damaged site. The proinflammatory MPs express the inducible nitric oxide synthase (iNOS) and synthesize nitric oxide from L-arginine. In addition, previous study suggested that SCs migrate via a nitric oxide-dependent way (2). Therefore, the present study investigated the effect of unloading conditions during muscle regeneration on the recruitment of iNOS expressing proinflammatory MPs and SC migration into the injury area.
METHODS: 8-week old male Wistar rats weighing 180-200g were used in the present study. To induce muscle injury, animals were anesthetized with isoflurane and exposed the extensor digitorum longus muscle, then the middle part of the muscle belly was crushed for 30s using forceps, to which a weight (500g) was attached, as previously reported method (3). After the crush injury, animals were randomly divided into ambulatory control group (Con) and hindlimb unloading (HU) group. Muscles were harvested for analysis at 6, 12, 24, 48, 72h ($n = 3$, respectively) after the injury and frozen cross sections of the muscles were obtained by cutting with a cryostat. Sections (10 μm) from all rats were subjected to hematoxylin and eosin (H-E) staining, and to the immunohistochemical analysis for CD68 (a pan-MP marker), iNOS, and Pax7 (a specific marker of SCs).
RESULTS: At 6h post injury of the Con group, CD68/iNOS double-positive cells recruited into the injured site and some of those cells infiltrated within the necrotic myofibers. In contrast, in the HU group, the recruitment of the double-positive cells was less than those in the Con group. Similarly, until 48h after the injury, the number of infiltrated double-positive cells in the HU group was smaller than those in the Con group. Notably, a large number of Pax7-positive cells was observed in the injured site in the Con group at 72h post injury, while not detected in the HU group.
CONCLUSION: These findings suggest that unloading stress during muscle regeneration might perturb SC migration into the injured site via disturbed iNOS expressing MP recruitment in the early phase of muscle regeneration.

POTENTIAL SEX DEPENDENT BIOMECHANICAL RISK FACTORS FOR PATELLOFAMERAL PAIN SYNDROME.

BJÖRGVINSDÓTTIR, M., SIGURÐSSON, H., PETROVIC, M., BRIEM, K.

UNIVERSITY OF ICLEAND

INTRODUCTION: A myriad of risk factors for patellofemoral pain syndrome (PFPS) have been identified, that include non-modifiable factors such as the female sex (1), and biomechanical risk factors (2). Kinematic studies have usually involved a cross-sectional study design on individuals suffering from PFPS. Moreover, risk factors during drop jump (DJ) landing have mainly been studied for the sagittal plane, while less is known about transverse and frontal plane variables (3). Therefore, the aim of this prospective research is to identify biomechanical changes through the pubertal years in males and females during the performance of the DJ. The primary focus is on hip and knee kinematics in the frontal and transverse plane of both legs (limb) at initial contact and at individual's lowest position (timepoints) of healthy youngsters from childhood through adolescents (phase).

METHODS: Participants were recruited from local handball and football clubs and signed an informed consent form together with a legal guardian. Athletes were 9-12 years old at phase 1 (n=224) and at phase 2 (n=30), these same athletes were aged 14-17 years old for a mean time from baseline to follow up of 5 years. Height and weight were measured before a short warm-up on a stationary bike. Standard 3D motion capture methods were used with an eight camera system (Qualisys) and two force plates (AMTI) while participants performed 5 repetitions of a bilateral DJ. Data were digitized, exported in c3d format and further calculations performed in Visual 3D (c-motion). Mixed model analysis of variance was used for statistical analysis, using an alpha of 0.05 for significance.
RESULTS: For frontal plane hip kinematics, both males and females showed a significant 3-way interaction (phase by limb by timepoint; $P<0.05$) demonstrating greater changes towards hip adduction over time on the right side. For transverse plane hip kinematics, both males and females demonstrated a phase by limb interaction due to greater asymmetry as children, which was not detected as adolescents ($P<0.001$). At the knee, both sexes demonstrated greater frontal plane excursion at phase 2 compared to phase 1, bilaterally ($P<0.001$). However for knee rotation, males showed no interaction for phase, while females demonstrated a 3-way interaction due to interlimb differences in excursion during landing leading to slightly greater internal rotation in phase 1 and external rotation in phase 2 ($P<0.05$).
CONCLUSION: This prospective study shows changes in kinematics over time that may predispose females towards developing PFPS via hip and knee kinematics through development across the pubertal years. Distinguishing biomechanical risk factors at multiple levels during jump landing tasks can contribute to more effective prevention strategies because these factors are modifiable.

CIRCULATING MYOKINES RESPONSE TO ENDURANCE AND CONCURRENT TRAINING AND ITS RELATIONSHIP WITH GLYCEMIC CONTROL IN POSTMENOPAUSAL WOMEN

PÉREZ-LÓPEZ, A.1, GONZALO-ENCABO, P.1, DE COS BLANCO, A.I.2, CALVO VIÑUELAS, I.2, SANTACRUZ, J.A.1, GARCÍA-HONDUVILLA, N.1, VALADÉS, D.1

1: UNIVERSITY OF ALCALÁ ; 2: HOSPITAL LA PAZ

INTRODUCTION: Myokines are critical metabolic mediators of exercise adaptation. Interleukin (IL)-6, IL-13, IL-15 and its alpha receptor (IL-15Ra), and fibroblast growth factor 21 (FGF21) promote fat oxidation and improve insulin sensitivity in several tissues, effects of particular interest in menopause given the metabolic disorders occurring in this period. The circulating presence of myokines is required to stimulate most of these effects, however, their interpretation is complicated due to a coexisting immune-metabolic function and the conflicting acute vs prolonged responses observed. Therefore, this study aimed at determining the effect of endurance and concurrent training on circulating IL-6, IL-13, IL-15, IL-15Ra and FGF21 expression in obese postmenopausal women.
METHODS: Thirty-seven sedentary and obese postmenopausal women were randomly divided into endurance training (EN, n=12), concurrent training (CON, n=12) or a control group (CT, n=12). Participants in EN and CON groups were involved in a 12-weeks supervised training program performing 3 sessions/week of 60 min/session. EN group performed endurance exercise at 70-75%HRR, while CON group performed 40 min of a resistance exercise involving major muscle groups (6 exercises, 3x8-12 at 65%1RM) plus 20 min of endurance exercise at 70-75%HRR. Physical activity and nutritional habits were controlled. Before and after the interventions body composition and fitness were assessed, and blood samples obtained to measure serum myokines levels by ELISA.
RESULTS: Total fat mass was decreased in both exercise groups (~2kg, ANOVA interaction, $P=.036$), while, in the CON group, lean body mass was increased (0.7kg, $P=.018$), and HbA1c, fasting insulin and HOMA were reduced (ANOVA, $P<.05$). Serum IL-6, IL-15 and IL-15Ra levels were decreased after training (ANOVA interaction, $P<.05$), finding a pronounced reduction in IL-6 (-42% vs -17%) and IL-15 (-52% vs -32%) when comparing EN to CON, respectively ($P<.05$). Serum FGF21 was significantly reduced in the EN (-27%; $P=.03$) but not in the CON group (-12%), while IL-13 was not significantly altered. Moreover, in the CON group, the reduction of HbA1c was associated with changes in IL-6, IL-15Ra and FGF21 ($r=-.45$, $-.72$ & $-.66$; $P<.05$), while the change in serum IL-15 was related to changes in fasting insulin and HOMA ($r=-.55$ & $-.57$; $P<.05$).
CONCLUSION: In postmenopausal women, insulin resistance is associated with an elevated risk of diabetes, cardiovascular disease and breast cancer. Concurrent training improved glycemic control and this response was inversely associated with a less pronounced diminution of circulating levels of IL-6, IL-15, IL-15Ra and FGF21 compared to endurance training. Therefore, resistance training could attenuate the reduction of circulating myokines bioavailability induced by endurance training with the potential purpose of improving glucose metabolism. Thus, the type of exercise may regulate the intricate immune-metabolic role of myokines in obese postmenopausal women.

DOES CUPPING TREATMENT CHANGE THE POSITION OF TRANSVERSALIS MUSCLOFASCIAL JUNCTION?

HUANG, Y.H., HU, C.H., TU, S.F., LIANG, J.M., WU, W.L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Evidence suggested that the musculofascial corset system [1], which is complex of deeper muscle and fascia, plays an essential role in spinal stability through its integrity of the tension balance [2]. For example, imbalance tension on the musculofascial corset system is considered as a factor of low back pain [3]. Applying sustained manual pressure on the lateral raphe (LR), which is a junction between the layers of the thoracolumbar fascia and transversus abdominis (TrA), is considered effective in releasing muscle tightness [2,3]. Cupping therapy, which recently attracts attentions from competitive sports, has been applied to relieve muscle tension related to pain[4]. This therapy is proposed to releases soft tissue, loosens adhesions, and lifts connective tissue by negative pressure [5]. However, few studies examined its actual effect and mechanisms. This study aimed to explore the mechanisms of cupping therapy on the LR. The hypothesis is that the TrA would increase sliding after treating LR with cupping and, therefore, an anterior shift on the musculofascial junction can be observed when the TrA is relaxed and contracted.
METHODS: Twelve healthy participants received cupping that applied at the LR for 5 minutes, and another twelve participants were recruited as the control. To examine if MFJ shifts present, ultrasound images of both anterior and posterior TrA MFJs were taken on a supine position before and after treatments. A biofeedback pressure pad was placed under the lumbar arch to ensure no lumbar movements during TrA contraction during ultrasound scanning.
RESULTS: Two-way ANOVA showed that the anterior MFJ significantly shifted forward both when TrA is contracted (0.156 ± 0.056 cm, $p = 0.01$) and relaxed (0.167 ± 0.026 cm, $p < 0.01$) after cupping intervention, while there was no difference in the control group. No shift was observed at the posterior MFJ, regardless muscle contraction status.

CONCLUSION: The results indicated immediate position changes of the MFJ after cupping therapy. This finding demonstrated a potential effect of the cupping technique on soft tissue relieving; future study should attempt to apply this technique to symptomatic cohort to verify its clinical relevance.

EFFECT OF SPORTS INSTRUCTOR ON TEACHERS' AWARENESS OF CHILDREN'S PHYSICAL ACTIVITY IN NURSERY SCHOOLS

KAMIMURA, A.1,2, MURAI, R.1, KAWATA, Y.3,4, KAMBA, M.5, NAGASAWA, T.5,6, MINATO, K.5,6

1: WAYO WOMEN'S UNIVERSITY, 2: JUNTENDO UNIVERSITY, 3: JUNTENDO UNIVERSITY, 4: WAYO WOMEN'S UNIVERSITY, 5: WAYO WOMEN'S UNIVERSITY

Introduction
The evident decreases in children's motor ability are regarded as social issues in many developed countries. Therefore, in Japan, guidelines have been proposed and interventions by sports instructors have been conducted in several schools. However, childcare profession has given little attention to awareness of children's physical activity. Understanding the awareness among nursery school teachers or effect of sports instructors' interventions can improve the capabilities of in-service teachers. Therefore, we aimed to examine effects of sports instructors' interventions on teachers' awareness of children's physical activity in Japanese nursery schools.
Method
We collected data from 1262 nursery school teachers (1191 male, 71 female; Mage = 35.74, SD = 9.72) in charge of 3-4 year-olds from public and private nursery schools. Participants were administered questionnaires for demographic information (sex, age, year of working experience, age in charge), state of sports instructor (the presence or absence of sports instructor, degree of satisfaction), and awareness of children's physical activity (awareness, confidence for teaching, efforts) using 3 items highlighted in the "Physical Activity Guideline for Japanese Young Children": (1) incorporating various games to experience diverse movement, (2) ensuring time to enjoy physical activity, and (3) conducting developmentally appropriate physical activity. We conducted chi-squared test and t-test to examine the effect of sports instructors' interventions on teachers' awareness.
Result
Approximately 30.2% teachers answered, "My class has sports instructor intervention," and this intervention was conducted on average of 39 minutes, once a week. An independent sample t-test was conducted to examine the differences in teachers' awareness of children's physical activity with or without sports instructors. Regarding satisfaction degree of exercise instruction support provided to children in nursery schools, results showed that the teachers' group with a sports instructor scored significantly higher than the teachers' group without a sports instructor ($p < .01$). Additionally, regarding teachers' awareness, confidence in teaching, and efforts for children's physical activity, there were no significant differences between teachers' group with or without a sports instructor.
Conclusion
We concluded that the presence of a sports instructor in nursery schools might increase teachers' satisfaction of exercise instruction support. However, the effect of sports instructor was not observed in teachers' awareness of physical activity regarding the three items highlighted in the Guideline. Thus, we propose the need to establish connection between activities conducted by a sports instructor and everyday education conducted by a nursery school teacher.

A VOLITIONAL INTERVENTION TO IMPROVE HEALTH BEHAVIOUR

MC CONELL DESAIVE, C., STRANG, H., KNISEL, E.

HUMAN SCIENCES

Introduction
The aim of the study was to promote the volitional skills, to improve individual movement and nutritional behaviour. The intervention consisted of the modules (1) coaching in the form of a volitional intervention, (2) exercise program and (3) nutrition program. The coaching was based on the GROW model by Whitmore (2006). Therefore, the participants should be able to set their own goals and to implement and maintain them against external and internal resistance.
Method
In the study 33 adults (f = 24, m = 9) participated, aged 28 to 60 years (M = 36.93, SD = 11.80). The intervention group consisted of 22 participants; the response control group consisted of 11 participants. The study examined the influence of the intervention on self-control, exercise and nutritional behavior, subjective health perception and the body mass index. The data was collected at the beginning and the end of the intervention of twelve weeks.
Results
The results of the Self-Control Inventory (SSI; Kuhl, 2001) showed significant changes on three subscales (alienation M1 = 1.03 (SD = .577), M2 = .876 (SD = .449), t (20) = 1.86, p = .076, non-implementation of intentions M1 = 1.26 (SD = .483), M2 = .924 (SD = .475), t (20) = 4.68, p = , 000; introjection inclination M1 = 1.2 (SD = .672), M2 = .895 (SD = .488), t (20) = 2.62, p = .016). The results of the Questionnaire on Eating Behaviour (FEV; Pudel & Westenhöfer, 1989) demonstrated significant change on the scales of cognitive control of eating behaviour (M1 = 6.71 (SD = 4.53) to M2 = 11.19 (SD = 4.85), t (20) = -3.9, p = .001). The calculated BMI value decreased significantly from the begin-

ning of the intervention to termination (M1 = 28.2 (SD = 5.14), M2 = 27.5 (SD = 4.82), t (21) = 4.4, p = .000). The results of the physical activity questionnaire showed high significant improvements M1 = 3.39 (SD = .916) M2 = 1.78 (SD = .732), t (17) = 7.46, p = .000).
Discussion
The present study shows effects of the intervention on volitional skills and health-related behaviour. Those, a volitional intervention together with an exercise and nutrition program, seems to be successful for health behaviour change. However, there is still a need for improvement. For further research it is important to analyse which of the modules effects the health behaviour changes.

ARE AREA-LEVEL CRIMES ASSOCIATED WITH OLDER ADULTS' PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR?

LIAO, Y., PARK, J.H.

NATIONAL TAIWAN NORMAL UNIVERSITY; PUSAN NATIONAL UNIVERSITY HOSPITAL.

INTRODUCTION: According to Ecological Model of Health Behavior, multiple levels of environmental attributes play important roles of older adults' active and sedentary behavior. However, most previous studies have focused on examining the built environment or perceived environmental factors, few research have investigated specific correlates of social-cultural environment (i.e. objectively-measured crime safety) related to active and sedentary behavior, especially in older adults. In particular, there is limited evidence on the associations of area-level crime with older adults' physical activity and sedentary behavior in Taiwan. Thus, the purpose is to examine the relationship between area-level crime with physical activity and sedentary behavior among older adults.
METHODS: A telephone-based cross-sectional survey of older Taiwanese adults was conducted in September-November of 2017. Data related to socio-demographic factors, residential neighbourhood (objectively area-level crime incidents), and time spent in physical activity and sedentary behavior were obtained from 1,068 older adults. The data were analyzed by performing adjusted binary logistic regression.
RESULTS: After adjusting for potential confounders, older adults living in the neighborhood with higher overall crime incident were less likely to meet meet minimum physical activity recommendation (150 min/week) and more likely to engage in excessive sedentary time (8 hr/day). Moreover, those living in the neighborhood with higher incident of drug crime (odds ratio (OR) = 0.71, 95% CI: 0.52-0.96), car theft incident (OR= 0.70, 95%CI: 0.51-0.95), locomotive theft (OR= 0.69, 95% CI: 0.51-0.94) were less likely to meet 150 minutes/week of total physical activity. In contrast, those living in neighbourhood with higher incident of theft (OR= 1.93, 95%CI: 1.05-3.55), drug crimes (OR=1.93. 95%CI: 1.05-3.55), break and enter (OR=2.04, 95%CI: 1.11-3.76) and rape (OR=2.20, 95%CI: 1.20-4.06) were more likely to have higher sedentary time.
CONCLUSION: To the best of our knowledge, this study is the first study to examine the association of area-level crime with older adults' physical activity and sedentary behavior in the context of Asia. Our results may have a significant implication for informing policy-makers and public health initiatives that crime prevention should be considered as a strategy for promoting active and non-sedentary lifestyle among older adults. Future prospective studies are warranted to further examine these associations using both subjective and objective measures.

PREDICTING RETENTION AND ATTENDANCE BEHAVIOUR OF LEISURE CENTRES MEMBERS

WILLINGER, N.1, STEELE, J.2,3, ATKINSON, L.4, MANN, S.5, JIMENEZ, A.1,6, HORTON, E.1

1COVENTRY UNIVERSITY, WEST MIDLANDS, UK; 2UKACTIVE RESEARCH INSTITUTE, LONDON, UK, 3SOLENT UNIVERSITY, SOUTHAMPTON, UK; 4ASTON UNIVERSITY, BIRMINGHAM, UK; 5PLACES FOR PEOPLE LEISURE, LONDON, 6GO FIT L

INTRODUCTION: Physical inactivity is a global health concern. Leisure centres may be an optimal environment to engage people in physical activity, and increasing the proportion of the population who are active members of leisure centres may contribute to tackling the inactivity pandemic. However, leisure centres are challenged with retaining their members in long-term (Sperandei, Vieira and Reis 2016). Therefore, our aim was to analyse retention of members of UK leisure centres, the factors predicting membership length, and attendance behaviour.
METHODS: This research will be conducted during February and May 2019. Data from 6-9 leisure centres (with a total of up to 80,000 members) in England will be obtained, in respect to member demographics (e.g. gender, age, postcode), each member's visits at the leisure centre between 2008-2019, and membership and leisure centre characteristics (e.g. facilities, joining date, membership freezes). Preliminary analysis was carried out on the basis of one leisure centre (8022 members) via multiple linear and logistic regression using SPSS. A significance value of 0.05 was set.
RESULTS: Multiple linear regression analysis aiming to predict membership length, with average attendance and each member's age when membership commenced as predictor variables, resulted in an R2 of 0.098 (SE=43.67; p<0.001). For each additional year of age and overall average number of visits at the leisure centre, membership length increased for 0.43 (95% CI (0.03, 0.055)) and 3.04 (95% CI (2.58, 3.48)) months. Multiple logistic regression with a membership length of at least 3 or 12 months as primary outcome resulted in an OR of 1.072 (95% CI (1.031, 1.114), Cox & Snell R2= 0.047, p<0.001) and 1.104 (95% CI (1.074, 1.135), Cox & Snell R2= 0.067, p<0.001) for each unit increase in age or average attendance.
CONCLUSION: Preliminary analysis suggests that although average attendance and member's age are significant predictors of membership length, more predictor variables must be considered to improve the overall fit of the linear and logistic models. Potential predictor variables include attendance over time, along with membership and leisure centre characteristics (e.g. membership freezes, and available activities and facilities), which will be included in the final analysis. On the basis of these findings, a separate analysis on attendance behaviour and factors predicting attendance will be carried out.
This research on retention of members of leisure centres and their attendance behaviour can contribute to the improvement of member retention strategies and increased attendance at leisure centres through the development of tailored interventions, to ultimately tackle inactivity rates using the capacity and resources of the physical activity sector.

DESIGNING A BEHAVIOUR CHANGE QUESTIONNAIRE TO ADDRESS PHYSICAL INACTIVITY OF LEISURE CENTRES' CUSTOMERS. A PILOT TEST.

LÓPEZ-FERNÁNDEZ, J., ATKINSON, L., SERRABLO, I., AYUSO, M., HORTON, E., MAYO, X., JIMÉNEZ, A.

1 COVENTRY UNIVERSITY, COVENTRY, UNITED KINGDOM; 2 GO FIT LAB, MADRID, SPAIN; 3 ASTON UNIVERSITY, BIRMINGHAM, UNITED KINGDOM; 4 UNIVERSIDAD REY JUAN CARLOS, ALCORCÓN, SPAÍN.

INTRODUCTION: Leisure centres are social places where community-based interventions may be developed to address physical inactivity. However, these kinds of interventions are scarce, despite the fact, that many leisure centre members do not meet the recommended 150-minutes of physical activity per week (Beedie et al., 2016; Middelkamp et al., 2017). While behaviour change science may help increase physical activity rates (Middelkamp et al., 2017), first it is necessary to identify what inactive members of leisure centres need to change to increase their physical activity. Thus, the purpose of this research was to design a questionnaire to determine the personal needs of inactive members of leisure centres to increase their current physical activity levels.
METHODS: The questionnaire was designed according to the guidelines of the behaviour change wheel (BCW; Michie et al., 2014). To identify the main barriers for an active behaviour (B) related to capability (C), opportunity (O) and motivation (M), we included the six areas on the COM-B model that keeps the inactive members of leisure centres from adopting an active lifestyle (Michie et al., 2014). Besides, one area to identify possible facilitators to exercise in leisure centres was added to the questionnaire. First, a pool of 62 items was identified using 3 focus groups of three people each and a pragmatic literature review. After an external revision of 4 experts in behaviour change and 4 experts in leisure centres, a total of 20 items were deleted. The remaining 42 items were modified according to experts' feedback to avoid leading questions. Afterwards, a pilot test with 50 members of leisure centres was completed to validate the questionnaire. Both construct and convergent validity of the questionnaire were calculated using the Cronbach's alpha, Pearson's correlation and a factorial analysis.
RESULTS: All items showed a Cronbach's Alpha higher than 0.9 while the whole questionnaire showed a Cronbach's alpha coefficient of a 0.911. Pearson's correlations analysis did not show unexpected correlations among items. The factorial analysis grouped the items into 10 different dimensions that explain the 80% of the variance saturations.
CONCLUSION: Our pilot data showed that the BCW is a useful tool to design a questionnaire to identify what inactive population needs to change to increase their current physical activity levels at a leisure centre The questionnaire designed showed sufficient concurrent and convergent validity so a further validation and reliability assessment can be performed to confirm the questionnaire is a valid tool to address physical inactivity in leisure centres.

INCLUSION, EXCLUSION, AND BELONGING AMONGST GROUP FITNESS INSTRUCTORS IN AUSTRIA: FOR A FITTER PLANET?

ANDERSSON, K., VOGL, U.

UNIVERSITY OF VIENNA, UNIVERSITY OF GHENT

"Inclusion, Exclusion, and Belonging amongst Group Fitness instructors in Austria: For a Fitter Planet?"
Andersson, K. University of Vienna
Vogl, U. University of Ghent
Introduction
Fitness centers have developed into what is called a "third place", a community outside of traditional categories of belonging such as family and work. According to statistics, there are 1045 gyms in Austria, and 8,6 percent of the population claim to be members of a fitness-studio, which indicates an increase of 100.000 people over the last five years alone. Currently, globalization and digitalization give rise to immersive, virtual, and global fitness communities. One example is the New Zealand based Māori friendly company Les Mills, which presents itself as a global fitness family or "tribe". Through an allegedly strong commitment to human equality, diversity, and the environment, Les Mills has gained 19.500 active tribe members in a hundred countries all over the world, Austria included.
Methods
This interdisciplinary paper combines a methodology of Critical Discourse Analysis, Cultural Studies, and Intersectionality. The study has a dual purpose. Firstly, Les Mill's declaration of intent or fitness "philosophy" is critically examined through a discourse analysis that will reveal how a "one tribe" identity is constructed and a reinvention of instructors' identities is encouraged by Les Mills. Secondly, we assess how Austrian based Les Mills instructors relate to Les Mill's "one tribe" ideology on a micro level in their everyday lives, on a meso level in their fitness-studios, and on a macro level to the global Les Mills community. The case study is a mixed-method survey consisting of semi-structured interviews and a questionnaire.
Results and Discussion
Our hypothesis suggests that inclusion and belonging to this fitness community depends on a variety of social factors such as socio-economic status, ethnicity, gender, age, and linguistic proficiency. In addition, inclusion within the "tribe" is conditioned by the willingness of instructors to "discipline" their coaching, their bodies, and their minds.

THE EFFECT OF JOB PERFORMANCE MEDIATED BY EXPERIENTIAL VALUE WHEN EXERCISING IN GYMS.

WU, Y.T., CHENG, C.F., WU, Y.F.

NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction

Many studies have proven that exercise has been an important factor for health benefits, these include enhance muscle strength better breathing, not only does it benefit physically but also psychologically, such as reducing stress, depression, anxiety, anger as well as improve moods. However, organized exercise such as, gyms contribute additional social and psychological benefits in comparison to informal and home-based exercise. How those social and psychological benefits affect individual job performance is seldom studied. Therefore, the major goal of this study is to explore the correlation between exercise value perception and job performance. Most theories have shown that cognitive processes connected to knowledge in benefits, threats, developed attitudes, and behavioral control as an important factor for exercise behavior. Cognitive evaluation theory puts more emphasis on motivation to perform a behavior in relation to its value as a reward. However, exercise is seen as a short-term and long-term consequences of ones actions. Thus, exercise could require people to sacrifice time to involve in job that may affect low job performance. This lacks evidence which is likely in part due to experiential value perception exists between job performance and exercise in gym.

Methods

In the study questionnaires were distributed to gyms and focused on Taiwanese participants that participated in gyms on a regular basis. 5-point Likert scale was used for the dimensions. These dimensions include: motivation, hedonic value, utilitarian value, social value and job performance. The participants took part in the study on a voluntary basis. The questionnaires were retrieved during the period from the 2nd of December 2018 to the 10th of January 2019. To verify the research model, VirtualPLS statistical software was used. A total of 200 questionnaires were gathered and after the elimination of invalid responses, 164 valid questionnaires were used. IBM SPSS 23.0 for Windows was used for the descriptive analysis.

Results

We designed a model to test the correlation between motivation, hedonic value, utilitarian value Social value and job performance, the result of the study on motivation, utilitarian value, social value and job performance indicated participants' perception. In the study we could see positive correlation for experiential value and job performance.

Conclusion

Experiential value perception exists between job performance and exercise in gym. Hedonic value and social value brings fun and excitement which is a positive experiment and reduces stress, depression, while utilitarian value is more fulfillment of functional needs which is linked to improve physical health's. Therefore, gyms in the work environment can bring enjoyment and personal value which gives a positive effect in their job performance.

YEAR-ROUND ENGAGEMENT IN TRACK AND FIELD ATHLETICS DURING EARLY ADOLESCENCE IS PREVALENT AMONGST ENDURANCE RUNNERS, BUT DOES NOT IMPACT ON ATHLETE RETENTION

KEARNEY, P.E.1, HAYES, P.R.2

1. UNIVERSITY OF LIMERICK; 2. NORTHUMBRIA UNIVERSITY

INTRODUCTION: There is growing concern that the youth sport experience is evolving in ways that are ultimately harmful for the young person (Bergeron et al., 2015). United Kingdom Athletics Athlete Development Model proposes that youth athletes' involvement in the sport should gradually increase from approximately six months of the year at Under 13 (U13) to year round training at Under 20 (U20). This study investigated the adherence to and appropriateness of this recommendation by examining (a) prevalence of year-round engagement by endurance runners in 2017, and (b) the impact of year-round engagement by endurance runners at U13 on retention at U20.

METHODS: To determine the prevalence of year-round engagement, all competitive performances in 2017 for the 100 top ranked male and female athletes in the 800m at each age category from U13 to U20 were identified via an online database: www.thepowerof10.info. Only athletes who competed on at least 10 days over a period of at least three consecutive months (N = 736) were included in the analysis.

To determine the impact of year-round engagement at U13 on subsequent retention, the same database was used. The 100 top ranked male and female athletes in the 800m at U13 in the years 2009, 2010 and 2011 were identified. Provided athletes had competed on at least 10 days over a period of three consecutive months (N = 490), their records were examined to determine whether they had also competed in their final year of eligibility at U20.

RESULTS: As the data was not normally distributed, Kruskal Wallis tests were used to compare the number of months in which athletes competed across age categories. Significant differences were revealed for both female ($\chi2(3) = 30.8$, $p < 0.001$) and male athletes ($\chi2(3) = 38.2$, $p < 0.001$). Holm-Bonferroni adjusted Mann Whitney U tests revealed that U20 athletes (female, Mdn = 10; male, Mdn = 9) competed in fewer months of the year than all other age grades (female, U13 11; U15, 11; U17, 11; male, U13, 10; U15, 11; U17, 10), all p-values < 0.008.There were no differences in number of months competed in between U13, U15 and U17.

As the data was not normally distributed, Mann Whitney U tests were used to investigate the impact of the length of the U13 season. Male athletes who were still competing at U20 had competed the same number of months (Mdn = 10, IQR = 3) at U13 as athletes who were no longer competing at U20 (Mdn = 10, IQR = 3), $Z = 0.824$, $r = 0.05$, $p = 0.41$. In contrast, female athletes who were still competing at U20 had competed for a longer season at U13 (Mdn = 11, IQR = 3) than athletes who were no longer competing at U20 (Mdn = 10, IQR = 3), $Z = 2.902$, $r = 0.19$, $p = 0.004$.

CONCLUSION: Youth endurance athletes are not adhering to the recommendations of United Kingdom Athletics Athlete Development Model with respect to season length. However, duration of engagement at U13 does not appear to be related to retention at U20.

PRIOR SELF-CONTROL EXERTION AND CAFFEINE MOUTH RINSING DURING ENDURANCE PERFORMANCE

BOAT, R., EDGELEY, T., LYONS, J., COOPER, S.

NOTTINGHAM TENT UNIVERSITY

INTRODUCTION: Exertion of self-control has been associated with impaired performance on subsequent physical tasks also requiring self-control (Hagger, Wood, Stiff, & Chatzisarantis, 2010). However, the mechanisms underpinning these effects remain unknown. This study explored whether prior self-control exertion reduces subsequent performance on a physically demanding task that requires self-regulation, and if any observed performance decrements could be explained by changes in perceptions of pain and motivation. Furthermore, the study examined the potential for a caffeine mouth rinse to moderate the effects of self-control exertion on subsequent exercise performance.
METHODS: Eight endurance-trained cyclists completed four simulated 10 km time trials on an electromagnetically braked cycle ergometer (Watt bike). Prior to each time trial, participants completed an easy Stroop task (control condition) or a difficult Stroop task (to deplete self-control). They also received either a caffeine mouth rinse (40 mg caffeine dissolved in 25 ml of a water and sugar free, non-caffeinated, lemon and lime squash solution) or a taste matched placebo and rinsed this solution for 10 s, prior to and every 2 km during the time trial. Participants' performance time, as well as perceptions of pain and motivation (measured via a Visual Analog Scale) were recorded throughout the time trials.
RESULTS: A 2 (self-control) x 2 (caffeine) repeated measures ANOVA revealed that there was no significant main effect for self-control ($p = .642$), or caffeine ($p = .214$), or interaction effect between self-control and caffeine ($p = .440$) for performance time. Furthermore, a 2 (self-control) x 2 (caffeine) x 6 (time) repeated measures ANOVA revealed that there was no significant three-way interaction for changes in perceptions of pain ($p = .469$) and motivation ($p = .613$), suggesting that the pattern of change in pain and motivation throughout the cycling task was not different between experimental trials.
DISCUSSION:
The results indicate that initial self-control exertion does not negatively affect subsequent 10 km cycling time trial performance in well-trained endurance athletes. Participant's perceptions of pain and motivation during the time trial were not influenced by prior self-control exertion. In addition, the results suggest that mouth rinsing caffeine during a physical task that requires self-regulation does not influence the effects of self-control exertion on subsequent physical performance, or participant's perceptions of pain and motivation during the task.

MORNING VS. EVENING CAFFEINE SUPPLEMENTATION: DOES TIME OF ADMINISTRATION DIFFERENTLY AFFECT SHORT-TERM MAXIMAL PERFORMANCE IN BASKETBALL PLAYERS?

STOJANOVIC, E.

UNIVERSITY OF NIS

INTRODUCTION: There are inconsistencies in the existing evidence regarding the effects of caffeine supplementation on short-term maximal performance in basketball players, which might be related to the timing of caffeine intake. The purposes of this study were to compare the effects of acute caffeine supplementation on short-term maximal performance when ingested in the morning and evening in elite basketball players.
METHODS: Eleven male basketball players (age: 16.5 ± 1.0 yr; body mass: 75.7 ± 7.4 kg; height: 184.7 ± 5.0 cm; body fat composition: 11.0 ± 2.7 %) underwent a battery of tests assessing short-term maximal performance on four occasions: 1) morning with caffeine ingestion (AMcaff); 2) morning with placebo ingestion (AMplac); 3) evening with caffeine ingestion (PMcaff); and 4) evening with placebo ingestion (PMplac). Caffeine and placebo dosages were administered at 3 mg/kg of body mass in capsules. The test battery consisted of countermovement jumps (CMJ) with and without arm swing, a squat jump (SJ), the Lane Agility Drill, 5-m, 10-m, 20-m linear sprints with and without dribbling, and Suicide Runs with and without dribbling. Data were analysed using two-way repeated measures analyses of variance and Bonferroni post hoc tests, with effect size (ES) statistics also determined for all pairwise comparisons.
RESULTS: AMcaff produced small, significant improvements in CMJ height with (ES = 0.43) and without arm swing (ES = 0.55), as well as SJ height (ES = 0.55) relative to AMplac, with trivial, non-significant differences compared to PMcaff and PMplac conditions. In addition, AMcaff resulted in a moderate, significantly faster Lane Agility Drill time relative to AMplac (ES = -0.66), as well as compared to PMcaff (ES = -0.81) and PMplac conditions (ES = -0.77). AMcaff and PMcaff produced trivial to small, non-significant improvements in 5-m, 10-m, and 20-m linear sprint times with and without dribbling relative to placebo conditions. AMcaff resulted in small to very large, significant improvements in repeated-sprint performance during the Suicide Run with and without dribbling relative to AMplac (ES = -0.25; ES = -0.25), PMcaff (ES = -2.04; ES = -2.32) and PMplac conditions (ES = -1.93; ES = -2.14).
CONCLUSION: Basketball practitioners should administer caffeine (3 mg/kg of body mass) to players in the morning to enhance short-term maximal performance, with no beneficial effects observed with caffeine supplementation in the evening.

EFFECTS OF DIFFERENT DOSES OF FISH OIL SUPPLEMENTATION ON ENERGY METABOLISM, MUSCLE DAMAGE AND EXERCISE PERFORMANCE IN ENDURANCE ATHLETES

PENG, S.C., CHO, Y.Y., LIU, H.C., CHANG, W.H.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Dietary supplementation may not only helps in improving performance in sports and exercise, but also contributes in reducing exercise-induced fatigue and in recovery from exhaustion. Fish oil (FO), which contains sufficient amounts of omega-3 polyun-

saturated fatty acids, especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), is effective for reducing inflammatory reaction and muscle damage (1). However, the current understanding of dose-response relationships in sports medicine is limited. Recent study has indicated that 3 g fish oil appears to be the appropriate supplementation dose in healthy normotriglyceridemic male volunteers (2). The study attempted to investigate an optimum dose for fish oil supplementation and evaluate the anti-fatigue effects of fish oil following long-term consumption in endurance athletes.
METHODS: In a randomized, single-blind, cross-over study, 16 healthy individuals (10 male and 6 female, 20.9 ± 1.36 yrs) who have been conducting endurance exercise for years were recruited. Each subjects were grouped to take the three stages of supplementation in random order, including FO3 group (3g fish oil, 3 capsules/d, each capsule provided 350mg EPA and 250mg DHA), FO6 group (6 capsules/d), and Placebo group (3g sunflower oil, 3 capsules/d) for 3 weeks. Before and after each intervention session, all subjects performed a continuous running test on treadmill at a speed according to 70%-80% maximal oxygen uptake (VO2max) for 30 minutes, and then the running speed was increased by 1km/hr every minute until exhaustion. Blood samples were taken before 50 minutes, during 10 and 20 minutes, at exhaustion, 30 and 60 minutes after exercise. Three key parameters were evaluated: 1) energy metabolism substances: glucose, lactate, and ammonia; 2) muscle damage: creatine phosphokinase (CPK) and lactate dehydrogenase (LDH); 3) exercise performance: rated perceived exertion (RPE) score and time to exhaustion.
RESULTS: After 3 weeks, there was a significant decrease in body weight (62.4 ± 8.59 vs. 63.6 ± 8.57 kg, p=0.01) in the FO6 group compared to the placebo group. Significant main effect of group was observed for the CPK and LDH concentration ($p = 0.0001$ and 0.0028, respectively). The FO6 group showed significant attenuation of exercise-induced muscle damage (FO6 vs. FO3 in CPK, p=0.02 and FO6 vs. placebo in LDH, p=0.01). A significant main effect of time was observed for the increase in blood glucose, ammonia, and lactate levels ($p < 0.0001$). However, no significant improvement was found in time to exhaustion.
CONCLUSION: Consumption of a higher dose of fish oil for 3 weeks could decrease body weight and exert potential protective effects on indices of post-exercise muscle damage. Therefore, Fish oil may act as an anti-fatigue supplements in endurance athletes.

EFFECT OF DIFFERENT CARBOHYDRATE MEAL INTAKE AFTER EXERCISE ON ARM MUSCLE GLYCOGEN AND URINE HEPCIDIN LEVEL IN ELITE NORDIC COMBINED ATHLETES.

ISHIBASHI, A., TAKUYA, Y., AKIKO, K., KAORU, Y., YUSUKE, I., KAZUSHIGE, G., HIDEYUKI, T.
JAPAN INSTITUTE OF SPORTS SCIENCES, GRADUATE SCHOOL OF SPORT AND HEALTH SCIENCE, RITSUMEIKAN UNIVERSITY

INTRODUCTION: Muscle glycogen depletion impairs endurance performance, therefore the glycogen level in the skeletal muscle plays an important role in a cross-country (XC) race performance. However, in Nordic combined (NC), athletes may not be able to consume sufficient level of carbohydrate (CHO) to replenish muscle glycogen during consecutive races or daily training to maintain their body weight for improvement of jump performance. Hepcidin is known as a crucial mediator of iron homeostasis and may affect exercise-induced iron deficiency. There is a possibility that prolonged exercise causes hepcidin elevation due to a large increase in the circulating cytokine interleukin-6 (IL-6) level. Importantly, the decrease in muscle glycogen increases IL-6 production; in other words, insufficient CHO intake after endurance exercise may evoke iron deficiency via hepcidin elevation. However, little is known about how much CHO intake is suitable to recovery of muscle glycogen level and to prevent hepcidin elevation after exercise. Therefore, present study aimed to investigate the influence of different CHO meal intake after a simulated XC race on recovery of muscle glycogen in the arm. We also determined the changes in the urine hepcidin level.
METHODS: Six male elite NC athletes (age 21 ± 1 yrs and maximal oxygen uptake 67 ± 2 ml/kg/min) were randomized to receive a low-CHO (LCHO; 3 g CHO/kg) or a high-CHO (HCHO; 5.5 g CHO/kg) intake after a 24 min 40 s of gliding exercise using a treadmill in a single-blind counterbalanced crossover design. In each trial, subjects performed exercise in the afternoon and consumed the prescribed meal between after exercise and dinner. The muscle glycogen level in the arm was evaluated using carbon magnetic resonance spectroscopy before exercise, after exercise and on the following morning. Moreover, urine hepcidin level was measured before exercise,3h after exercise and on the following morning.
RESULTS: The change in the body weight from before exercise to the following morning was not significantly different between the trials ($p > 0.05$). The muscle glycogen level in both trials decreased after exercise ($p < 0.05$, vs. before exercise). Moreover, the muscle glycogen level in the HCHO trial recovered to the before exercise level by the following morning ($p < 0.05$, vs. after exercise), but not in the LCHO trial. In addition, the following morning urine hepcidin level in the LCHO trial was significantly increased compare to that in the HCHO trial ($p < 0.05$).
CONCLUSION: It was demonstrated that an at least 5.5 g/kg of CHO meal after simulated XC ski is necessary not only for the recovery of muscle glycogen but also for preventing the hepcidin elevation.

THE EFFECT OF CARBOHYDRATE SUPPLEMENTATION ON SUBSTRATE OXIDATION DURING EXERCISE IN HYPOXIA AFTER BREAKFAST CONSUMPTION OR OMISSION

GRIFFITHS, A., DEIGHTON, K., KING, R., BOOS, C., ROWE, J., O'HARA, J.
LEEDS BECKETT UNIVERSITY

INTRODUCTION: Current research investigating the effect of carbohydrate supplementation during exercise on substrate oxidation responses at altitude remains divergent. Observational evidence suggests that this response may be influenced by pre-exercise breakfast consumption or omission within experimental designs. Consequently, this randomised controlled trial investigated the effect of carbohydrate supplementation on substrate oxidation during exercise in hypoxia after pre-exercise breakfast consumption or omission.
METHODS: Eleven men rested and performed exercise in normobaric hypoxia equivalent to 4300m (FiO_2 ~11.7%) twice after consuming a high carbohydrate breakfast (567 kcal, 68% carbohydrate, 12% fat, 20% protein) and twice after breakfast omission, in a randomised crossover design. One hour after breakfast consumption or omission, participants walked for 90-min at 10% gradient, carrying a 10kg backpack at 50% of hypoxic VO_2max. In a double-blind fashion, one breakfast consumption trial and one breakfast omission trial included supplementation with a carbohydrate beverage (1.2g·min-1 glucose), while the other included consumption of a placebo. Consumption of each beverage occurred immediately before (600ml), and then every 15-min (150ml) throughout exercise. Expired gas was measured throughout for quantification of carbohydrate and fat oxidation.
RESULTS: Relative carbohydrate oxidation was significantly higher after breakfast consumption compared with omission during the first 60-min of exercise in all trials (CHO: 49.0±10.5% vs 36.4±12.2%; p=0.01; PLA: 45.1±9.6% vs 29.4±12.5%; p<0.01). Relative carbohydrate

oxidation was significantly higher after breakfast consumption than omission during the last 30-min of exercise in the placebo (41.7±10.2% vs 25.2±13.7%; p<0.01) but not carbohydrate trials (49.9±11.6% vs 40.6±12.9%; p=0.09).
Carbohydrate supplementation during exercise did not significantly alter relative carbohydrate oxidation during the first 60 minutes of exercise after breakfast consumption (p=0.99) or omission (p=0.56). Relative carbohydrate oxidation was significantly higher after carbohydrate supplementation during exercise compared with placebo during the last 30-min of exercise after breakfast omission (p=0.02) but not breakfast consumption (p=0.30).
CONCLUSION: Breakfast consumption increased carbohydrate oxidation during the first 60-min of exercise regardless of carbohydrate supplementation during the exercise protocol. However, carbohydrate supplementation during the exercise protocol negated the effects of previous breakfast consumption during the last 30-min of exercise by increasing carbohydrate oxidation in the breakfast omission trial only. These findings suggest that carbohydrate supplementation during exercise in hypoxia is only effective at altering substrate oxidation when exercise is performed in the fasted state.

EFFECTS OF HIGH-CARBOHYDRATE MEAL ON MUSCLE GLYCOGEN AND PHYSICAL PERFORMANCE AFTER RAPID WEIGHT LOSS IN ELITE COLLEGIATE WRESTLERS

KONDO, E.1, SHIOSE, K.2, SAGAYAMA, H.1,3, MOTONAGA, K.1, NISHIMAKI, M.1,4, YAMASHITA, D.1,4, KAMEI, A.1, NAKAJIMA, K.1,4, NISHIGUCHI, S.4, TAKAHASHI, H.1

1 JAPAN INSTITUTE OF SPORT SCIENCES, 2 FUKUOKA UNIVERSITY, 3 JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, 4 JAPAN WRESTLING FEDERATION

INTRODUCTION: Severe rapid weight loss (RWL), reduction over 5% of body mass (BM) within 1 week, would induce decrease in muscle glycogen (mGly) and physical performance. It however, could be attenuate of a decrease in the mGly and performance for matches if the recovery of diet, especially carbohydrate, is adequate following RWL. The purpose of this study was to compared the effect of two different carbohydrates content as recovery meals following RWL on mGly and physical performances.
METHODS: We designed as a randomized parallel-group trial. Elite sixteen male collegiate wrestlers were randomly assigned to HC meal (n=8, 10.0±0.4 g/kg carbohydrate) or HPF (n=8, 5.2±0.2 g/kg carbohydrate). Then they were instructed to lose 6% of their BM over 7days followed by a 13-h recovery period by the prescribed meal (HC or HPF). The participants chose their own weight reduction method. The mGly concentration was measured at three time points (pre [T1], post-RWL [T2], and post-recovery [T3]) with carbon-13 magnetic resonance spectroscopy (13C-MRS). Vertical jump, counter movement jump, squat jump, 30-s Wingate test and measurement of substrate oxidation ratio by a cycling ergometer were conducted at T1 and T3 time point. All food and fluid intake, and the weight were recorded through this experiment.
RESULTS: Changes in BM from T1 to T2 (HC, -4.3±0.6 kg; HPF, -4.4±0.6 kg) and from T2 to T3 (HC, 2.3±0.4 kg; HPF, 2.3±0.2 kg) were similar between the groups. The mGly concentration in both groups decreased by 71% from T1 to T2. The mGly synthesis ratio was significantly greater with the HC than HPF (2.5 vs 0.5 mmol/h, p<0.05), and mGly level relative to baseline was higher in HC than in HPF (110±26% vs 80±19%, p<0.05). Although significantly main effect for time was observed in squat jump and mean power of the Wingate test (P<0.05), changes in these parameters did not differ between the groups. There was no significant interaction on vertical jump, counter movement jump and substrate oxidation during progressive cycling between the groups.
CONCLUSION: These finding suggest that high-carbohydrate meal contributes muscle glycogen recovery after rapid weight loss. However, there was no significant meal effect on physical performance in this study.

EFFECTS OF VITAMIN D SUPPLEMENTATION ON MUSCLE FUNCTION IN FEMALE COLLEGE VOLLEYBALL PLAYERS

LIU, Y.H., CHANG, W.H.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Vitamin D is an important hormone with a wide range of functions from calcium homeostasis to the integrity of the innate immune system (1). Vitamin D supplementation has recently been receiving increasing attention in sports medicine as a potential ergogenic aid to improve muscle strength and athletic performance (2). Previous studies have shown some benefits of Vitamin D supplementation in professional athletes including basketball, handball, rugby union, hockey, judo, taekwondo, and dancer. However, none of the studies has examined the effects of vitamin D on muscle function in volleyball players. Thus, the main purpose of this study was to examine whether the safe upper intake level (UL) of vitamin D supplementation over a 4-weeks period can enhance muscle function in female college volleyball players.
METHODS: Fourteen collegiate female volleyball players, aged 18-22 years who had been regularly training three times a week for at last three hours per day participated in this parallel study. Participants were randomly assigned to receive either 2000 IU vitamin D3 per day (N=7) or no vitamin D (control group, N=7) during 4 weeks of training. The training program included their normal volleyball training, squat, lunges jump, core exercise, and short sprint training. Before and after the immediate intervention, all participants were evaluated three key parameters: 1) muscular strength: hand grip; 2) muscular power: vertical jump height, triple jump, and volleyball spike jump height; 3) speed: repeated sprint ability.
RESULTS: After four weeks of vitamin D supplementation, there was a significant decrease in absolute percent body fat of 1.6% (21.1 ± 4.14 vs. 19.5 ± 3.26 %, p=0.009) and a significant increase in lean body mass of 3.5% (22.5 ± 1.45 vs. 23.3 ± 1.90 kg, p=0.007). Compared to the control group, it also showed a significant improvement in vertical jump height (mean change in vitamin D vs. control groups: +4.80 ± 2.93 vs. +2.00 ± 1.13 cm, p=0.04) and triple jump (+37.6 ± 6.68 vs. +23.9 ± 14.4 cm, p=0.04). However, no significant differences were found for hand grip strength and repeated sprint ability.
CONCLUSION: Oral supplementation of 2000 IU vitamin D3 during 4 weeks of training could improve body composition and enhance muscular power in female college volleyball players. Our findings suggest that Vitamin D supplementation can become recommended practice in volleyball player.

THE EFFECTS OF 32 WEEKS OF BETA-ALANINE SUPPLEMENTATION ON CROSSFIT-SPECIFIC PERFORMANCE, BODY COMPOSITION AND DIETARY HABITS IN CROSSFIT ATHLETES

KUMSTÁT, M., ŠIRC, P., STRUHÁR, I., KAPOUNKOVÁ, K., HRNCIRÍKOVÁ, I., GRMELA, R., HLINSKÝ, T.
MASARYK UNIVERSITY

INTRODUCTION: Beta-alanine (BA) has been proposed to enhance performance in high-intensity exercise via increase of intracellular acid buffer carnosine content in muscles (1). CrossFit is an attracting form of exercise performing numerous forms of high-intensity workouts of the day (WOD)(2) in which high glycolytic demand and acidosis may limit performance (3). Therefore, athletes may benefit from BA supplementation. The purpose of the study was to investigate the longitudinal effects of BA supplementation on CrossFit performance, body composition and dietary habits.
METHODS: Fifteen recreationally-trained (~3 yrs experience) CrossFit athletes (26.8±5,3yrs) were randomly assigned to receive either BA (6.4 g day−1) or placebo (PLA, maltodextrin, same dosage) for 32 weeks in a double-blind design. CrossFit performance (time to complete modified Fran WOD, duration ~ 5-6 min) and body composition parameters were assessed pre- and post-supplementation period. Blood samples during the WOD were collected for lactate determination. Total daily energy intake (EI) and macronutrient distribution changes were analysed via nutritional software for the pre-, middle and post-supplementation period. Repeated analysis of variance was used to assess performance-related changes between the experimental groups and experimental sessions. Cohens d effect size was used to explore the nutritional (EI, macronutrient intake) influence of the intervention.
RESULTS: Pre- to the post-supplementation difference in times to complete the WOD was not different between BA (- 6.8±23.2 s) or PLA (+ 3.0±35.0 s) trials (p=0.56). The supplementation period does not affect acute post-exercise lactate response as well as body mass or fat mass changes over time and between treatments (p >0.05). Energy intake significantly decreased from pre- to the post-supplementation period (34.7±7.8 and 28.2±5.3 kcal.kg day−1, respectively) in BA group (d=1.19), corresponding with a significant decrease of carbohydrate intake (3.4±0.9 to 3.0±0.6 g.kg day−1, d=0.92). No significant changes were observed in the PLA group for either EI (d=0.12) or any macronutrient.
CONCLUSION: In conclusion, 32 weeks of beta-alanine supplementation does not enhance CrossFit-specific performance in recreational-trained athletes over placebo. Longitudinal supplementation may, however, affect the nutritional behaviour of participants resulting in manipulation energy and carbohydrate intake.

CHRONIC 2S-HESPERIDIN INTAKE IMPROVES POWER OUTPUT AT VO2MAX AND BODY COMPOSITION IN CYCLISTS

MARTÍNEZ-NOGUERA, F.J., MARÍN-PAGÁN, C., CARLOS-VIVAS, J., MARÍN-CASCALES, E., CAMPOY, L., ALCARAZ, P.E.
UNIVERSIDAD CATÓLICA DE MURCIA

INTRODUCTION: Flavonoids are bioactive substances that are mainly found in fruits and vegetables, although they are also present in other foods (1). Specifically, hesperidin is a flavanone (subclass of flavonoids) predominantly found in citrus fruits, being the 2S isomer the main one in orange or in the juice (almost 100%). Cardiose®, which is manufactured to maintain the maximum possible quantity of the 2S isomer, has been shown to improve sports performance by modulation of endogenous antioxidant enzymes, metabolism, production of nitric oxide and anti-inflammatory activity (2). In addition, it has also been seen that the ingestion of polyphenols improves the oxidation of fatty acids during long-term exercise of moderate intensity (3). The main objective of this study was to assess the chronic effects 8-wk supplementation with 500mg of 2S-hesperidin (Cardiose®, Ferrer HealthTech, Murcia, Spain) compared to placebo (500mg microcellulose) on sports performance (anaerobic power and aerobic metabolism) and body composition.
METHODS: A parallel, randomized, double-blind design was performed. Forty healthy cyclists (33.8±9.1 years; 1.76±6.2m; 70.7±6.4 kg; and VO2max: 57.7±8.1 mL·Kg-1·min-1; 6-12 training h·wk-1) were recruited and distributed in 2 groups: experimental and placebo. Participants visited the laboratory in 3 different days in both pre- and post-test: 1) medical examination and blood test; 2) body composition analysis by densitometry (DXA) and Wingate test to determine anaerobic performance; 3) incremental test until exhaustion to determine aerobic performance. Subjects daily ingested 500 mg of Cardiose® (2S-hesperidin) or placebo during intervention.
RESULTS: Within-group pre-post differences showed significant increases in power output at VO2max (p=0.049) and absolute and relative peak power during the Wingate test (p<0.001) in Cardiose®. Moreover, there was a decrease in body fat mass percentage (p<0.001) and total body fat mass (p<0.001) for the Cardiose® group. However, pre-post differences in the placebo group only revealed a significant increase in absolute (p=0.016) and relative (p=0.014) peak power during the Wingate test. Between-group comparison only showed significantly greater improvements in power output at VO2max (p=0.042) and body fat mass percentage (p=0.035) in favour of Cardiose® compared to placebo. Additionally, a trend to significant was obtained in the decrease of total fat mass (p=0.055) in favour of Cardiose®.
CONCLUSION: The chronic intake of 500mg of 2S-hesperidin improves the maximal power output at VO2max and decreases the percentage of body fat mass. These improvements could enhance performance in endurance sports.

MUSCLE SIZE-SCALED SHEAR ELASTIC MODULUS IS STRONGLY CORRELATED WITH MUSCLE FORCE DURING SUB-MAXIMAL ISOMETRIC CONTRACTION

YAGI, M., TATEUCHI, H., UMEHARA, J., MOTOMURA, Y., HIRONO, T., NOJIRI, S., PATAKY, T.C., ICHIHASHI, N.
KYOTO UNIVERSITY

INTRODUCTION: Muscle force is fundamental to human movement control, and because it cannot be measured directly in vivo, muscle force properties have attracted considerable attention in many studies. Muscle force has been measured using electromyography and normalized by maximal voluntary contraction (MVC) [1], but this method might not be suitable for patients, whose pain could affect neural activity. Recently, shear elastic modulus (G) has been more frequently used as an index of muscle force. However, G can differ among individuals due to their muscle size, even for constant muscle force. This muscle-size dependence may be a limiting factor for comparison amongst subjects. This study aimed to determine whether a new indicator of muscle force, G scaled by muscle size, is more strongly correlated with absolute joint torque than G or muscle activity [EMG].

METHODS: Twelve healthy males participated in this study. Subjects lay prone, with their arms fixed at 90° shoulder abduction and 90° elbow flexion in a dynamometer. Cross-sectional area (CSA) and muscle thickness (MT) of the lateral head of triceps brachii (LTB) were measured at rest using ultrasound. During isometric elbow extension MVC, EMG of LTB and elbow extension torque were measured using electromyography and the dynamometer, respectively. Subjects were asked to maintain a target torque for 10s. The target torque started at 5 Nm and was gradually increased in 5 Nm steps until 60% MVC. G and EMG of LTB were measured during each task. Scaled G was calculated in two ways: as a product of G and CSA (G-CSA) or G and MT (G-MT). Within-subject linear regressions were conducted between absolute torque and the three force indicator variables: unscaled G, G-CSA and G-MT. The regression slopes' coefficient of variation (CV) was calculated for each indicator. Between-subject correlation coefficients (r) were calculated by pooling all data across subjects into a single regression analysis for each indicator and were compared among indicators. In addition, an 'activity-CSA' force indicator variable was calculated by multiplying normalized muscle activity by CSA, and the r values were calculated as above. Statistical significance was set at 0.05.
RESULTS: Linear regression found that the cross-subject CV for slope increased in the following order: G-CSA, G-MT and unscaled G. Pearson correlation coefficients (r) were significantly higher in G-CSA (r = 0.950) and G-MT (r = 0.928) than in unscaled G (r = 0.780) (P=0.007 and P=0.03, respectively), but no differences were found between G-CSA and G-MT (P=0.29). Activity-CSA (r = 0.864) exhibited stronger correlation with absolute torque than unscaled G, it also exhibited weaker correlation than scaled G.
CONCLUSION: Compared to unscaled G and activity-CSA, G-CSA and G-MT showed stronger correlation with absolute torque. We conclude that scaled G may be a useful indicator of muscle force.

MUSCLE AND TENDON INTERACTION OF THE HUMAN GASTROCNEMIUS MEDIALIS DURING BODY WEIGHT SUPPORTED RUNNING USING THE VERTICAL TREADMILL FACILITY

RICHTER, C.1,2, BRAUNSTEIN, B.1,3,4, STAEUDLE, B.1,2, ATTIAS, J.5, SUESS, A.6, WEBER, T.6, MILEVA, K.7, RITTWEGER, J.8, GREEN, D.5,6, ALBRACHT, K.1,2

1: GSU , 2: UAS , 3: CHIPS , 4: MOMENTUM , 5: KCL , 6: EAC , 7: LSBU , 8: DLR

INTRODUCTION: To attenuate physiological deconditioning due to a lack of gravity, current ISS crew members perform a daily exercise countermeasure program, including frequent treadmill running. However, the maximum vertical loading applied is usually not more than 70-80% of body weight (BW) [1] leading to a reduced requirement of the gastrocnemius medialis (GM) muscle-tendon unit (MTU) to generate force and work to support and propel the human body [2]. As lower forces are acting on the Achilles tendon during unloading, we expect a smaller tendon elongation but its impact on fascicle and MTU length is still unknown. Therefore, the aim of this study was to confirm a smaller tendon elongation and to determine, whether it is compensated by a shorter MTU (different joint angles), longer fascicles or smaller pennation during running at 70% and 38% BW (Mars G).
METHODS: Eight male subjects (31.9 ± 4.7 yrs) ran at 125% of their preferred walk-to-run transition speed at 70% and 38% BW on the vertical treadmill facility, and with 100% BW. GM fascicle length and pennation were measured via ultrasonography. Further, joint kinematics (goniometers) were analyzed to determine GM MTU length. Tendon length was estimated by using a MTU model [3]. Plantar pressure (loadsol) was measured to determine stance phase. One-way repeated measures ANOVA for dependent samples (38% vs 70% vs 100% BW) followed by post-hoc tests with Holm-Sidaks corrections for multiple comparisons were used to test for significant differences in joint angles, MTU and tendon elongation, fascicle length and pennation when running at different loadings.
RESULTS: Compared to 100% BW, maximum ankle dorsiflexion and knee flexion during early stance was significantly smaller at 38% BW (-6.4 ± 3.6°, $p = 0.003$; -8.1 ± 3.8°, $p = 0.001$), whereas for 70% BW no significant differences were found. Tendon and MTU elongation was significantly smaller at 70% BW (18.70 ± 13.7%, $p = 0.005$; 25.50 ± 20.3%, $p = 0.009$) and 38% BW (35.2 ± 11.5%, $p < 0.001$; 47.3 ± 17.3%, $p < 0.001$). Although, GM fascicles operated at a significantly longer length and smaller pennation at 70% BW (8.9 ± 5.8%, $p = 0.024$; 8 ± 4.4%, $p = 0.015$) and 38% BW (12.4 ± 6.4%, $p < 0.001$; 9.5 ± 6%, $p = 0.015$), fascicle shortening showed no significant differences.
CONCLUSION: Reduced tendon elongation proves that less force is acting on the Achilles tendon resulting in a reduced storage of elastic energy. The reduced tendon elongation has shown to be compensated by a smaller MTU elongation, smaller pennation and longer fascicles, which leads to a more economical force generation due to the force-length relationship. These effects are observed at 70% and exaggerated at 38% BW. To determine if running with 70% BW is sufficient to maintain muscle mass and function, additional measurements of torque and neuromuscular activation are required to estimate the strain on the GM.

ASSESSMENT OF ACHILLES TENDON LENGTH DURING WALKING AND RUNNING: A NEW IN VIVO APPROACH

KHARAZI, M.R., BOHM, S., ARAMPATZIS, A.

HUMBOLDT UNIVERSITÄT ZU BERLIN

INTRODUCTION: Due to their compliance, tendons influence essentially the functioning of the muscle-tendon unit (MTU). Achilles tendon (AT) length is derived indirectly by a simple two-planar model[1] that likely not reflects the MTU appropriately or measured experimentally from the origin at the muscle-tendon junction (MTJ) to the insertion on the calcaneus bone[2]. However, this approach may have several limitations: 1) AT length is measured as a straight line that do not reflect the curvature of the tendon, 2) the orientation of the MTJ with respect to the skin surface is not taken into account, and 3) potential displacements of the skin underneath the calcaneus marker are not considered. Therefore, we present a new experimental approach to measure AT length during locomotion.
METHODS: Nine participants walked and ran at 0.7 and 2.5 m/s on a treadmill, while the MTJ of the gastrocnemius medialis muscle was captured using ultrasonography (146 Hz). An automatic tracking algorithm was developed to determine the MTJ position from the ultrasonographic images and validated against manual MTJ tracking. A reflective marker-tripod was mounted on the transducer, the MTJ position was than projected to the global coordinate system. Eight small reflective foil markers were positioned in line on the skin from the calcaneus bone (insertion of AT) to the edge of the transducer to elaborate the curvature of AT and length was measured as fitted curve from origin to insertion. The horizontal orientation of the MTJ to the skin in the ultrasound images was measured by projecting the tracked MTJ to the reconstructed skin surface frame-by-frame. Potential skin-to-bone displacements of the calcaneus marker were assessed separately throughout a passive rotation of the ankle joint by means of ultrasonography and referred to the heel angle during locomotion.

RESULTS: The automatic tracking showed good agreement with the manual tracking (r=0.92). AT length calculated by the new approach was different compared to both straight-line (maximum differences 3 and 3.4 mm for walking and running respectively) and curved-shape approach (maximum differences 2.8 and 3.8 mm for walking and running). The maximum difference due to the MTJ position with respect to the skin corresponded to length differences of 2.3 and 3.4 mm for walking and running. The effect of the skin-to-bone displacement was up to 0.43 mm in both conditions.
CONCLUSION: Our findings provide evidence for significant inaccuracies in the assessment of AT length by the currently established straight-line method resulted to errors between 10 and 39% for the evaluation of the AT length changes during the stance phase of walking and running. Although the curved approach improved the assessment the errors in the AT length changes remained significant (3 to 24%) indicating an important contribution of the orientation of the MTJ with respect to the skin surface and the skin artifact.

CHANGES IN ECHO INTENSITY AND SHEAR ELASTIC MODULUS OF THE HAMSTRINGS WITH PASSIVE KNEE EXTENSION

NAKAO, S., IKEZOE, T., YAGI, M., MOTOMURA, Y., NOJIRI, S., HIRONO, T., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: While shear elastic modulus measured using ultrasound shear wave elastography has been used as an index of muscle elongation (Umegaki H, et al. 2015), high costs prevent its general / clinical adoption. It has been reported that echo intensity (EI) of the gastrocnemius, which can be measured using general B-mode ultrasonography, increases with passive ankle dorsiflexion. However, the relation between EI and elongation has not been tested in other muscles. The purpose of this study was to determine whether EI and shear elastic modulus of the hamstrings would increase with passive knee extension.
METHODS: A total of 16 healthy young males (age, 26.0 ± 4.2 years) participated in this study. The participants lay in a supine position with their hip at 90° flexion. Shear elastic modulus (G) and EI of the semimembranosus (SM), semitendinosus (ST), and biceps femoris (BF) were measured at 90°, 70°, 50°and 30° of knee flexion in a randomized order. Shear elastic modulus was measured using ultrasound shear wave elastography (Aixplorer; SuperSonic Imagine, France). EI was quantified using the average grayscale value of a given region of interest (ROI) in an ultrasound B-mode image. Because grayscale values can differ depending on size and depth of ROIs, grayscale analysis was performed using two ROIs: one which included as much of the muscle as possible while avoiding fasciae (maximum ROI), and a rectangular one whose size and depth was identical for all images (rectangular ROI). To quantify the changes in G and EI with passive knee extension, Pearson's correlation coefficients were calculated separately for each participant and each variable. The knee angle used for correlation analysis was determined as the change from 90° flexion (i.e., the angle between the shank and the horizontal plane).
RESULTS: Average (±SD) Pearson's correlation coefficients between knee angle and G were 0.97 ± 0.02, 0.95 ± 0.02, and 0.96 ± 0.03 for SM, ST and BF, respectively. For EI (maximum ROI), the coefficients were 0.85 ± 0.14, 0.78 ± 0.22, and 0.75 ± 0.22, respectively. For EI (rectangular ROI), the coefficients were 0.84 ± 0.15, 0.82 ± 0.17, and 0.77 ± 0.25, respectively.
CONCLUSION: Relatively strong positive correlations with knee angle suggest that both EI and G increase as the hamstrings were stretched. While EI's correlations with knee angle were not as strong as G's, EI may be useful for quantifying muscle elongation in the clinic because of its comparatively low cost.

CHARACTERISTICS OF LOWER LIMB TENDONS AND THEIR RELATIONSHIPS WITH THE JAVELIN THROW PERFORMANCE

KUNIMASA, Y., IWASAKI, M., ISHIKAWA, M.

OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: Tendons have a diverse set of function such as elastic recoil, amplification of muscle power output and attenuation of muscle power input (1). These functions depend on movement tasks. Specific loadings and movement patterns, such as competitive sport activities, could affect tendon morphology. However, it is not well known whether the tendon architectures are related to sport performance. Therefore, it is focused on the asymmetry leg movement functions of javelin throwers, 1) to examine morphological characteristics of Achilles tendon (AT) and patellar tendon (PT) in elite male javelin throwers and 2) to investigate the relationships between the tendon parameters and javelin throw performance.
METHODS: Thirteen elite male javelin throwers (JAVELIN) and nineteen control subjects (CTRL) participated in this study. The lengths and cross-sectional areas (CSA) of AT and PT were measured using ultrasonography. Lengths of thigh and shank, as well as circumferences of the knee and ankle were measured using a tape measure to calculate the relative values, respectively.
RESULTS: The absolute and relative AT lengths did not show any unilateral characteristics between both groups. Both AT CSA in JAVELIN were significantly greater than in CTRL. However, there were not any significant differences between blocked and non-blocked legs in JAVELIN. On the other hand, the PT CSA in the blocked leg of JAVELIN was significantly greater and its length was shorter as compared to those of the non-blocked and the CTRL legs. There were not any significant relationships between the tendon parameters and javelin throw performance.
CONCLUSION: These great AT CSA of both legs and the great CSA and short length of PT in the blocked leg in JAVELIN can be related to common loading and movement patterns in javelin throwers but are not related to the javelin throw performance.

EFFECTS OF FASCICLE LENGTH FILTERING ON MUSCLE-TENDON BEHAVIOURAL PARAMETERS DURING CYCLING

WALKER, J.1, CRONIN, N.J.2, JONGERIUS, N.1, WAINWRIGHT, B.1, BISSAS, A.1

1 LEEDS BECKETT UNIVERSITY, 2 UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: The introduction of semi-automated tracking algorithms in recent years have allowed biomechanists to observe muscle contractile behaviour during modes of locomotion such as walking and running more efficiently (Cronin et al., 2011). However, unlike most forms of data in human movement science and biomechanics, ultrasound data is seldom filtered to remove any noise induced by processing the signal. Investigation is warranted here, as the potential sources for error appear comparable to those of kinematic data, which has been routinely filtered for over 30 years.

METHODS: The muscle belly of a participant's right Gastrocnemius medialis (GM) was imaged using a 60 mm linear array ultrasound probe (Telemed, Lithuania) recording at 61 Hz. Twenty sequential pedal cycles were analysed during cycling at 150 W. GM fascicle tracking was carried out using the Ultratrack v.4.2 semi-automated tracking algorithm (Farris & Lichtwark, 2016). Key frame corrections were applied at top-dead-centre (TDC) for each of the twenty pedal cycles. Crank and joint angles were tracked using retroreflective markers and were recorded at 250 Hz using a four-camera optoelectronic system (Qualisys AB, Sweden). Fascicle and kinematic data for each revolution were interpolated to 360 data points using a custom-written Matlab script (MathWorks, USA). Raw fascicle length data were first filtered using a low-pass fourth-order Butterworth filter, with a cut-off frequency of 7.8 Hz (OCF), determined using residual analysis. Raw fascicle data were then filtered with a cut-off frequency 50% above (HCF; 11.7 Hz) and below (LCF; 3.9 Hz) the determined OCF.
RESULTS: Raw fascicle data produced a fascicle range of 5.18±1.72 mm. Applying a filter with HCF reduced this by 3.9%. OCF and LCF reduced fascicle range by 6.6% and 15.2%, respectively. For net fascicle velocity (from TDC to TDC), HCF showed a 47% reduction in magnitude, when compared to the raw data. OCF showed a 56% reduction, whilst the LCF reduced the magnitude of net fascicle velocity by 95%. Peak fascicle shortening velocity was also reduced by 14%, 15% and 20% in the HCF, OCF and LCF conditions, respectively.
CONCLUSION: Whilst the application of a filter to track fascicle data appears only to make subtle differences to measured fascicle length, the impact on variables calculated from length and time may be more significant. This could lead to meaningful changes in key variables used in muscle-tendon behaviour research. Although it remains unclear whether or not the techniques used here are the best way to filter ultrasound data, these findings do warrant further discussion amongst scientists about how to carry out the processing of fascicle data in human locomotion.

EFFECT OF WEIGHT LOAD ON MUSCLE-TENDON COMPLEX BEHAVIOR DURING SQUAT EXERCISE

NORO, H.1, TAKESHITA, T.1, HATA, K., YOSHIDA, T.1, TAGURI, A.1, FUKUNAGA, T.2, YANAGIYA, T.1
1.GRADUATE SCHOOL OF JUNTENDO UNIVERSITY 2.NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Visco-elastic property of muscle-tendon complex (MTC) is considered to play an important role in squat exercise. The present study is to observe the effect of exercise load performed squat on the behavior of MTC.
METHODS: Six healthy, resistance-trained male sprinters who habitually performed loaded squat, participated in the study (age: 22.3±0.5 yrs; height: 178.8±6.2m; weight: 70.8±5.5kg). Subjects performed barbell squat at 0, 20, 40, 60kg weight condition on a dual-force platform. Subjects were instructed as "Conduct counter-movement as fast as possible". Fascicle length of the vastus lateralis muscle (VL) was measured from real-time ultrasound apparatus. Tendon length changes were calculated from the relationship between the fascicle length and muscle-tendon complex length (Ishikawa et al., 2003). In addition, the electromyogram obtained from right VL and ground reaction force were recorded. In each condition, knee joint kinematics, vastus lateralis fascicle and tendon length were estimated using ultrasonography, motion capture system, and force platform recordings. And, fascicle force, tendon force and mechanical power of fascicle and tendon were calculated using inverse dynamics. In the present study, two phases were defined as descending phase and descending phase from the viewpoint of knee joint kinematics.
RESULTS: It is observed that changes in fascicle length were larger with heavier load squat, and tendon length was dependent on the load. Peak MTC, fascicle and tendon velocity were not affected by the load. Moreover, fascicle and tendon force were higher in heavier condition. No differences were observed in mechanical power of fascicle throughout all phase. However, higher mechanical power of tendon was observed in the ascending phase of heavier weight compared with lighter weight.
CONCLUSION: From the viewpoint of force-length relationship, fascicle length was thought to be almost corresponding to optimum length. In addition, higher mechanical power of tendon was indicated even if in the case of lower motion velocity.

VISCOELASTIC PROPERTIES OF VASTUS LATERALIS MUSCLE-TENDON COMPLEX IN COLLEGIATE SPRINTERS

HATA, K.1, YOSHIDA, T.1, TAKESHITA, T.1, NORO, H.1, FUKUNAGA, T.2, YANAGIYA, T.1
1.GRADUATE SCHOOL OF JUNTENDO UNIVERSITY 2.NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Viscoelastic properties of tendon structures are considered to affect stretch-shortening cycle exercise performance. Previous studies indicated the significant linear relation between elastic properties of vastus lateralis (VL) muscle-tendon complex and 100 sprint time (Kubo et al. 2000, Kubo et al. 2011). The aim of this study was to clarify the relation between viscoelastic properties of VL muscle-tendon complex and 100-m race time.
METHODS: Eleven well-trained male collegiate splinters were served as participants (21±1years, 175.8±4.6cm, 68.2±4.8kg, 100-m seasonal record: 10.48s to 11.77s). Ramp-isometric knee extension force up to maximum was developed with their knee angle fixed at 90deg for three times. Ultrasonic prove was attached on the VL muscle belly. The cross-point of the ultrasonic echo between deep aponeurosis and muscle fascicle were digitized and calculated as the elongation (L) of VL tendon and aponeurosis (Arampatzis et al. 2006). Knee extension force of VL (F) was estimated from the previous study (Kubo et al. (2009). Stiffness of muscle-tendon complex was calculated from the slope of regression equation between F and L. On the other hand, to estimate hysteresis the area of F-L loop curve was calculated. In addition, the sum of the T-score value of stiffness and hysteresis was defined as the viscoelastic properties index. The relationship between viscoelastic parameters and a season best record of their 100-m race were analyzed by Pearsons correlations. Significance level was set at 0.05.
RESULTS: A linear regression analysis revealed a significant relationship between 100-m race time and hysteresis ($r = 0.7093$, $P < 0.02$). Furthermore, significant relationship was indicated between maximum F and stiffness ($r = -0.7829$, $P < 0.01$) and/or stored elastic energy ($r = 0.8730$, $P < 0.01$).
CONCLUSION: It was clarified that faster sprinters indicated lower hysteresis, considering lower viscosity for VL tendon, although not always necessary to have higher knee extension force. It is necessary to develop training for improving hysteresis rather than stiffness.

RELATIONSHIP BETWEEN DECREASED STRETCH-SHORTENING CYCLE PERFORMANCE AFTER CYCLING AND STRETCH REFLEX OF TRICEPS SURAE MUSCLE

TAKAHASHI, K., SHIRAI, Y., NABEKURA, Y.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Running and hopping involve the stretch-shortening cycle (SSC) muscle function of the lower extremities. It is widely recognised that pre-activation prior to ground contact, stretch reflex of contribution, neural potentiation and storage and reutilisation of elastic energy play a key role in SSC. Several lines of evidence indicate that the amplitude of the soleus H-reflex is reduced after cycling exercise (Robert and Rod, 2003). This suggests that prior cycling exercise influences the stretch reflex activity of the triceps surae muscle during hopping, which induces decreased SSC function. This study thus aimed to (1) determine whether SSC function decreases after cycling exercise and (2) clarify whether a decrease in SSC function is related to the attenuation of stretch reflex activity in the triceps surae muscle after cycling exercise.
METHODS: Nine male endurance athletes (six triathletes, three cyclists) completed two tests: a cycling test to determine ventilatory threshold (VT) and a hopping-cycling (30 min of cycling at 90% VT)-hopping test. Hopping variables and electromyographic signals in the triceps surae muscle (GL: gastrocnemius lateralis; SOL: soleus) were recorded during the hopping sections. SSC performance was calculated as the ratio of jump height to time spent in contact with the ground (RSI: reactive strength index). Short-latency spinal reflex activity (M1) was analysed during the 31-60 ms after ground contact. Heart rate, blood lactate concentration and ratings of perceived exertion (RPE) were also collected.
RESULTS: The RSI significantly decreased after the cycling exercise (-11.1%; $p < 0.01$), while the M1 in the GL and SOL did not change significantly ($p = 0.57$ and 0.15, respectively). However, the M1 change in the GL and SOL was significantly associated with the change in the RSI (both: $r = 0.77$). The relative heat rate (% of maximal heart rate) during the cycling exercise and the RPE and blood lactate accumulation after the cycling exercise were not significantly associated with the change in RSI after cycling exercise.
CONCLUSION: SSC function decreases after 30 min of low-intensity cycling exercise. The altered stretch reflex of the triceps surae muscle caused by cycling activity is a key factor for SSC function after exercise. These findings imply that prior cycling exercise adversely influences activities involving SSC function such as running.

DECREASE IN PASSIVE TENSION IS ASSOCIATED WITH AN INCREASE IN SOLEUS HOFFMANN-REFLEX AMPLITUDE DURING A 1-MIN CONSTANT LENGTH STRETCHING OF THE PLANTAR FLEXOR MUSCLES

DATOUSSAID, M., BAUDRY, S., GUISSARD, N.

UNIVERISTÉ LIBRE DE BRUXELLES

INTRODUCTION: The viscoelastic properties of the muscle tendon unit imply a gradual decrease over time in the passive tension produced by a muscle stretched at a constant length (2). Such a decrease in passive tension may change spinal excitability that is largely reduced during short-duration stretching manoeuver (1). The aim of this study was to investigate the spinal excitability during a 1-min constant length stretching of the plantarflexor muscles.
METHODS: Thirteen subjects underwent a passive ankle dorsiflexion from a neutral position of the ankle (90°) to the maximal tolerated dorsiflexion position (about 30° range of motion) that was maintained for 1min. The 1-min epoch corresponded to a constant-length stretching of the muscle-tendon complex. Maximal M-wave (Mmax) and Hoffmann-reflex (Hmax) amplitudes were recorded in the soleus, in response to electrical stimulations (1 ms) of the tibial nerve. Five Hmax and one Mmax were evoked at the beginning and the end of the constant length stretching. The passive tension was measured prior to the electrical stimulations over a 2-s epoch.
RESULTS: Passive tension increased by 251±97 N from the neutral to the maximal tolerated dorsiflexion position of the ankle, and then decreased by 36±12 N during the constant-length stretching ($p<0.05$). Mmax amplitude did not change throughout the stretching procedure ($p>0.05$). Hmax amplitude decreased from 42±15% Mmax to 32±19% Mmax between neutral and maximal dorsiflexion position, and then increased to 34±20%Mmax during the constant-length stretching ($p<0.05$). Correlation analysis revealed that the amount of change in passive tension was associated with the extent of change in Hmax amplitude during the constant-length stretching ($r^2 = 0.59$, $p<0.05$), such that greater the decrease in passive tension, greater the increase in Hmax amplitude.
CONCLUSION: The increase in Hmax amplitude in the absence of change in Mmax indicate that the net excitatory input of group I afferents onto soleus motoneurones pool increased during a 1-min constant length stretching. This could result, at least in part, from stress relaxation within the muscle-tendon complex (3), as supported by the negative association between passive tension and Hmax changes.

GIRLS JUST WANT TO HAVE FUN… OR DO THEY? A MACHINE LEARNING ANALYSIS OF WOMEN'S PARTICIPATION IN NORWAY'S ULTIMATE MASS PARTICIPATION SKI EVENT.

CALOGIURI, G., ROSSI, A., JOHANSEN, P.F., THURSTON, M.

INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

Background
Mass participation sporting events have increased in popularity in the last two decades, thought concerns have been expressed about the extent to which they are inclusive for different groups of the population, including women (Murphy & Bauman, 2015). For instance, in the iconic cross-country ski race Birkebeinerrennet (BR), women make up less than 20% of the total participants. To boost women's participation, the event organizers have introduced a women-only race (W-BR). It is however important to shed light on the factors that encourage women's participation in the main BR event. Using a machine learning approach, this study aims to: i) predict future trends of women's participation rates in the BR, and ii) identify characteristics of women participating in the BR, as compared with those in the W-BR.
Methods
To predict future trends in women's participation rates in the BR, a time-series analysis (i.e., autoregression) was performed on official entry records from 1996 to 2018. Secondary analysis of data from a market survey conducted in 2016 among BR and W-BR participants

was also carried out in relation to women's sociodemographic characteristics, exercise habits, motives and perceptions (n = 1187). The data were preprocessed using a recursive feature elimination with cross-validation process (RFECV) based on logistic regression to reduce the dimension of the feature set. The logistic regression was able to correctly gather the woman who took part in either the BR or W-BR (recall = 76%) with a precision of 77%.
Results
The time-series analysis predicted a gradual increase of women's participation rates in the BR (MSE = 4.51%, residual error = 3.70 ± 2.58%), meaning that in 15 years the prevalence of women might match that of men. The analysis of the survey data revealed that, as compared with the W-BR, more women in the BR saw the race as a 'motivational exercise goal' (explained variance = 0.11; $p < 0.001$) and perceived themselves as 'extreme' and 'fit' (explained variance = 0.24 and 0.01; $p < 0.001$). At the same time, they assigned less importance to social aspects such as 'sociability', 'personal tradition', and 'feeling part of a community' (explained variance = 0.36, 0.09, and 0.06; $p < 0.001$), and were less satisfied with the race (explained variance = 0.12; $p < 0.001$). The likelihood of participating in the BR, as compared with the W-BR, also decreased with increasing age (explained variance = 0.02; $p = 0.041$).
Conclusions
Although women are still largely under-represented in the main BR event (as well as other mass-participation sporting events), a gradual increase is evident. This growing group appears to be primarily concerned with performance-oriented rather than social-oriented aspects. Further studies are needed to investigate the factors that might explain the lower age and satisfaction of the women in BR compared to the W-BR.

COMPARING THE PRACTICES OF USA SKIING AND SNOWBOARDING AGAINST A GLOBAL MODEL FOR INTEGRATED DEVELOPMENT OF MASS AND HIGH PERFORMANCE SPORT

SCHOEN, C., SMOLIANOV, P., DION, D., NORBERG, J.

SALEM STATE UNIVERSITY

This study was designed to help and improve international skiing and snowboarding performance as well as increase domestic sport participation in the United States. Over 200 sources of literature on sport delivery systems from 28 Australasian, North and South American, Western and Eastern European countries were analyzed to construct a globally applicable model of high performance skiing and snowboarding integrated with mass participation, comprised of the following seven elements across three levels:
Micro level (operations, processes, and methodologies for development of individual athletes):
1. Talent search and development,
2. Advanced athlete support.
Meso level (infrastructures, personnel, and services enabling sport programs):
3. Training centers,
4. Competition systems,
5. Intellectual services.
Macro level (socio-economic, cultural, legislative, and organizational):
6. Partnerships with supporting agencies,
7. Balanced and integrated funding and structures of mass and elite sport.
The above model was used to design a questionnaire of 54 statements reflecting desired practices. The 54 statements were validated by 12 international experts, including executives from sport governing bodies and academics who published on high performance and sport development. The survey samples of 2,000 skiing and snowboarding professionals' email addresses were collected from various sources, including web pages of national and regional skiing and snowboarding associations, college and university athletics as well as high school and club skiing and snowboarding teams. Completed online questionnaires were returned by 102 coaches from all key regions of the country for a response rate of 5.1%. Additionally, 8 regional administrators were interviewed to suggest possible sport system improvements.
The proportion of the US Ski and Snowboard mass participation budget should be increased, particularly to grow cross country skiing which has great potential for increasing US medal count and benefiting community health. Opportunities will grow for corporate and media incomes if mass participation brings more consumers and viewers devoted to skiing and snowboarding. More US skiing and boarding events can attract both mass and elite participants similar to how running marathons do. Innovative facility technologies can make the sport less dependent on climate and provide year-round training for all. Better coach education should be part of the US Ski and Snowboard budgetary plans: it is necessary for the sport's development according to the surveyed coaches and administrators.

ASPECTS OF STORIES ABOUT PHYSICAL ACTIVITY IN CHILDHOOD AMONG OLDER WOMEN IN JAPAN: A TEXT MINING APPROACH IN LIFE HISTORY

KOZAKAI, R.

HOKUSHO UNIVERSITY

Introduction
Physical activity is essential for the maintaining active life throughout the life time. The environment for growth in childhood continues to affect mental and physical functions even in adulthood and old age (Birnie K, et al: 2011). However, little is known about the lifelong effects of physical activity in childhood on later life in context. The purpose of the present study was to describe aspects of physical activity in childhood by life histories using text mining among community-dwelling older women in Japan.
Methods
The participants were 27 women aged 84.6±3.0 years. They were interviewed about their life histories including family, school, occupational history, life events, exercise experience, present life situation, and future hopes. The interview time was about 60-90 minutes for each person. All voice data were saved as text files. The key word "playing" was used for detecting the statements about physical activity in childhood. The characteristics of the story were analyzed qualitatively. Text mining was performed using the IBM SPSS Text Analytics for Surveys ver. 4.0.1. Current mental and physical conditions were assessed by MOS 36-Item Short-Form Health Survey (SF-36), the Center for Epidemiologic Studies Depression Scale (CES-D) and Mini Mental State Examination (MMSE).
Results and discussion

In current mental and physical conditions, 28.0% and 7.4% of participants showed depression and low cognitive function, respectively. Physical function of the SF-36 was lower (62.4±29.5) and general health was higher (64.0±20.8) compared to the average Japanese women aged 70 to 79 years. In the text analyses, the 298 target sentences were extracted based on the concept of playing in childhood. The frequent words in the target sentences were "brothers", "boys", "skiing" and "commuting to or from school". After executing qualitative analysis, these words were interpreted as meaning that active movements had been considered "not girl-like". The aspect may be related with traditional and social barriers to engaging in exercise among women. The participants' daily life in childhood was characterized as hard, however, they found various pleasures in nature and basic motions such as running and walking in childhood. Meanwhile, participants who had a hard childhood described now as being the best time in their life.
Conclusion
Life stories about childhood physical activity showed the social barriers to exercising for women and the process of finding pleasure in daily activities in childhood. Negative memories in childhood did not necessarily lead to negative effects on later life.

HISTORICAL PREREQUISITES FOR CREATING AND DEVELOPING MODERN TYPES OF FENCING WEAPONS

DRIUKOV, O., DRIUKOV, V.

STATE SCIENTIFIC RESEARCH INSTITUTE OF PHYSICAL CULTURE AND SPORTS

INTRODUCTION: Modern fencing weapons (epee, foil, sabre) – a product of rational human activity, a part of material and spiritual culture of society.
METHODS: Analysis of special literature, chronological and comparative-historical analysis.
RESULTS: It is believed that sword was prototype of modern fencing weapons. For many centuries, sword has undergone significant changes. New types appeared; old ones were improved and complicated. In the middle of the XV century sword was superseded by sideswords. Sidesword represented stabbing long-bladed weapon, with double-edged blade and developed hilt (crosspiece, crossguard and head). A characteristic feature of sidesword was crossguard for hand protection. Sidesword came into common use in Europe in the XVI – XIX centuries as combat and duel weapon.
Simultaneously with sidesword, a new weapon called foil appeared. It is a thrusting long-bladed weapon, a kind of sidesword. It is believed that emergence of new, thrusting weapon was not an "evolution" of existing types of bladed weapons, but an adaptation to changing social conditions and the need for self-defense. The foil quickly spread among the nobility in many European countries, as it was lighter than sidesword, which allowed to wear it every day. And most importantly, foil was suitable not only for everyday and ceremonial wearing, but also proved to be a good weapon for self-defense and a weapon for duels. Until the XVIII century, sidesword was in service in all branches of armed forces, until it was replaced by sabre. Sabre represents a cut and thrust long-bladed weapon with curved blade and sharpening on a convex part of it. At the beginning of the 18th century,sabre gained wide popularity throughout Europe as a weapon of cavalry. Over time, the development of combat and civilian long-bladed weapons was completed, whereas sideswords, foils and sabres continued to evolve as sports weapons. Thus,modern sports weapons - epee, foil and sabre went through a difficult path of development and did not immediately acquire their characteristic features that are used today in sports fencing.
CONCLUSION: The millennial development of long-bladed weapon contributed to emergence of its new types, such as epee, foil and sabre, which for some time became the main weapon for both military and civilian population. The widespread distribution of these weapons led to development of sports fencing. Fencing with foils, epees and sabres becomes highly specialized and aimed at formal competitive fights of opponents on one-on-one base with specific type of weapon.

THE RELATIONSHIP BETWEEN EXPECTED VALUE AND BRAND LOYALTY FOR SPORTS BRANDS SUPPORTING FEMINISM: VERIFICATION OF THE MEDIATING EFFECT OF BRAND EMOTION

KIM, I.G., CHO, C.O., CHANG, M.J., PARK, J.C.

*1.KOREA NATIONAL SPORT UNIVERSITY 2,3.KOREA PARALYMPIC COMMITTEE *GERMAN SPORT UNIVERSITY COLOGNE*

Introduction
Since October 2017, #MeToo movement has spread worldwide and its social consciousness on feminism is also increasing in Korean society. In this context, corporations and brands are promoting feminism as a new marketing strategy, and sports brands that actively target female consumers in their marketing activity are no exception. It can be seen as a reflection of consumer trends of active consumers who pursue value rather than merely recognizing feminism as a social issue. Recently, the importance of expected value has become increasingly important. Expected value indirectly evaluates a product or a brand before consumption, and is considered as an important indicator for understanding consumer attitudes and behaviours (Zeithmal et al., 1991). The expected value could change across whether a corporation or a brand has stated a clear position on social issues such as feminism. Therefore, the aim of this study is to examine how the expression of sports brands supporting feminism influences the expected value of consumers, brand emotion, and brand loyalty.
Methods
A sample of 188 adults in Korea was used for analysing data. The questionnaire consisted of expected values (functional, economic, emotional, social, and altruistic), brand emotion, and brand loyalty as variables. The research hypothesis was verified by descriptive statistics, CFA, correlation analysis, and SEM using SPSS 22.0 and AMOS 21.0. Sobel's Z test was analysed to verify the significance of mediator variable between independent and dependent variables.
Results and discussion
The overall validity and fit showed $\chi 2(df)=768.740$ (384, $p<.001$), CFI=.922, TLI=.911, RMSEA=.073, which correspond to fit index suggested by Bagozzi & Dholakia (2002). First, functional value ($\beta=.215$, $p<.01$) and social value ($\beta=.535$, $p<.001$) significantly affected brand emotion. It seems that sports brands supporting feminism provide consumers with functional benefits of the product, and consumers feel the emotion associated with the symbolic benefit of engaging in social issues. Second, economic value ($\beta=.171$, $p<.05$) statistically influenced

brand loyalty. It is inferred that the sports bench coat used in the survey would be cost effective for consumers. Third, brand emotion (β=.215, p<.001) influenced brand loyalty. Lastly, brand emotion was found to act as a complete mediation between functional value and brand loyalty (Z = 2.45, p <.05), as well as social value and brand loyalty (Z = 3.86, p <.001). It means that although consumers recognize the functional and social value of a product, they do not directly affect loyalty, but were transferred to brand loyalty through brand emotion.

CP-SH04 Psychological factors in sport

PHYSIOLOGICAL STRESS IN ELITE HANDBALL PLAYERS. INFLUENCE OF GENDER, POSITION AND PLAY TIME.

MARISCAL, G., PLATERO, J.L., VERA, P., BODÍ, F., DE LA RUBIA, J.E., BARRIOS, C.
UNIVERSIDAD CATÓLICA DE VALENCIA

INTRODUCTION: Differences in the effort needed, distance covered and speed between the positions vary in elite handball. The saliva quantification markers have been used to determine a stress response, highlighting the cortisol hormone. The aim of this study was to evaluate the pre and post-match behavior of cortisol in elite handball players. Then second, to test the influence of the position, the play time and the perception of subjective effort.
METHODS: This was an observational, analytical and longitudinal study. Saliva samples of 14 male and 21 female handball players were collected. They were then analyzed 5 minutes before and 10 minutes after a league competition match in the Spanish 1st Division. The cortisol concentration in each sample was determined by ELISA. The Borg Scale was used to assess the self-effort perceived by each individual.
RESULTS: There was a significant increase of cortisol between pre-match and post-match in both groups (4.5 ± 5.3 ng/ml in males versus 4.8 ± 6.7 ng/ml in females; p <0.01). A higher concentration of cortisol was observed in female players before the match (2.4 ± 1.2 ng/ml in men vs 4.5 ± 2.8 ng/ml in women, p <0.01). The cortisol concentration was significantly higher in the defenders than in the forwards (1.71 ± 3.08 ng/ml versus 8.89 ± 8.80 ng/ml, Z: -2.147, p <0.05). This increase was also observed in the male group but there were no significant differences. However, there was a significant correlation between the subjective effort perception and the post-match cortisol concentration (r = 0.535, p <0.05). There was no correlation between playing time and cortisol increase (r = 0.177, p = 0.511).
CONCLUSION: Handball competition increases stress levels. This increase is higher in women and in defenders. In addition, this stress has a correlation with subjective effort perception. Finally, playing time does not influence cortisol levels.

ASPECTS OF PSYCHOSOMATIC DISORDERS IN HIGHLY QUALIFIED ATHLETES

IGOLKINA, A., MITIN, I., BARSHAK, S., ZHOLINSKIY, A.
FEDERAL RESEARCH AND CLINICAL CENTER OF SPORTS MEDICINE AND REHABILITATION OF FEDERAL MEDICAL BIOLOGICAL AGENCY

INTRODUCTION: The positive effect of physical activity and sport for one's state of health is shown in various studies. However, it is also well known that training and competitive loads of nowadays sport often decrease the level of athlete's functional state, and, most significantly, are being the risk factor for injuries and diseases. Specificity of extreme factors influence on the athletes body is related to the necessity of maximum mobilization of functional reserves and compensatory-adaptive mechanisms followed by accumulation of changes in the structure and functions of organs and systems with the constant risk of failure of compensatory-adaptive mechanisms, attended by the development of acute or chronic health cases. The main purpose of this research was to study psychological, psychophysiological and neurophysiological traits of highly qualified athletes suffering from psychosomatic disorders.
METHODS: The sample comprised 2826 highly qualified athletes of different Russian national teams (M=26,5). The results of psychometric testing were analyzed; that is data from instrumental attention tests, thinking processes tests, operational memory test, and results of Yahin-Mendeleevich clinical questionnaire for evaluation of neurotic states. Specific traits of athletes were studied by semi-structured interviews, and by Russian versions of several questionnaires, such as MMPI, COPE and MSCEIT V2.0. Brain bioelectrical activity was registered by 31-x canal digital DC electroencephalograph «Mitsar 202». Evoked potentials were registered by Visual Continuous Performance Test.
RESULTS: Results show high frequency of psychosomatic disorders among athletes of different Russian national teams — 28,1% of the sample. The most common conditions in various psychosomatic disorders among athletes of Russian national teams appeared the ones in locomotor system, in the digestive tract, and in nervous system. Gender and age specific differences were also shown (by Mann–Whitney U-test, p < 0,05). 50,3% athletes with diagnosed psychosomatic disorders show decrease of neurodynamic markers, such as the recession of functional activity of the brain prefrontal regions, the P300 wave amplitude decrease, and behavioral indicators deformation in the go-nogo trial. Psychologically, these athletes appear to have high level of the achievement motive, make high demands on themselves, use nonoptimal coping strategies, and tend to demonstrate everyone their success along with tendency to denial the possibility of having any psychosomatic problems. Statistically significant were the dependences of neurophysiological deviances' incidence rate and existence of athletes psychosomatic diagnosis (by Pearson $\chi 2$, p <0.01).
CONCLUSION: Data suggest that further work in this research area seems to have major practical significance especially when concerned with development and implementation of preventative care and rehabilitation program for highly qualified athletes.

IMPLICIT PERSONALITY TRAITS AND SUCCESS IN SPORTS

SPRECKELS, C., WOLLESEN, B.
UNIVERSITY OF HAMBURG

INTRODUCTION: Investigation showed that only exceptional talented people have the breakthrough in professional sports (Kang et al 2015). Are there besides technical, tactical, constitutional, athletic factors personality traits which are a predictive part of a successful

career? Some authors (Kang et al 2015) suggest that novelty seeking persons are more successful in sports. According to the Personality System Interaction Theory (PSI, Kuhl 2001) this factor is included in the personality traits Need for Stimulation and the Extension Memory and has an impact on perceptional-cognitive performance factors like anticipation and decision-making. Another factor like the tendency to avoid mistakes theoretically depends on the Need for Security and the Object Recognition System and should have an impact on being successful. Aim of this study was to explore if it is possible to predict a successful career by measuring these personality traits.
METHODS: N= 538 athletes, aged 27 ± 11 years, coming from different disciplines (e.g. soccer, tennis, golf, beachvolleyball, surfing) were ranked due to their success (from world champions and gold medal winners at the olympic games to 4th division athletes) and examined regarding their implicit personality traits. Due to the investigation that implicit personality traits are motivating people we used the appropriate Visual Questionnaire (ViQ) which was developed in support of the PSI-theory. This test includes the 4 main characters (worker, teamplayer, creative and dominant) as well as 4 motivational factors, which sums up to 16 different types. The personality traits were correlated (IBM SPSS 25.0, Armonk, NY) with success in sports.
RESULTS: Results show that there is a very low correlation (,118; p=0,05) between the personality factors and success in sports. There is no significant difference of the personality types between world champions and 4th division athletes.
CONCLUSION: "Ambition" which theoretically is based on a highly developed Need for Security in combination with the Object Recognition System is not correlated with success. Many athletes of the ambitious type are theoretically not that successful due to the fact that this combination is also responsible for avoiding mistakes, what prevents perceptual-cognitive performance and quick decision-making processes. On the other hand athletes with a high Need for Stimulation are quick in decision-making processes but they are often not that ambitious what prevents them from being successful. To sum up both traits do not predict any success in their pure form. But knowing certain unconscious personality traits of talented athletes, it is possible to work with a highly individual training program to develop these traits in combination with the cognitive and physical skills.

A QUALITATIVE CONTENT ANALYSIS OF SPORTS-RELATED THOUGHTS IN COMPETITIVE ATHLETES

KRÖHLER, A., BERTI, S.

JOHANNES GUTENBERG-UNIVERSITY MAINZ

Introduction
In interviews with athletes, statements such as "I didnt have a clear head" are often used as an explanation for poor performance. In addition, coaches would almost unanimously agree that negative thoughts have an impact on athletic performance. So far, however, there is no clear empirical evidence that this direct relationship between negative thoughts and athletic performance actually exists. Therefore, the first step of this study is to analyze the content of sports-related thoughts in the context of competitive sports. In a second step, the study attempts to provide an approach to explain the discrepancy between athletes and empirical research.
Methods and Results
We collected 788 negative thoughts within an online survey of 101 athletes (59 female; 42 male) aged between 15 and 30 years (M = 20.61; SD = 3.70) from different individual and team sports. An initial qualitative content analysis identified seven main categories including ever-day life stress, self-esteem, performance pressure, current competition, sportive and physical load, general training and sports-related stress and worry. Athletes also rated the impact of these thoughts, which was estimated to be comparable relatively small. This comes to surprise because subjective reports by athletes and coaches stress the importance of mostly dysfunctional thoughts on competitive performance. Therefore, we carried out a second content analysis on a structural level in order to search for underlying cognitive errors as described in the categorization system provided by Beck (1976).
Discussion
Our results suggest that two cognitive errors are quite common, namely overgeneralization and "have-to" statements. This is also in line with previous studies, which indicated that basic cognitive distortions occur in a normal population, but differ qualitatively and quantitatively from those found for example in depressed patients (Kumari & Blackburn, 1992; Wiemer-Hastings et al., 2004). This suggests that the effect of negative thoughts may depend on the specific pattern of thinking. In other words, future studies should identify the underlying cognitive error in order to unravel a potential negative impact of competition-related thoughts on athletes' performance. This may also lead to diagnostic tools identifying those athletes, who are especially vulnerable to these dysfunctional cognitive mechanisms.

WHAT IS ORIENTEERING SPORT? A CASE STUDY OF THE ATHLETES PERCEPTION IN BRAZIL

SCOPEL, A., PIMENTEL, G., QUEIROZ, A.

INSTITUTO FEDERAL DO CEARÁ (IFCE) / UNIVERSIDADE ESTADUAL DE MARINGÁ (UEM) / CENTRO DE ESTUDOS SOCIAIS - UNIVERSIDADE DE COIMBRA (CES-UC)

Introduction
The orienteering sport are in increasing development in Brazil. However, there is a gap in knowledge about how this practice is perceived. Thus, we have analyzed how orienteering sport is characterized by Brazilian athletes.
Methods
A quantitative and qualitative nature cross-sectional study was made. The population was composed of competitors from the VII Northeast Orienteering Cup. A non-probabilistic sample was composed of 110 athletes (41 women and 69 men). The majority of the study participants were adults between 41 to 60 years (32.7%), followed by 31 to 40 years (31.8%). It is also noticeable a high degree of education among the volunteers, 56.4% affirmed to have complete higher education. The data were collected through the GEL Questionnaire - Definition and Characterization of Adventure Activities (Balbim, Oliveira & Pimentel, 2009) adapted for orienteering. For this paper it was

considered the answers regarding the Orienteering Sport characterization. The Agreement Level (AL) was analyzed on a scale from 1 (I fully disagree) to 5 (I fully agree).
Results and discussion
The data analysis indicates a relationship between orienteering and leisure: the sample considered the Orienteering Sport as a leisure option (AL - 4,78); A way to relieve the everyday life stress (AL - 4,63); Moreover, the athletes do not consider competition as the main objective of orienteering practice (AL - 2,6). About the terminology the volunteers had four options to indicate their agreement levels: risk sport (AL - 2,9); extreme sport (AL - 3,16); adventure sport (AL - 4,08); Physical Activity of Adventure in Nature (AFAN) (AL - 4,47). The words related to orienteering was: fear (AL – 2,3); Adventure (AL - 4,12); Nature contact (AL - 4,73).
According to the data the competitors showed higher levels or agreement when the orienteering was related with leisure, stress relief, adventure and nature contact. Yıldız et all (2017) had concluded some similarities, in their study the main themes related to orienteering activities were socialization, career development, health development, mental development, leisure activities and love of nature.
These results showed the importance of considering more than technical and competitive aspects of sports related to nature and environment such as the orienteering, which is in fast development around the world. Also brought elements can contribute to the progress of the sport management and practice.

POSSIBILITIES OF PARTICIPATORY ACTION RESEARCH AND ART-BASED METHODOLOGIES IN SPORT AND EXERCISE PSYCHOLOGY

MASHREGHI, S.
MALMÖ UNIVERSITY

Introduction
In the recent years, in response to the criticism of post/anti/decolonial (Ryba & Schinke, 2009; Said, 2003) and critical whiteness studies (Butryn, 2009; Golash-Boza, 2016), a number of cultural sport and exercise psychologists (CSP), specially within North America, have utilized innovative ways of knowledge production that has epistemologically challenged the ethnocentrism of the field of sport and exercise psychology (Blodgett et al., 2011; Schinke et al., 2017). In Europe, however, sport and exercise psychology research in relation to acculturation of racialized others has remained mostly an unchallenged territory.
Method
This paper explores the convergence of participatory action research (PAR) (Freire, 2005) and art-based methods (ABM) (Eales & Peers, 2016) within anti/de colonial and critical paradigms in relation to CSP and acculturation.
Result and Discussion
Utilizing ABM and PAR intersection works with non-alienating, strength-based and culturally relevant methodologies that centralize the worldviews and epistemology of racialized others and treat people as active agents capable of critical reflection and knowledge production (Blodgett et al., 2013). Moreover, ABM operate to strengthen local, anti/decolonial ways of knowledge production and knowledge transference that have been eroded due to Eurocentric and Westernized research approaches.

ALTERATIONS IN FUNCTIONAL CONNECTIVITY IS ASSOCIATED WITH COGNITIVE IMPROVEMENT INDUCED BY ACUTE EXERCISE

SAITO, S., SENOO, A., WANG, S., MIZUGUCHI, N., SUDO, M., OHKAWARA, K., ANDO, S.

THE UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: Acute aerobic exercise improves cognitive performance. A previous study suggested that enhanced activations in the dorsolateral prefrontal cortex are associated with cognitive improvement elicited by acute exercise (1). However, underlying mechanisms for cognitive improvement are not fully understood. In the present study, we used functional magnetic resonance imaging (fMRI) and tested the hypothesis that alterations in functional connectivity play an important role in cognitive improvement. The aim of this study was to clarify whether alterations in functional connectivity is associated with cognitive improvement induced by acute exercise.
METHODS: Participants were 10 healthy right-handed young men (age: 21.6 ± 1.4 yr., peak oxygen uptake: 46.5 ± 8.7 ml/kg/min). They performed the experiments in two conditions with a crossover design. In the Exercise condition, participants cycled at 40% peak oxygen uptake for 30 minutes, and fMRI scan was performed during the Go/No-Go task before and after exercise. In the Control condition, participants rested for 30 minutes instead of exercise. fMRI scan was performed in the same time course as the Exercise condition. We first analyzed regions specifically activated by exercise as region of interest. Then, we identified regions where functional connectivity was altered before and after exercise. We also identified regions where amount of alterations in functional connectivity was correlated with alterations in reaction time (RT) of the cognitive task.
RESULTS: In the Exercise condition, RT significantly reduced after exercise ($p<.05$). Acute exercise specifically activated the right supplementary motor cortex, the right temporal pole (rTP), the right insula cortex (rIC) and the right inferior frontal gyrus (rIFG) during the cognitive task. Alterations in functional connectivity between (a) rTP and left amyglada, (b) rTP and rIC, and (c) rTP and rIFG ($p<.001$, $p<.05$, and $p<.05$, respectively) were correlated with alterations in RT.
CONCLUSION: We observed cognitive improvement after exercise. The present results suggest that activation in rTP and altered functional connectivity between rTP and other brain regions may contribute to improved cognitive performance.

RELATIONSHIP OF MULTIPLE ASPECTS OF PHYSICAL FITNESS TO COGNITIVE CONTROL: AN FMRI INVESTIGATION WITH OVER 1,000 YOUNG AND MIDDLE-AGED ADULTS

ISHIHARA, T., MIYAZAKI, A., TANAKA, H., FUJII, T., TAKAHASHI, M., MATSUDA, T.

TAMAGAWA UNIVERSITY BRAIN SCIENCE INSTITUTE

INTRODUCTION: There is a growing consensus about the positive relationship of physical fitness to cognitive control (higher-order cognitive function). However, what aspects of physical fitness (e.g., cardiorespiratory fitness, gait speed, muscular strength, and hand dexterity) are more strongly and independently related to cognitive control is still controversial. Here we show the cross-sectional relationships of multiple aspects of physical fitness to cognitive control task (N-back task) performance. In addition, we examined whether functional brain activity during the cognitive control task could account for these relationships.
METHODS: We used data derived from 1,040 healthy participants (563 women and 477 men) aged 22 to 37 years from the Human Connectome Project (HCP) database. Performances on each physical fitness domain were obtained using four tests: 2-minute walk test (cardiorespiratory fitness), 4-meter walk gait speed test (gait speed), 9-hole pegboard dexterity test (hand dexterity), and grip strength test (muscular strength). To obtain the participant's cognitive control and task-evoked functional brain activity (task-fMRI data), all participants performed the HCP version of the N-back task in the MRI scanner.
RESULTS: Cardiorespiratory fitness and hand dexterity were positively and independently associated with accuracy on the N-back task ($\beta \geq .14$, $p < .001$) after controlling for age, sex, and other domains of physical fitness, although no such association was found for gait speed or muscular strength. The task-evoked functional brain activation in specific parts of the fronto-parietal network (FPN, including frontal and parietal cortex) and default mode network (DMN, including medial prefrontal cortex, posterior cingulate cortex, and the occipital-parietal junction) mediated the relationships of cardiorespiratory fitness and hand dexterity to accuracy in the N-back task ($\beta \geq .02$, $p < .02$). Cardiorespiratory fitness was associated with task-evoked functional activation in broader regions of the FPN relative to hand dexterity. Hand dexterity moderated the relationship between task-evoked functional activity in the FPN and DMN ($\beta = .10$, $p < .001$).
CONCLUSION: The current results indicate that the relationship between physical fitness and cognitive control may be moderated by physical fitness domains. In addition, these differences were accounted for by functional brain activity during the cognitive control task. More specifically, greater cardiorespiratory fitness and hand dexterity, relative to gait speed and muscular strength, were more strongly and independently related to higher cognitive control. These relationships were mediated by task-evoked functional activity in the FPN and DMN. Hand dexterity was also associated with moderating the interaction in terms of task-evoked activation between the FPN and DMN. Greater cardiorespiratory fitness could moderate the relationship of activation in the FPN and DMN to cognitive control via activation in broader regions of the FPN.

ASSOCIATION BETWEEN ENDOGENOUS DOPAMINE RELEASE AND COGNITIVE IMPROVEMENT DURING EXERCISE

KONNO, T., TASHIRO, M., FUJIMOTO, T., WATANUKI, S., NASIR, B.M.F., HIRAOKA, K., KOBAYASHI, A., LIN, Y., WATABE, H., ANDO, S.

THE UNIVERSITY OF ELECTRO-COMMUNICATIONS, CYCLOTRON AND RADIOISOTOPE CENTER , TOHOKU UNIVERSITY

INTRODUCTION: A number of studies have shown that acute exercise improves cognitive performance (1). However, physiological mechanisms underlying the cognitive improvement remain to be elucidated. Positron emission tomography (PET) is a valuable tool to investigate neurotransmission in living human brain. In the present study, we tested the specific hypothesis that endogenous dopamine release is associated with cognitive improvement induced by acute exercise. As far as we know, this is the first study examining the association between endogenous dopamine release and cognitive improvement during exercise.

METHODS: Young male participants (n=11, 22.3±0.7yrs) performed the Go/No-Go task (2) in two conditions. In the Exercise condition, the participants performed the cognitive task before and during exercise. They performed voluntary exercise at 35% peak oxygen uptake for 40 min in a supine position. [11C]raclopride was injected 10 min after the start of exercise, and PET scan was performed for 90 min. In the Control condition, they performed the cognitive task and PET scan without exercise. Time course was the same as the Exercise condition. We used reaction time (RT) and accuracy to assess cognitive performance. We calculated binding potential (BP) for left and right caudate and putamen from nine participants using the Logan graphical analysis (3).
RESULTS: In the Exercise condition, RT significantly decreased during exercise (403±61ms, P=0.01) relative to rest. BP of right caudate was significantly lower in the Exercise condition (2.05±0.28, P=0.04) than that in the Control condition (2.22±0.22), indicating that acute exercise released endogenous dopamine. Furthermore, alterations in RT tended to be correlated with alterations in BP (r = 0.53, P =0.14).
CONCLUSION: The main findings of the preset study were: 1) acute exercise improved cognitive performance; 2) acute exercise released endogenous dopamine; 3) endogenous dopamine release tended to be associated with improvement in cognitive performance during exercise. Our preliminary results suggest that exercise-induced cognitive improvement may be associated with endogenous dopamine release.

QUADRICEPS ACTIVATION DURING SELECTED FUNCTIONAL EXERCISES WITH AND WITHOUT ENHANCED ABDOMINAL CORE ACTIVATION

ERDEM, M.M., DEMIREL, G.N., CALIK, M., CIGERCIOGLU, N.B., GUNDUZ, S., HARPUT, G.
RECEP TAYYIP ERDOGAN UNIVERSITY

INTRODUCTION: There is some evidence that show the beneficial effect of abdominal core activation on dynamic stability of the lumbopelvic-hip complex and hip muscle coactivation during lower extremity exercises (1-3). However, it remains unclear whether enhanced abdominal core activation (ECA) modify quadriceps activation during functional exercises. The aim of this study was to investigate quadriceps muscle activation levels during selected functional exercises with and without ECA.
METHODS: Eleven healthy individuals (Age: 24.6±1.9 years; BMI: 22.7±2.9 kg/m2) were included in this study. Surface electromyography was used to measure internal oblique/transversus abdominis (IO/TA), vastus medialis obliquus (VMO), rectus femoris (RF), vastus lateralis (VL) muscle activation levels during single leg raise (SLR), single leg squat (SLSQ) and forward lunge (FL) exercises. The exercises were performed in a randomized order with two conditions: neutral (NT) and ECA. The pace of the exercises was standardized with the use of metronome (60 beats/min) and the exercises were divided into 3 phases (concentric, isometric, eccentric) with synchronized video camera. Maximum voluntary isometric contraction was used to normalize the muscle activations during the exercises. 2-way (phase by condition) repeated measures of ANOVA was performed for statistical analysis.
RESULTS: There were significant phase by condition interactions for VMO ($F(2,22)=3.95$, $p=0.03$) and VL ($F(2,22)=6.89$, $p=0.005$) muscles during SLR. When compared to NT, VMO and VL muscle activation levels were greater with ECA during concentric phase of SLR ($p=0.006$, $p=0.03$, resp). A significant phase by condition was also observed during SLSQ for VMO ($F(2,22)=6.23$, $p=0.007$) RF ($F(2,22)=4.83$, $p=0.02$) and VL ($F(2,22)=4.96$, $p=0.02$) muscle activation levels. Compared to NT condition, VMO and VL activation levels were greater in eccentric phase of the SLSQ ($p=0.04$, $p=0.03$, resp.) while RF activation levels was lower in isometric phase of the SLSQ ($p=0.03$). There was no significant phase by condition interaction for muscle activation levels during FL ($p>0.05$).
CONCLUSION: The present findings suggest that the coactivation of abdominal core muscles may have a potential to modify quadriceps activation levels that may improve the efficacy of therapeutic exercises. Thus, the exercises with enhanced abdominal core activation may be an option in patients with knee pathologies where quadriceps weakness is the primary problem.

EFFECTS OF HOLDING EXTERNAL LOADS WITH DIFFERENT MASSES ON POSTURAL CONTROL SYSTEM DURING QUIET STANDING

YAEGASHI, M., KIMURA, T.
KOBE UNIVERSITY

INTRODUCTION: We often stand with baggage in our hands unlike the normal quiet standing task in the laboratory. During bipedal stance, the baggage may be considered as an external disturbance because it increases gravity torque around the ankle joint and therefore can result in postural instability. However, on the other hand, there is also a possibility that it increases the moment of inertia around the ankle joint and therefore can result in reduced postural sway. Actually, previous studies (1, 2) have suggested that carrying external load contributes to postural stability in elderly people. However, the concomitant sensory effect of hand contact with external object on the postural control system (3) has not been considered. The aim of this study was therefore to investigate the mechanical effects of external load on the postural control system by controlling the sensory effect of hand contact.
METHODS: Ten young subjects (21-28 yrs) maintained quiet standing on a force platform with eyes closed. During standing, both hand hold a customized weight of 0.05kg, 1.5kg, and 3kg (W0, W3, and W6 conditions, respectively). The W0 (i.e., control condition) was not the normal quiet standing with empty handed, because we aimed to unify the sensory effect of hand contact with an external object (3). The subjects performed eight trials for each weight condition. During each trial, anteroposterior center of pressure (CoP) was obtained by the force platform. Simultaneously, surface electromyography (EMG) was recorded from triceps surae muscles.
RESULTS: The main effect of weight condition was significant for the mean velocity (MV) of CoP ($F1.24,11.1=4.96$, $P < 0.05$), but not for the average position of CoP ($F2,18=1.68$, $P > 0.05$). The post hoc test revealed that the MV of CoP was significantly decreased at W3 compared to W0 ($P < 0.05$). On the other hand, the main effect of weight condition was significant for the integrated EMG of soleus muscle ($F1.23,11.0=6.05$, $P < 0.05$) and the post hoc test indicated that it was significantly increased at W6 compared to W0 ($P < 0.05$), while there was no significant difference between W3 and W0 ($P > 0.05$).
CONCLUSION: Main result of this study was the reduction of CoP MV, a sensitive measure of postural stability, only at W3 condition. Because the present study unified the sensory effect of hand contact (3) among the three weight conditions, it can be said that the mechanical effect of external load with optimal mass (i.e., 3kg in total) also enhances the postural stability during quiet standing.

EFFECTS OF MUSCLE CONTRACTION ON SUBJECTIVE PERIPHERAL SENSATION AND SPINAL EXCITABILITY

TAKAHARA, T., YAMAGUCHI, H., SEKI, K., ONODERA, S.

KIBI INTERNATIONAL UNIVERSITY

INTRODUCTION: It is known that subjective peripheral sensations (SPE), such as pain, are suppressed during sports activities. It is considered that the suppression of the peripheral sensations contributes to facilitate the motion by eliminating unnecessary sensory information in the execution of the movement. However, there are a lot of unclear points about the factor which suppresses sensory information. This study focused on spinal excitability. This study aimed to investigate the changes in SPE and evoked EMG F-wave during voluntary muscle contraction.
METHODS: Seven healthy males participated in this study. Informed consent (both oral and in writing) to participate in this study was obtained from all participants as per the Declaration of Helsinki. This study was conducted after obtaining approval from the Kibi International University Ethical Review Board (No. 18-37). Prior to the experiment, SPE threshold in the dorsal surface of the hand was measured using a Semmes-Weinstein Monofilament test. Then, the maximum isometric pinch force (MIF) of the both hands were measured. Sufficient rest after measuring MIF participants maintained 20% MIF in right hand (R-condition) and left hand (L-condition). A condition in which tension was not exerted was used as the control condition (C-condition); the R, L, and C-conditions were evaluated randomly in each subject. SPE and F-waves of the right hand were measured in each condition. After establishing their peripheral sensory threshold, patients orally answered if they detected the presence or absence of peripheral cutaneous stimulation during SPE measurement. Patients received 20 cutaneous stimulations to calculate the accuracy rate of their answers. A square wave pulse of 0.5 ms electrical stimulus duration was generated in the median nerve in the carpal area, and F-wave was inducted from the abductor pollicis brevus using surface EMG. The electrostimulation intensity was 1.2 times greater than the maximum M-wave. Stimulation frequency was set to 1 Hz for 30 s. The frequency appearance of F-waves was analyzed.
RESULTS: The SPE was significantly lower in the R and L-conditions than in the C-condition. The frequency of F-wave appearance was significantly higher in the R-condition compared to the C and L-conditions.
CONCLUSION: Voluntary muscle contraction revealed that the SPE of the hands on the contraction side and on the other side changed. However, because the F-wave frequency appearance did not occur in conjunction with changes in SPE, the relationship between suppression of peripheral sensory input during exercise and the spinal excitability has been suggested that less.

ACTIVITY DURING CONTRACTION AND RELAXATION IN A VARIETY OF MUSCLES

TETSU, T.1, KOUKI, K.1, KAZUYUKI, K.1, KENJI, K.2

1:WASEDA UNVERSITY, 2:NATIONAL RESEARCH AND DEVELOPMENT CORPORATION NATIONAL INSTITUTE OF LONGEVITY RESEARCH

INTRODUCTION: Neural mechanisms during contraction and relaxation of various muscles have been investigated utilizing muscle activity and muscle reaction time (1) (2) (3). However, since target muscles and ways to measure reaction time are different among these studies, common conclusions concerning the relationship between contraction and relaxation have not yet been obtained. The purpose of the present study was to quantitate the muscle activity during contraction and relaxation in a variety of muscles with a common criterion, and to clarify individual differences.
METHODS: Participants were asked to volitionally contract or relax their finger (first dorsal interosseous: FDI), wrist (extensor carpi radialis: ECR / flexor carpi radialis: FCR), elbow (biceps brachii: BB / triceps brachii: TB) muscles in response to an auditory stimulus. Each task was executed with 50% maximum voluntary contraction. Each target muscle activity during trials, reaction start time, reaction completion time were analyzed.
RESULTS: Significant positive correlation between reaction completion times of contraction and relaxation was obtained in all muscles except the finger muscles. There was no correlation between reaction start time in any muscles.
CONCLUSION: The correlation between the completion times of contraction and relaxation means that the individuals having fast contraction can also do relax fast. This would suggest that there were same common mechanisms in muscle contraction and relaxation. Interestingly, the correlation was not observed for the finger muscle, which is frequently used on a daily basis. But how to use it might differ among individuals. Thus, the reaction time would also be influenced with training.

EFFECT OF MUSCLE RELAXATION ON CORTICOSPINAL EXCITABILITY OF OTHER MUSCLES IN THE SAME LIMB

ITO, M.1, KATO, K.2, KANOSUE, K.2

1: GRADUATE SCHOOL OF SPORT SCIENCE, WASEDA UNIVERSITY, 2: FACULTY OF SPORT SCIENCES, WASEDA UNIVERSITY

INTRODUCTION: Muscle relaxation with appropriate strength and timing is required for high performance in sports. A previous study suggests that expert badminton players showed decrease in muscle activity of the triceps branchii immediately after smash impact compared to that of novices (Sakurai and Ohtsuki,2000). Furthermore, volitional muscle relaxation from contraction of one limb affects corticospinal excitability of the other limb (Kato et al.,2015). However, the effect of muscle relaxation on the other muscles within the same limb has not been well understood. The purpose of the present study was to clarify the effect of muscle relaxation on corticospinal excitability of other muscles in the same limb.
METHODS: Participants (n=12) were asked to voluntarily relax their right shoulder from its abduction (deltoid muscle: DM relaxation) in response to an auditory stimulus. Single-pulse TMS was delivered to the hand (Exp.1) or the wrist (Exp.2) areas of the left primary motor cortex at different time intervals after auditory stimulus. Motor evoked potentials (MEPs) were recorded from right first dorsal interosseous (FDI) and abductor pollicis brevis (APB) for Exp.1, and extensor carpi radialis (ECR) and flexor carpi radialis (FCR) for Exp.2.
RESULTS: In Exp1, there was no significant difference between the MEP amplitudes of FDI and APB compared to the resting control. In Exp2, MEP amplitudes of ECR and FCR before DM relaxation were significantly larger than resting control. After DM relaxation, those MEP amplitudes showed no significant difference compared to resting control.
CONCLUSION: In this study, we clarified that relaxation of shoulder abductor does not affect corticospinal excitability of finger joint muscle, while it does in wrist joint muscles. It indicates that relaxation of shoulder abductor has different influences on finger joint muscles and

wrist joint muscles. Since finger muscle performs precise movement compared with the wrist joint muscle, there is possibility that finger muscles are less affected by other muscles.

WITHIN AND BETWEEN DAY RELIABILITY OF MUSCLE SYNERGIES IN A COMPLEX STRENGTH TRAINING TASK

SANTOS, P., VAZ, J.R., CORREIA, P., VALAMATOS, M.J., VELOSO, A.P., PEZARAT-CORREIA, P.
HUMAN KINETICS FACULTY, LISBON

INTRODUCTION: Muscle synergy extraction has been utilized to investigate muscle coordination in human movement, namely in sports field (1). The reliability of the method has been proposed (2), although it has not been assessed previously during a complex sportive task. Therefore, the aim of the study was to evaluate within- and between-reliability of a strength training complex task, the power clean, assessing subject's variability in the task across repetitions, sets and days.
METHODS: Twelve unexperienced participants performed four sets of power cleans in two test days after strength tests, and muscle synergies were extracted from electromyography (EMG) data of 16 muscles. To evaluate within- and between-day reliability we determined the correlations for the muscle synergy components and individual EMG profiles at three levels: inter-repetition, inter-set and inter-day.
RESULTS: Three muscle synergies accounted for almost 90% of variance accounted for (VAF) across sets and days. Within-day VAF, muscle synergy vectors, synergy activation coefficients and individual EMG profiles showed high similarity values. Between-day VAF and muscle synergy vectors had moderate similarity, while the variables regarding temporal activation were still strongly related. A cluster analysis revealed that subjects with anterior background in general strength training presented less variation in muscle synergy vectors, which may be an indicator of the flexibility of muscle synergies.
CONCLUSION: The present findings revealed that synergistic organization of muscle coordination during power clean remained stable across repetitions, sets and days in unexperienced subjects. Thus, the extraction of muscle synergies through NMF may be considered a reliable method to study muscle coordination adaptations from muscle strength programs.

VENTILATORY RESPONSE AT REST AND DURING MAXIMAL EXERCISE TESTING IN PATIENTS WITH SEVERE OBESITY BEFORE AND AFTER SLEEVE GASTRECTOMY PROCEDURE.

FAVERO, C., BAIOCCATO, V., BORASIO, N., QUINTO, G., FOCCARDI, G., NEUNHAEUSERER, D., GASPERETTI, A., ERMOLAO, A.
UNIVERSITY OF PADOVA

INTRODUCTION: Although sleeve gastrectomy (SG) has become a widespread treatment option in patients affected by severe obesity, studies investigating the effect of consistent weight loss on the ventilatory response after SG are lacking.
The objective of this study is to investigate whether a significant weight loss results in a change of exercise capacity and of the ventilatory response, at rest and during strenuous physical activity.
METHODS: This is an observational study on 51 (39 F; 12 M) obese patients (BMI >30 kg/m2), comparing ventilatory function parameters before and 6 months after undergoing SG. The patients were evaluated at rest by spirometry and performing an incremental cardiopulmonary exercise test on a treadmill, before and after surgery
RESULTS: At rest, the significant weight loss (27 ± 7% of body weight; BMI from 42.93 ± 5.84 to 31.88 ± 4.97 Kg/m2) led to an improvement in lung volumes and flows (FVC, FEV1, MEF25), while resting ventilation, absolute oxygen uptake ($p < 0.001$) and PetCO2 ($p = 0.002$) were reduced. During cardiopulmonary exercise testing, exercise time and oxygen uptake per kilogram at maximum exertion were increased, but absolute oxygen uptake and ventilation were decreased during all phases of the test (all $p < 0.001$). Moreover, at maximum exertion, a reduction of VE/VCO2slope ($p = 0.008$) and an increase in saturation ($p = 0.002$) were observed. Finally, an increase in Breathing Reserve (BR%) ($p < 0.001$) was also noted.
CONCLUSION: Weight loss due to SG led to less burdensome restrictive limitations of the respiratory system and to a reduction of ventilation at rest, possibly explained by a decrease in energy demands, increased ventilatory efficiency and, possibly, reduced respiratory drive.
Exercise tolerance during cardiopulmonary exercise testing increased, while absolute aerobic capacity decreased. The ventilatory response appeared reduced for both internal and external workload, unexpectedly with no evident changes in the respiratory pattern. The decrease in ventilation during exercise could be explained partly by a lower ventilatory demand at the same workload and partly by an increase in its efficiency, the latter emphasized by the greater ventilatory reserve.

THE RELATIONSHIP BETWEEN SLEEP HABITS AND MEETING THE CHILDREN'S PHYSICAL ACTIVITY GUIDELINES IN FIFTH- AND SIXTH-GRADE JAPANESE CHILDREN

AOKI, T.1,2, SUZUKI, K.3, WATANABE, M.4, FUKUDA, K.5, TANAKA, C.6, KAMIKAWA, Y.7, TSUJI, N.8, TANAKA, H.9, ASAI, H.10, YAMAMOTO, N.10, YAMATSU, K.11, ISHII, K.1

1: DOSHISHA UNIV., 2: JSPS, 3: YAMAGATA UNIV., 4: IBARAKI UNIV., 5: EDOGAWA UNIV., 6: J. F. OBERLIN UNIV., 7: TOYAMA UNIV., 8: SHIGA UNIV., 9: HIROSHIMA INT'L UNIV., 10: EHIME UNIV., 11: SAGA UNIV.

INTRODUCTION: The physical activity (PA) guidelines for children and young people in Western countries recommend that PA is carried out for more than 60 min per day (Janssen and LeBlanc, 2010). This guideline is also recommended in Japan. The outcomes of the guideline concern obesity, mental health, health-related physical fitness, general malaise, and sociability; however, the relationship between sleep habits and meeting the children's PA guideline is still unclear. This study aims to assess the relationship between sleep habits and meeting the children's PA guideline among fifth- and sixth-grade Japanese children.
METHODS: We conducted a cross-sectional study that included 1,313 students in grades 5 and 6 (656 boys, 657 girls) in Japan. School-night and weekend bedtime, school-day and weekend wake-up time, total school-night and weekend sleep time, and social jetlag (the absolute difference between midpoint of sleep on school-days and midpoint of sleep on weekends) were assessed using questionnaires. The Japanese version of the Pediatric Daytime Sleepiness Scale (PDSS-J) was used to measure daytime sleepiness. To assess vigorous PA (VPA) and moderate PA (MPA) per day, we used the International Physical Activity Questionnaire for Japanese Early Adolescents (IPAQ-JEA). VPA and MPA per day were summed to calculate moderate-to-vigorous PA (MVPA) per day. First, depending on the children's achievement status (whether they had met the children's PA guidelines of >60 min of MVPA per day), subjects were divided into an achieved (314 boys, 198 girls) and a non-achieved group (342 boys, 459 girls). After that, analysis of covariance (ANCOVA) was conducted with adjustments for age and BMI for each gender.
RESULTS: The results of this ANCOVA showed that, in boys, no significant differences were observed between the achieved group and the non-achieved group for all sleep variables and daytime sleepiness. On the other hand, in girls, the average weekend wake-up time of the achieved group was significantly earlier than that of the non-achieved group (07:46 am ± 91 min vs. 08:05 am ± 80 min, $p = 0.006$). Additionally, in girls, the achieved group had a shorter average total weekend sleep time (528 ± 97 min vs. 543 ± 85 min, $p = 0.043$) and a smaller average social jetlag (55 ± 52 min vs. 66 ± 47 min, $p = 0.016$) compared with the non-achieved group.
CONCLUSION: These results suggest that favorable sleep habits, such as less discrepancy between circadian and social clocks, are related to meeting the children's PA guideline in girls in grades 5 and 6.

IMPACT OF DECREASE IN FATNESS ON CHANGES IN MENSTRUAL PATTERN IN JAPANESE COMPETITIVE ADOLESCENT RUNNERS.

UCHIYAMA, E., KINOSHITA, N.

HOSEI UNIVERSITY

INTRODUCTION: Previous cross-sectional studies have demonstrated that percent body fat (%BF) does not differ between eumenorrheic and amenorrheic athletes. However, the question how menstrual patterns will change in relation to %BF decrease has not been addressed on adolescent runners. The purpose of this study was to compare 2 groups of adolescence with different changes in %BF and to assess impact of %BF decrease on changes in menstrual pattern among Japanese competitive girl runners.
METHODS: Consecutive 18 freshmen (H1, 14.9y/o, 158.6cm, and 46.9kg) and 20 juniors (H2, 15.9y/o, 158.3cm, and 43.9kg) in competitive high school teams were separately evaluated at 2 time points; preparatory (PRE) and competitive (PEAK) seasons, 5.7 ± 0.5 (H1) and 5.5 ± 0.5 (H2) months apart. H2 had experienced intensive training of running for a year. Body composition was measured by DXA. Menstrual history was investigated by questionnaire with personal interview. The runners were categorized according to frequency of the cycle in the last 12 months at each time point; eumenorrheic (EU, 10-13 cycles) and menstruation disturbed (MD, <10 cycles). Paired t-test was used to compare body mass (BM), %BF, fat mass (FM) and lean mass (LM) between 2 seasons. Percentages of MD were compared between 2 seasons by Fishers exact test. The changes (c) in variables from PRE to PEAK were compared between H1 and H2 by Student's t-test. Written informed consent was obtained from the runners and their parents. $P<0.05$ was considered as statistically significant.
RESULTS: BM, %BF, and FM decreased and LM increased significantly from PRE to PEAK in H1 (46.9 to 44.7kg, 18.9 to 12.6%, 9.1 to 5.6kg, and 35.3 to 37.1kg, respectively), while percentage of MD significantly increased (27.8% to 72.2%). Percentage of MD was significantly higher (75.0%) in H2 than in H1 even at PRE and had been sustained higher level at PEAK (80.0%). In contrast to H1, BM, %BF, FM, and LM did not change in H2 from PRE to PEAK (43.9 to 43.7kg, 13.8 to 12.9%, 6.1 to 5.7kg, and 35.6 to 36.0kg, respectively). Regarding the magnitude of the changes in body composition variables, runners of H1 showed significantly larger decreases in BM, %BF, and FM from PRE to PEAK than H2 (cBM: -2.2 vs. -0.1kg, c%BF: -6.3 vs. -0.9%, and cFM: -3.4 vs. -0.4kg, respectively).
CONCLUSION: Newly developed menstrual disorders is related to the substantial decreases in %BF and FM among adolescent runners. This will likely occur in the freshman year of high school. High prevalence of menstrual disorders after 1 year of training is sustained in the junior year along with very low level of fatness. It is important to monitor %BF carefully at the beginning of athletic career in high school for early recognition of menstrual disorders.

THE COMBINED EFFECTS OF ACUTE EXERCISE AND FREQUENT BREAKS IN SITTING ON POSTPRANDIAL METABOLISM IN OLDER ADULTS

WHEELER, M.

UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: The proportion of overweight/obese individuals increases with age, and both are important markers of cardiovascular disease (CVD) risk. Postprandial metabolism orchestrates fat and glycogen storage and thus can be a harbinger for the development of obesity, insulin resistance and type 2 diabetes (T2D). While the effects of both exercise and sedentary behaviour on postprandial metabolism have been studied separately, no study has investigated whether there is a combined effect of these behaviours on postprandial metabolism in overweight/obese older adults. We hypothesised that exercise-induced reductions in postprandial glucose, insulin and

triglycerides would be attenuated by exposure to prolonged sitting, but enhanced by subsequent breaks in prolonged sitting over a period of 8-hours.
METHODS: Sedentary older adults (n=67; 67±7years; 31.2±4.1kg/m2), completed three experimental conditions in a random order (6-day washout): SIT: uninterrupted sitting (8hr, control condition); EX+SIT: sitting (1hr), moderate-intensity walking (30min, 65-75% of age-predicted max heart rate), uninterrupted sitting (6.5hr); EX+BR: sitting (1hr), moderate-intensity walking (30mins), sitting interrupted every 30 minutes with 3 minutes of light-intensity walking (6.5hr). Participants were fed a standardised breakfast and lunch. Fasting and post-prandial blood samples were collected over 8-hours for analysis of serum insulin, plasma glucose and triglycerides. Postprandial responses were summarised as total area under the curve (tAUC) and marginal means, adjusted for potential confounders, were compared using linear mixed models
RESULTS: Small increases in glucose tAUC were observed in EX+SIT (43 mmol·hr·mL-1, 95% CI: 42-44) and EX+BR (43, 42-44), relative to SIT (42, 41-43, p<0.05). Insulin tAUC decreased in both EX+SIT (1950 pmol·hr·mL-1, 1716-2216) and EX+BR (1772, 1559-2013), relative to SIT (2372, 2087-2696, p<0.001). Insulin-to-glucose tAUC decreased in EX+SIT (17833 pmol:mmol·hr·mL-1, 15195-20930) and EX+BR (16409, 13983-19256) relative to SIT (22674, 19316-26617, p<0.001), representing a 21% and 28% reduction in EX+SIT and EX+BR, respectively (p<0.05 EX+SIT vs EX+BR). Triglyceride tAUC was reduced in EX+BR (12 mmol·hr·mL-1, 12-13), relative to SIT (13, 12-14, p=0.02) and EX+SIT (13, 12-14, p=0.047).
CONCLUSION: These results demonstrate for the first time that exercise-induced reductions in postprandial insulin-to-glucose ratio and triglycerides are attenuated by the subsequent exposure to prolonged sitting, but enhanced by subsequent active breaks in sitting. Such reductions indicate improved insulin efficiency and clearance of lipids in response to a meal by combining exercise with breaks in sitting. These insights from comparing ecologically valid strategies to mitigate the risks of prolonged sitting, may help to inform future recommendations, with implications for the prevention of CVD and T2D.

COMBINED EFFECTS OF PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR ON FUNCTIONAL FITNESS IN MIDDLE-AGED AND OLDER COMMUNITY-DWELLERS : A PRELIMINARY STUDY

WU, H.J., CHEN, L.H.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Physical activity (PA) is beneficial for health. However, it was estimated that 27.5% of the population worldwide are considered physically inactive (1). The double burdens of the prevalent physical inactivity together with the increase of sedentary behavior (SB) may lead to worsen health condition with age, especially for older adults. Research showed that either some increase in PA or decrease in SB could be valuable to health for sedentary older population. The effects of different PA levels taking into account of SB on functional fitness for older adults is yet to be defined in Taiwan.
METHODS: This was a cross-sectional study design. The sample were recruited from Taipei Lohas EXPO in Sept., 2018. PA levels was determined from a validated 7-question scale by Porteijs, et al. (2017). Ranking from 0 to 6 (sedentary to active), the subjects selected the question which best describe their PA level for the past 6 months, while the sitting time (ST, in hours) was collected by a self-reported question. Two functional fitness test items, the handgrip strength (HGS) (TKKI 5401, Japan) and 30-sec sit to stand test (STS), were implemented in the study. PA levels, combined with SB, were defined into 4 groups: group 1 (G1) : PA level <3 and ST> 6 hours (HRs) per day; group 2 (G2) : PA level < 3 and ST < 6 HRs; Group 3 (G3) : PA level ≥ 3 and ST > 6 HRs; and Group 4 (G4) : PA level ≥ 3 and ST < 6 HRs. One-way ANCOVA (adjusting for age) was used to analyze the data. Statistical significance was set at $\alpha < .05$.
RESULTS: One hundred fifty-six subjects aged between 52 to 90 year-old were recruited (mean age = 67.7 ± 6.9 y/o, male 37.2%). The number of subjects included from G1 to G4 were 31, 54, 19, and 52, respectively. The mean test values for both HGS and STS were 26.5 Kg (SD =9.01) and 19.76 times (SD = 5.50). HGS was significantly different between G2 and G4 (p =.01) with the higher the PA levels, the better the HGS. Though the near significant differences were found between G1 and G2 in HGS (p =.052), and G1 and G4 in STS (p =.054), no other significant differences were found.
CONCLUSION: Results from our study indicated that the higher the PA levels, the higher the HGS. Moreover, though not necessarily statistically significant, the higher the PA levels, the better in STS performance. Our study showed that in accounting for both PA and SB, SB seemed not play as an important role as PA in functional fitness performance. The British cohort study was in concordant with our findings (3), however, it is critical to replace SB to more active lifestyle, such as light, or moderate-to-vigorous PA to enhancing health and preventing physical dysfunction for the ageing population in Taiwan. Future studies may consider to include more subjects, use of different cut-off point for SB, and analyze gender difference when PA and SB are simultaneously studied.

PHYSICAL ACTIVITY, HEALTH PERCEPTION, BARRIERS TO EXERCISE IN ADULT NON-ATHLETES AND ATHLETES – INFLUENCE OF SPORT DURING YOUTH

LEYK, D.1,2, HARTMANN, N.2, NESTLER, K.3, RÜTHER, T.1, SIEVERT, A.2, ROHDE, U.2, WITZKI, A.2

(1) GERMAN SPORT UNIVERSITY COLOGNE; (2) BUNDESWEHR INSTITUTE FOR PREVENTIVE MEDICINE; (3) BUNDESWEHR CENTRAL HOSPITAL KOBLENZ

INTRODUCTION: The vast majority of the German population has established sedentary lifestyles: Almost permanent sitting periods during work, traffic and leisure time [1-2]. Regular physical activity in youth is supposedly an important preventive factor against adopting adverse lifestyle habits later in life [3-5]. Our aim was to identify differences between persons with physically active and inactive youth and to determine their present sport activity status, life style and health parameters as well as perceived barriers to exercise.
METHODS: The nationwide "ACTivate Inactive Individuals" survey (www.dshs-koeln.de/acti-iv) served as data source for individual sport activities, sport history, motivation/barriers for sport, daily habits (nutrition, sitting times etc.) and anthropometric data (e.g. BMI). Two groups, "active youth" (+Bio; n=447, age 50±8 years, 60.2% women) vs. "inactive youth" (-Bio; n=448, age 50±8 years, 60.7% women) from the age range 35-65 yrs. were matched by age and gender. Groups were then split by actual exercise status into "non-athletes" (no/rarely sport) and "athletes" (≥ 1x training session a week). Data are reported as means, standard deviations, and percentages. Statistics were performed using ANOVA, T-Test and Chi-Quadrat-Test.
RESULTS: Training frequencies were virtually identical in the +Bio ("active youth") and -Bio ("inactive youth") groups (3.1±1.5 vs. 3.0±1.5/wk, p=0.502, T=0.671), and no significant differences in BMI were found (p=0.250, F=1.327). Some 50% of the non-athletes reported engage-

ment in regular exercise during youth (= +Bio). Compared to athletes, significantly more non-athletes felt less healthy (18.3% vs 31.1%, p<0.001, Chi²=18.077), less comfortable with body weight (48.5% vs 60.9%, p=0.001, Chi²=11.810) and physical performance (19.6% vs 40.9%, p<0.001, Chi²=44.403). Almost 60% of non-athletes quoted none or a maximum of one barrier for not exercising (p<0.001, Chi²=66.943). "Lack of time" (35.5%) and "sports are no fun" (18.9%) were the most frequent reasons in non-athletes.
CONCLUSION: In contrast to common assumptions, this study shows only limited evidence for persisting influences of a positive sport biography during youth. Physical activity, weight status, perceived health, and fitness were similar in the +Bio and –Bio group. Moreover, a significant number of non-athletes reported regular training during youth. As expected, pronounced differences were confirmed between athletes and non-athletes. The present results underline (i) the importance of life-long exercise and (ii) to strengthen the culture of health and fitness by tailored health and fitness campaigns.

THE EFFECT OF ONE YEAR OF AEROBIC EXERCISE ON LIPIDS AND LIPOPROTEINS IN OLDER ADULTS

BERGLUND, I.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Dyslipidemia is one of the major risk factors for CVD [1], and is the leading cause of death in older adults [2]. One potential approach for obtaining and/or maintaining optimal lipid and lipoprotein levels in older adults is aerobic exercise, which has been shown to induce a favorable effect on HDL in middle-aged adults [3]. However, a longer time frame is suggested to be necessary to see a change in older adults [4]. The purpose of this study is to see how long-term exercise affect lipid and lipoproteins in older adults.
METHODS: Blood samples were obtained from an arm vein at baseline and after 1 year of exercise, in older adults (70-77 years). Serum triglycerides (TG), high-density lipoprotein (HDL), total cholesterol (TC) were measured immediately using standard procedures at St Olavs Hospital, Trondheim, Norway. Low-density lipoprotein (LDL) was calculated using the Friedewald formula. Participants were randomized to either five years of two weekly sessions of high intensity training (HIT) (10 min warm-up followed by 4x4 min intervals at ~90% of peak heart rate) or, moderate-intensity training (MOD) (50 min of continuous work at ~70% of peak heart rate) or to a control group (CON) that followed the national recommendations for physical activity. Of the total sample (n = 1567), participants who followed the exercise program after one year, and had valid blood samples at both pre- and post-intervention, were included (n = 682).
RESULTS: HDL increased by 3.4 % after HIT (P = 0.002), and was significantly different from CON (P=0.042) after the intervention. TC, LDL and TG were significantly reduced in all groups after the intervention, but the change in TG was significantly higher in HIT and MOD (7.7% (p=0.031) and 7.9 % (p = 0.011) respectively).
CONCLUSION: All groups induced a favorable change in TC, LDL and TG, however the change in TG was higher for HIT and MOD compared to CON. Only HIT induced a favorable change in HDL after one year of exercise. Thus, HIT induce a more favorable change in lipid profile compared to MOD and CON after one year of intervention.

EFFECT OF COMBINED EXERCISE AND DIETARY INTERVENTION ON SELF-CONTROL IN OBESE ADOLESCENTS

XIANG, M.Q., HU, M.

GUANGZHOU SPORT UNIVERSITY

INTRODUCTION: For obese individuals, maintenance of long-term body weight loss is likely to require strong self-control, to sustain positive health behavior patterns. The results of previous research studies have supported the idea that exercise alone can help with cognitive self-control abilities in obese individuals (Liu et al., 2018). However, little evidence has been provided that a combined exercise and dietary intervention can achieve similar results, even though this represents the mainstay of obesity treatment. Furthermore, the focus of previous studies has been on the effect of physical exercise on cognitive self-control, with little attention paid to other aspects of self-control such as physical self-control. The aim of this study was to evaluate the effects of combined exercise and dietary intervention on cognitive and physical self-control, as well as BMI, in obese adolescents. An additional study aim was to assess whether pre-to-post intervention changes in self-control were mediated by changes in BMI and maximal grip strength (MGS).
METHODS: Forty-four obese adolescents were randomly assigned to a 6-week combined exercise and dietary program or a control group, and data from 36 participants (n=18 for each group) were analyzed. The combined exercise and dietary program was performed over 6 weeks, supervised by qualified trainers in a closed boot camp. The primary outcomes of this study were cognitive self-control and physical self-control, assessed by the Stroop task and a handgrip task, respectively. Secondary outcomes included BMI and MGS.
RESULTS: The combined exercise and dietary intervention improved both cognitive and physical self-control. Similar beneficial effects were also found for reduced BMI and enhanced MGS. The pre-to-post intervention changes in BMI and MGS significantly mediated improved physical self-control but not cognitive self-control.
CONCLUSION: In obese adolescents, a combined exercise and dietary intervention is an effective approach to improving multiple aspects of self-control while reducing BMI and enhancing MGS. These findings also suggest that reduced BMI and enhanced MGS mediate specific aspects of self-control.

HIGH-VELOCITY LEG STRENGTH BUT NOT HANDGRIP STRENGTH IS ASSOCIATED WITH FUNCTIONAL CAPACITY IN OLDER ADULTS

VETROVSKY, T., OMCIRK, D., MALECEK, J., STASTNY, P., STEFFL, M., TUFANO, J.J.
FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY, PRAGUE

INTRODUCTION: To evaluate functional status of older adults, the assessment of handgrip strength is widely used in research and practice, mainly due to its affordability and simplicity. Leg strength is an important predictor of functional capacity [1] and recent studies have indicated its superiority over handgrip strength in assessing functional performance and health characteristics among older adults [2, 3]. Thus, the aim of our study was to compare associations of leg strength and handgrip strength with functional capacity assessed by the 6-minute walk test (6MWT) in adults over 60 years of age.
METHODS: Twenty nine older adults (age 68.6±6.3, BMI 26.1±3.6, 22 females) performed the 6MWT as well as a handgrip strength test and nine different tests of leg strength on a dynamometer. The leg strength tests included concentric and eccentric strength of the quadriceps and hamstrings at low (60 degrees/sec) and high (180 degrees/sec) angular velocities and isometric strength. Associations between the strength tests and the distance walked during the 6MWT were analyzed using Pearson correlation coefficients having its p-values adjusted for multiple comparisons by a Holms method and using linear models with age, sex, and BMI as covariates.
RESULTS: Most tests of leg strength correlated significantly with the distance walked during the 6MWT with the test of concentric quadriceps strength at high velocity showing the strongest correlation ($r = 0.69$, $p < 0.001$). The correlation between handgrip strength and 6MWT was not significant ($r = 0.42$, $p = 0.054$). In the linear model, the test of concentric quadriceps strength at high velocity together with BMI explained 66% of variability in the distance walked during the 6MWT. Adding either age, sex, or handgrip strength did not improve the model ($p = 0.621$).
CONCLUSION: Although handgrip strength is frequently assessed due to its simplicity and previously established relationships with other physical and functional parameters, isometric and isokinetic leg strength seems to be a better indicator of functional capacity in older adults, especially when testing using higher velocities. Future intervention studies should explore whether leg strength reflects the improvements in functional capacity of older adults better than handgrip strength.

CONTROLLED AND IN-SITU EVALUATION OF INDUSTRIAL EXOSKELETONS: PRELIMINARY RESULTS.

DE BOCK, S., GHILLEBERT, J., ELPRAMA, S.A., JACOBS, A., MEEUSEN, R., DE PAUW, K.
VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Despite the revolution towards industry 4.0, workers are still exposed to factors that increase their risk of injury and, more specifically, musculoskeletal disorders. Exoskeletons aim to support the worker and reduce musculoskeletal stress. While multiple industrial exoskeletons reached the market and multiple exoskeletons have been tested in laboratory conditions, no in-situ comparison between exoskeletons has yet been published. In this study we aimed to evaluate two industrial exoskeletons, the Laevo and the BackX exoskeletons, supporting the lower back and hip in both a controlled and in-situ environment.
METHODS: Twelve industrial workers completed a test in which the physical work was evaluated without exoskeleton. Subsequently, the test was repeated with two different exoskeleton devices. Each test consisted of two parts; part 1 in which isolated movements (e.g. squat) were performed, and part 2 in which the normal working routine was executed. During each trial heart rate was recorded, as well as electro-myographic (EMG) data of the right lumbar erector spinae, quadriceps vastus medialis, biceps femoris and trapezius pars descendens muscle. Session rate of perceived exertion (sRPE) scores were gathered after each set of isolated movements and after the in-situ testing. Furthermore, questionnaires regarding the devices usability, workload and heat were gathered. The non-parametric Friedman test was used to compare between different testing trials.
RESULTS: Seven subjects who work in an industrial environment (Age: 34.8 years (SD 5.1), 82.4 kg (SD = 14.2)) particpated in this study. Heart rates during isolated movements did not change when using an exoskeleton and no differences were found between both types of exoskeleton ($p > 0.417$). No differences in erector spinae muscle activity were found between all three testing trials ($p > 0.882$). Session rate of perceived exertion data revealed a trend to a reduced perceived exertion during squatting with one exoskeleton in comparison to other the testing conditions ($p = 0.073$). During movements in which the hip joint was more stationary, e. g. overhead lifting, sRPE scores were higher during the exoskeleton trials compared to the non exoskeleton testing condition ($p = 0.007$).
CONCLUSION: Exoskeletons reduce the perceived exertion while performing the specific movements it was designed for, i. e. movements which involve hip flexion. A higher effort was perceived while wearing the exoskeletons during overhead working. Muscle activity and heart rate were not influenced by the industrial exoskeletons.
These preliminary results only suggest improvements in perceived exertion during moves in which hip flexion is involved. The reverse effect has been shown when performing a overhead lifting task. When the data of the remaining subjects is processed, and more powerful statistical analysis can be performed, we expect to provide a more refined exoskeleton evaluation.

THE MECHANICAL ROWER: CONSTRUCTION, VALIDITY, AND RELIABILITY OF A MEASURING STATION FOR WIND BRAKED ROWING ERGOMETERS

MENTZ, L., TREFF, G., STEINACKER, J.M., SCHULZ, G., ENGLEDER, T.

UNIVERSITY HOSPITAL OF ULM

INTRODUCTION: Even though wind braked rowing ergometers like the C2-ergometer (Concept 2, Morrisville, USA) are used worldwide for training and testing of rowers, only very limited data is available on the validity and reliability of the ergometers' calculation of power output. All studies dealing with this issue used human rowers, thereby adding biological variability without the option to clamp certain variables like stroke structure or catch to recovery ratio precisely. To this end, we aimed to develop a measuring station for rowing ergometers.
METHODS: The station consists of a 4.4 kw servo motor (1FT7065-7SF70-1CG0, Siemens, Munich, Germany). The rowing ergometer is fixed within the test bench and its handlebar is mounted to a sledge moving on a linear drive (Festo, Esslingen am Neckar, Germany). Pneumatic springs on the sledge simulate the elasticity of human bone and tissue. To allow for calculation of work per time, a force transducer is mounted between handle bar and chain (U9C, 2 kN, HBM, Darmstadt, Germany), an incremental magnetic measurement system allows to measure stroke distance (Limes LI20/B1, Kübler, Villingen-Schwenningen, Germany). At the software end the station is operated using Simatic Step 7 TIA Portal v13 (Siemens, Munich, Germany). To produce rowing specific force-distance curves, the motor is controlled by torque-curves, based on the nearly perfect correlation between motor torque and –power, while an envelope curve limits the velocity of the sledge. Since torque and speed curves were generated on data of elite rowers, this set-up produces rowing strokes that are very similar to human rowing strokes, while reflecting their biomechanical limitations. All strokes can be repeated ad libitum.
RESULTS: To test for reproducibility, 50 consecutive strokes where performed 10 times with a 10-minute break between series. Mean power output was 444 ± 1 W with a Coefficient of Variation (CV) of 0.23% between series. Stroke-by-stroke variability was 0.92% for all test series
CONCLUSION: We conclude, that the measuring station allows to test wind-braked rowing ergometers with high validity and reliability.

PRECISE AUTOMATED PASSING IN AMERICAN FOOTBALL

HOLLAUS, B., RASCHNER, C., MEHRLE, A.

MCI INNSBRUCK AND UNIVERSITY OF INNSBRUCK

INTRODUCTION: Passing and pitching machines are widely used during training in ball related sports like baseball, tennis and American football. The intention is to have highly reliable, accurate and precise passes or pitches to train an athlete. In American football state of the art passing machines do not fulfill the high expectations of coaches concerning their precision. We hypothesized; A well designed passing machine with state of the art technology and an adequate pass prediction model can excel expectations of a precision of ±1% of the throwing distance for 90% of all relevant passes.
METHODS: There are many aerodynamic models, which describe the trajectory of an American football (Rae, 2003). Most of them rely on initial conditions like release angle and velocity. For this experiment a prediction model for the initial conditions was found with respect to the specifically designed passing machine (Hollaus et al., 2018). Together with a simple trajectory model 15 different passes and their target have been predicted (target height was considered as 1m in the distance of approx. 7, 10, 13, 16 and 19m with release angles of 11, 18 and 25°). For all passes a measurement environment was set up with the self-made passing machine and a target board, which is hit by the pass. With a marker, the location of the tip of the ball could be observed, when it hits the target board. Every pass has been released 15 times for the corresponding settings (225 passes in total).
The experiment was done indoors under constant conditions (NCAA Wilson GST 1003 Game Ball with 0.9bar, every pass was done with the same ball, the surface of the ball has been visually checked for damages, changes or a like before every pass). For the analysis the gained data will be normalized with the mean throwing distance of each setting to get comparable results.
RESULTS: The statistical analysis showed that the precision for all settings of the experiment was better than ±1% of the throwing distance for 90% of all relevant passes (209 of 225 passes or approximately 92.9% of all passes were within the limits). The distribution of the samples cannot be considered as normal distribution (a Shapiro-Wilk test with P=0.05 was used). Therefor the distribution can be described with a mean of 1, a standard deviation of 0.57% and a skewness of 0.5.
CONCLUSION: With state of the art technology and adequate design, it is possible to pass an American football in a precise manner. This opens up the possibility of automated training of receiving players, which will probably lead to better performing athletes.
With a precise passing machine an automated test routine can be developed to test receiving players for their weaknesses and strength. This will be an importand input for coaches in decision processes, who is playing in which position in a specific play. Another benefit would be the comparability of receiving players, which is not possible in that detail nowadays.

EFFECTS OF CYCLING SHORTS PADDING ON PERCEIVED DISCOMFORT AND SADDLE PRESSURE DISTRIBUTION AMONG FEMALE CYCLISTS IN LABORATORY CONDITIONS

LARSEN, A.S., HANSEN, E.A., MADELEINE, P.

AALBORG UNIVERSITY

INTRODUCTION: Female cyclists often report genital discomfort and non-traumatic injuries (1) that can be reduced using an ergonomics approach (2). However, no studies have investigated the effects of using ergonomically designed cycling shorts pad among female cyclists. Our objective was to assess the differences in perceived discomfort and saddle pressure distribution as a function of cycling shorts pad design in females during ergometer cycling.
METHODS: Two pad types were designed and produced; a traditional pad with padding at the ischial tuberosities and crotch area (full-pad) and a novel pad with padding exclusively at the ischial tuberosities (half-pad). Fourteen female club cyclists
were bike-fitted to ensure a uniform riding position. The cyclists pedaled on a cycle ergometer for one hour at a constant power output of 130 W and a target cadence of 80 (80±3 rpm) with two pad designs in blinded counterbalanced order over two separate sessions separated by at least 48 hours. Rate of perceived discomfort (RPD) over the ischial tuberosities and crotch area were determined using a visual analogue scale. The displacement of the center of pressure (COP) was measured in anterior-posterior and medial-lateral direction using a pressure mat. Standard deviation and sample entropy of the COP displacement were computed.

RESULTS: Pad design had no effect on RPD at ischial tuberosities or crotch area as well as on the standard deviation and sample entropy of the COP displacement. Time had an increasing effect on RPD and on the standard deviation of the COP displacement in the anterior-posterior direction. Session had an increasing effect on RPD at the ischial tuberosities.
CONCLUSION: The novel ergonomically designed cycling shorts half-pad did not result in changes in RPD and COP displacement as compared to the full-pad, among female cyclists. The effect of session suggests discomfort summation over the ischial tuberosities suggesting the crotch area to be less prone to discomfort adaption. Future tests in more ecologically conditions, e.g. during road cycling and for longer duration, are needed for a more comprehensive understanding of the topic.

COMPARISON OF PUSH-IN HARDNESS METERS: HAND-HELD TYPE AND ULTRASONOGRAPHIC DEVICES

MURAYAMA, M.1, NISHIYAMA, D.2, UCHIYAMA, T.2, INAMI, T.1, YONEDA, T.3

1 KEIO UNIVERSITY, 2 KEIO UNIVERSITY, 3 JUNTENDO UNIVERSITY

INTRODUCTION: The evaluation of the hardness of tissue is helpful in the understanding of physiological changes in the body. In particular, muscle hardness conveys important information in sports science because it could be caused by changes in muscle tension and/or volume due to intense exercise. There are many commercial muscle hardness meters, and the hand-held type that uses indentation is most commonly used. However, these devices also measure the hardness of the skin and subcutaneous tissue through the process of indentation. Recently, an ultrasonographic device consisting of a force sensor built onto a probe was developed for evaluating tissue hardness. This device can estimate muscle hardness via skin indentation, which is done by the ultrasonographic probe. The purpose of this study was to compare the measurements taken with a hardness meter using ultrasonography probe indentation with those taken with hand-held-type tissue hardness meters.
METHODS: A hardness meter using ultrasonography probe indentation, Views i (VI) (Sakai Iryo, Japan), was used as the basis for comparison. The following hand-held-type tissue hardness meters were also used: Softgram (SG) (Shinko-denshi, Japan; new device), PEK-1 (PK) (Imoto machinery, Japan), and M123KNT-5 (MK) (Shiro sangyo, Japan). Eighteen healthy subjects (9 male and 9 female) volunteered to participate in this study (mean age: 21.2 ± 2.5 yr, mean height: 164.7 ± 9.3 cm, mean weight: 58.3 ± 9.7 kg). The tissue hardness of the upper arm (belly of the biceps brachii (BB)) and thigh (belly of the rectus femoris (RF)) were measured by VI, SG, PK, and MK. In VI, the hardness of the subcutaneous tissues, BB and RF, were also measured.
RESULTS: The hardness of subcutaneous tissue evaluated by VI showed a significant difference between the sex (male: 3.2 ± 2.5 kPa/mm, female: 2.0 ± 1.1 kPa/mm). The muscle hardness evaluated by VI showed a significant difference between the BB (25.2 ± 6.8 kPa) and RF (45.8 ± 11.5 kPa). The hardness evaluated by SG showed significant differences between sex (male: 21.9 ± 5.5 kPa, female: 17.3 ± 4.2 kPa) and the limbs (upper arm: 15.9 ± 2.4 kPa, thigh: 21.6 ± 6.0 kPa). The hardness evaluated by MK showed a significant difference between the upper arm (17.9 ± 3.4 kPa) and thigh (13.5 ± 2.1 kPa). There were no significant correlations between the hardness evaluated by subcutaneous tissue evaluated by VI and that evaluated by SG, PK and MK. However, the hardness evaluated by SG showed a significant correlation with muscle hardness evaluated by VI in a case of the BB and RF combined ($r = 0.663$, $p < 0.01$).
CONCLUSION: The results showed that there were no significant correlations between the hardness evaluations using VI and those using hand-held type tissue hardness meters; however, there was a significant correlation between the muscle hardness as evaluated by VI and that evaluated by SG. SG, which is a new hand-held-type tissue hardness meter, might be able to measure the muscle hardness.

MICROCURRENT DEVICE IMPROVES LACTATE REMOVAL, PRESERVES LEAN MASS, AND ATTENUATES MUSCULAR SORENESS IN ENDURANCE ATHLETES: A PILOT STUDY

SEIJO, M., LARUMBE-ZABALA, E., MORENO-PEREZ, D., LARROSA-PEREZ, M., GARCÍA-MERINO, J.A., CENTENO, A., NACLERIO, F.

UNIVERSITY OF GREENWICH

INTRODUCTION: Combining Microcurrent with regular exercise configures an attractive strategy to optimise training outcomes. The aim of the present investigation was to analyse the effects of regularly wearing a new commercially available microcurrent device (Arc4health, UK) in well-trained endurance athletes. Measured variables were changes in body composition, performance, post-exercise lactate concentration and delayed onset muscle soreness (DOMS).
METHODS: According to individual baseline body composition and peak oxygen consumption values, 16 participants (33.2±8.5 yr) were pair-matched and subsequently randomly assigned to one of the following experimental groups: microcurrent (MC, n=8) or sham (SH, n=8). Both groups trained 6 to 7 days per week over a period of 8 weeks, with a polarized training intensity distribution. Either a microcurrent or a sham device was used for 3-h immediately after every workout or at night on non-training days. Assessment of body composition (body mass, whole body fat mass, whole body lean mass, total trunk fat mass, estimated visceral fat mass, and fat and lean mass for upper and lower limbs) via DEXA, and a progressive-to-volitional exhaustion running test to determine peak oxygen consumption (VO2peak), first (VT1) and second (VT2) ventilatory thresholds, along with the post lactate concentration over 5 min post-test were conducted at pre and post-intervention. DOMS was measured via VAS scale at pre, 24-h, 48-h and 72-h after performing an exhaustive 100-repetitions exercise-induced muscle soreness protocol (10x10 reps semi-squat) (EIMS).
RESULTS: Fourteen participants completed the study (MC, n=6, SH, n=8). Only SH significantly increased body mass ($p=0.025$) and decreased whole-body lean mass ($p=0.014$). Both groups similarly increased ($p<0.05$) the speed at VT1 with no significant changes in VT2 and VO2peak. Compared to SH, MC significantly ($p=0.05$) lowered the lactate concentration measured 3 min after exercise and reduced the perception of DOMS at both 24-h ($p=0.042$) and 48-h ($p=0.009$) after the completion of the EIMS.
CONCLUSION: Wearing an Arc4health device during 3-h post workout or at night during the non-training days may help to preserve lean mass, accelerate lactate removal and reduce DOMS in cross country male athletes following 8 weeks of periodized endurance training. Even though no differences were observed in performance outcomes, the present pilot study highlights the potential benefits of microcurrent technology to preserve optimal body composition and improve recovery in well-trained endurance athletes.

THE DEVELOPMENT OF AN ATHLETE SPECIFIC CHRONOTYPE INDEX

RYAN, R., SIEGLER, J., TAYLOR, C., LOVELL, R.

WESTERN SYDNEY UNIVERSITY

INTRODUCTION: Athletic performance is impacted by diurnal variation, yet there is discord regarding the relationship between performance outcomes and athlete chronotype (CT; e.g. morning type [MT] intermediate type [IT], evening type [ET]1). The disparity may be due to common application of the current gold standard, the Morningness Eveningness Questionnaire [MEQ2] for CT classification, which has limited validity for team-sport athletes1. Therefore, the aim of this study was to a) develop an athlete-specific CT index (ACTi) and b) validate ACTi against criterion measures of diurnal variation used to categorise CT (e.g. dim light melatonin onset [DLMO] and core body temperature [CBT]).
METHODS: a) 297 athletes completed a CT questionnaire, including MEQ (19) and newly-developed ACTi questions (15). Principle component analysis (PCA) was used to identify common themes and reduce the final number of questions.
b) Responders' CT was categorised by MEQ; 30 (10 per CT) participated in a 24-hour laboratory study. Participants abided by their typical sleep/wake cycle, provided hourly saliva samples (for DLMO analysis) whilst awake and hourly CBT readings (ingestible thermistor) for the 24-hours. Stepwise multiple linear regression analysis to predict DLMO onset and CBT was used to further refine the ACTi. Independent samples T-tests and magnitude-based inferences were used to assess between CT differences.
RESULTS: a) PCA of the extended ACTi responses were performed, identifying 7 themes. Multiple regression identified 11 questions that predicted DLMO (R2=0.81), forming the final ACTi.
b) DLMO CT differences between MEQ MT vs IT were small (64±61.6min, P=0.02), MT vs ET were large (114±71.2min, P=0.002) and unclear for IT vs ET (P=0.06). ACTi increased effect magnitudes for differences between MT vs IT DLMO (large [113±51.6min], P=0.0001) and MT vs ET (large [134±53.7min], P=0.001). No CT differences were observed in CBT for MEQ or ACTi. Cohen's Kappa revealed moderate CT classification changes between MEQ and ACTi (0.62).
CONCLUSION: The ACTi is an 11-point index that enhances CT determination of athletes versus MEQ, based on the criterion measure DLMO. The ACTi may be used in team-sports to examine the impact of CT upon performance, monitoring of training responsiveness and athlete wellbeing.

ASSESSMENT OF MUSCLE SWELLING AFTER EXERCISE USING BIOELECTRICAL IMPEDANCE ANALYSIS

IWATA, A., ARIMITSU, T., GOTO, K.

RITSUMEIKAN UNIV.

INTRODUCTION: Intensive exercise causes muscle damage and inflammation, leading to augmented muscle swelling. Exercise-induced muscle swelling is known to reflect inflammatory response during recovery process in damaged muscle. The level of muscle swelling is generally evaluated indirectly using several procedures, including ultrasound, magnetic resonance imaging (MRI) and circumference. However, these procedures include some limitations, such as higher cost for preparing the equipment, taking much time for analysis and lower reliability. Therefore, development of "easy" and "reliable" procedure for evaluation of muscle swelling is currently required. Moreover, change in muscle swelling during post-exercise may reflect the recovery of muscle function after the exercise. The aim of this study was to determine the effects of acute damaging exercise on bio-impedance (BI) in working muscles during 72 h of post-exercise.
METHODS: Six untrained males (22.2 ± 0.9 years, 170.7 ± 4.2 cm, 61.2 ± 7.0 kg) performed two conditions (EX, REST) in a random order. In the EX, the subjects performed 100 bouts (10 × 10sets) of drop jump from 60 cm box to induce exercise-induced muscle damage for quadriceps femoris muscle. Before and during 72 h of post-exercise, changes in local BI for vastus lateralis muscle, scores of subjective feeling (e.g. muscle soreness, fatigue and swelling), T2 relaxion time (evaluated by MRI), muscle thickness (evaluated by ultrasound), circumference and maximal voluntary contraction (MVC) were evaluated. Blood samples were also drawn to investigate blood glucose and lactate, serum creatine kinase (CK), myoglobin, high-sensitive C-reactive protein (hsCRP), hematocrit and hemoglobin levels (for calculation of the plasma volume shift).
RESULTS: In EX, BI was significantly lower immediately after exercise compared with that in REST ($p=0.003$). The MVC significantly decreased after exercise in EX ($p<0.0001$). The plasma volume significantly decreased after exercise in EX, with significant difference from REST ($p=0.018$). Moreover, in EX, scores of muscle soreness ($p=0.005$), muscle fatigue ($p=0.007$) and muscle swelling ($p=0.005$) showed significantly higher values after exercise compared with those in REST.
CONCLUSION: Local BI decreased acutely after exercise, with concomitant reductions of MVC and plasma volume. Therefore, these findings suggest that exercise-induced BI reduction reflects muscle swelling due to increased water volume in the muscles.

POSTURAL STABILITY AND REGULATION BEFORE AND AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION – A TWO YEARS LONGITUDINAL STUDY

HERMASSI, S., BARTELS, T., BREHME, K., PYSCHIK, M., POLLAK, R., SCHAFFRATH, N., FIESELER, G., DELANK, K.S., LAUDNER, K., SCHWESIG, R.

QATAR UNIVERSITY

INTRODUCTION: The longitudinal development of postural stability and regulation in patients with anterior cruciate ligament (ACL) damage has not been previously described (1). The aim of this study was to evaluate the postural regulation and stability of a group of patients who underwent ACL reconstruction (ACLR) throughout a two years follow-up period.
METHODS: Initial, 77 patients with ACL were included in the study. 30 physically active subjects (age: 32.0 ± 12.2 years, 14 males) were examined at six time points using the Interactive Balance System (IBS): before ACLR, six weeks, twelve weeks, six months, one year and two years after ACLR using a hamstring tendon graft and standardized rehabilitation program. The average period of time from injury to

surgery was 48 days. Data were calculated with unifactorial and univariate analysis of variance and pair matched with asymptomatic reference data.
RESULTS: Significant time effects (pre- vs. two-years postoperative) were found for WDI (•2=0.466), synchronization (•2=0.368), mediolateral weight distribution (•2=0.349), ST (•2=0.205), visual/nigrostriatal systems (•2=0.179) and peripheral-vestibular system (•2=0.102). The largest difference (preoperative: •2=0.180) to the matched sample was calculated for WDI. The most significant differences to the matched sample were observed for ST (preoperative: •2=0.126; six-weeks postoperative: •2=0.103) and WDI (preoperative: •2=0.180; six-weeks postoperative: •2=0.174).
CONCLUSION: ACLR and rehabilitation influence postural subsystems, postural stability, weight distribution and foot synchronization. The normalization of the mediolateral weight distribution needs one year. The ACLR leads to a suppression of the somatosensory and cerebellar system which was compensated by a higher activity of the visual and nigrostriatal systems. This investigation provides further insights into underlying mechanisms of postural regulation and in the understanding of the interaction of postural subsystems. In line with Bartels et al. (2018), the widespread isolated orthopedic view (flexibility, strength, pain) should be replaced by a more holistic approach.

RECOVERY EFFECT ON ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE BY CONTRAST WATER THERAPY

LEE, J.H., TSENG, W.C., LAI, C.C., LIN, H.M., CHANG, J.N.
UNIVERSITY OF TAIPEI

INTRODUCTION: Exercise-induced muscle damage (EIMD) frequently occurs after high intensity repeated eccentric contraction. It also induces mechanical damage to muscle fibers resulting in inflammation response and even causes delayed-onset muscle soreness (DOMS). The previous meta-analysis reported that contrast water therapy (CWT) was beneficial to alleviate muscle fatigue but not to neuromuscular recovery (Higgins et al., 2016). Therefore, this study examined whether enhancing the duration and intensity of hot water immersion would have positive effect on neuromuscular recovery compared to passive recovery control group (CON).
METHODS: Sixteen health college men were recruited for this study, and they were randomly assigned to contrast water therapy (CWT) or passive recovery (CON). Each subject performed 100 times of maximal eccentric contractions (MAX) of the bilateral knee extensors. The MAX was followed by either contrast water therapy (cold water 8°C × 1 minute and hot water 45°C × 4 minutes, 3 rep total 15min), or passive recovery at 30min, 24.5, 48.5, and 72.5 hours post-MAX. Muscle soreness (SOR), knee joint range of motion (ROM), maximal voluntary isometric contraction (MVIC), and countermovement jump (CMJ) were measured before, immediately and 1-4 days after MAX.
RESULTS: Both groups showed significant decreases in ROM, MVIC, and CMJ height from immediately to 3 days post-MAX ($P < .05$), and increases in SOR from 1-3 days after MAX ($P < .05$). However, there was no significant difference between CWT and CON group in any change of variables during the 4-day recovery period ($P > .05$).
CONCLUSION: The results showed that recovery of indirect muscle damage markers after eccentric exercise was not modified by increasing the duration and intensity of hot water immersion in CWT group. As a result, repeat contrast water therapies in 73 hours have no positive effect on the neuromuscular recovery from muscle damage.

A NOVEL BEHAVIOURAL INTERVENTION TO REDUCE SEDENTARY TIME IN OLDER ADULTS UNDERGOING ELECTIVE HIP OR KNEE SURGERY (INTEREST): A RANDOMISED CONTROLLED FEASIBILITY STUDY

AUNGER, J.A., GREAVES, C.J., DAVIS, E.T., GREIG, C.A.
UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Osteoarthritis is a highly prevalent condition in older adults which often necessitates joint replacement surgery in order to reduce pain and improve quality of life. Individuals waiting for hip or knee replacements are often highly sedentary, thus, we aimed to assess whether reducing their sedentariness prior to surgery may improve post-operative outcomes.
METHODS: The study was a randomised controlled feasibility trial design, with 2:1 randomisation into an intervention and usual care group respectively. We aimed to recruit a target of 45 participants aged 60 years or older from Russells Hall Hospital, Dudley, UK, approximately 10 weeks before surgery. The intervention, informed by Self-Determination Theory (SDT), was composed of multiple Behaviour Change Techniques (BCTs), namely, motivational interviewing, feedback on objectively-measured sedentary behaviour and activity, goal-setting, environmental modification, self-monitoring, and social support. The intervention was delivered in a single visit and three follow-up phone calls. Assessments occurred at baseline, 1-week pre-surgery, and 6 weeks post-surgery. The primary outcome was the feasibility of intervention and study delivery, assessed quantitatively based on rates of recruitment and retention, measures-completion, and intervention fidelity assessment, and with mixed-methods assessment of satisfaction, practicality, acceptability, safety and adaption for the participant. Exploratory outcomes included physical function, cardiometabolic biomarkers, measurement of SDT constructs, and both objective and subjective measurement of daily activity and sedentariness.
RESULTS: The study is now closed to recruitment with follow-up visits underway. Of 246 participants approached about the study, 14.5% enrolled (n=15 men and 20 women). The recruitment rate was 2.9 participants per month. The mean age was 73.1±5.8 years, and 65.7% of participants had 3 or more medical conditions. At baseline the mean Short Physical Performance Battery score was 6.9±2.8 (range 2-12), where 12 is the maximum, indicating high variability in physical function. The mean body mass index was 30.7±42, showing a high prevalence of overweight in the sample. Mean objectively-assessed sedentary time was 9.84±1.87 hrs/day and mean standing time 4.28±1.65 hrs/day. Mean step counts were 5088±3320 per day. Self-reported daily sitting time was 8.9±2.9 hrs/day.
CONCLUSION: This is the first study to assess both the feasibility of an intervention to reduce sedentary behaviour in older adults with mobility limitations, and whether such a reduction could work in a prehabilitative context prior to surgery. The results of this study will help inform the design of a definitive randomised controlled trial.

TREATMENT EFFECTS OF FUNCTIONAL ELECTRICAL STIMULATION ON PATHOLOGICAL TREMOR

KANG, N., KIM, R.K., KIM, H.J.
INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Pathological tremor indicates rapid and rhythmic movements of a body part, involuntarily shown in individuals with Parkinson's disease, essential tremor, and multiple sclerosis. It is important to minimize the abnormal tremulous movements for therapists and rehabilitation researchers. Although medications and deep brain stimulation were often used for dealing with pathological

tremor, these options are still very expensive and potential high surgery risks. Functional electrical stimulation (FES) may be an effective rehabilitation protocol because this technique is economical, portable, and easily accessible. Thus, the current meta-analysis investigated the treatment effects of FES on pathological tremor.
METHODS: Our computerized literature searches using PubMed and Web of Science identified 10 total studies that performed quantitative estimation of FES on pathological tremor. Tremor quantification was based on calculating changes in amplitude and power of tremor during active movement (i.e., eight studies) and resting position (i.e., two studies). We calculated effect sizes using Hedgesg and reported heterogeneous test results.
RESULTS: A random effects model meta-analysis revealed a significant overall effect sizes: Hedges'g = 0.86 (SE = 0.16; Z = 5.55; P < 0.001; 95% CI = 0.56-1.17). Heterogeneous tests revealed relatively low level of variability across 10 studies (Q = 14.43 and P = 0.11; T-squared = 0.08; I-squared = 37.61%). Publication bias was relatively minimal based on the P-value of Begg and Mazumdar rank correlation (=0.07). Moderator variable analysis on co-contraction versus out-of-phase protocols reported significant effect sizes: co-contraction (Hedges'g = 0.85; P < 0.001) versus out-of-phase (Hedges'g = 0.94; P = 0.02).
CONCLUSION: The current meta-analytic results are the first to report the positive treatment effects of FES on pathological tremor. Despite some methodological limitations in prior studies, FES intervention may be an effective and safe way to minimize pathological tremor in patients.

PREDICTION AND VALIDATION OF AN ACCURATE AND SIMPLIFIED TOOL TO CONFIRM SARCOPENIA AND RISK OF PHYSICAL DISABILITY IN PEOPLE LIVING WITH HIV/AIDS

DOS SANTOS, A.P.S.1, ALVES, T.C.2, SCHWINGEL, A.3, CHODZKO-ZAJKO, W.3, ABDALLA, P.P.1, MARINI, J.A.G.1, MACHADO, D.R.L.1

1: UNIVERSITY OF SAO PAULO, BRAZIL, 2: UNIVERSITY OF MINAS GERAIS STATE, BRAZIL, 3: UNIVERSITY OF ILLINOIS, USA

INTRODUCTION: Sarcopenia (SA) is a progressive and generalized loss of strength and skeletal muscle mass. People living with HIV/AIDS (PLWHA) even in young age present accelerated aging process and high risk of SA. SA is associated with increased risk in development of physical disability, poor quality of life, and mortality. Early detection of initial stages of SA might help PLWHA on the engagement in exercise program, sports, and increase the level of physical activity; preserving strength and skeletal muscle mass. Appendicular skeletal muscle mass measured by Dual energy X-ray absorptiometry (ASMDXA) is adopted for calculating index to confirm SA and risk for disability due to sarcopenia. Currently, there is no anthropometric predictive model for ASMDXA in PLWHA considering sex and lipodystrophy diagnosis. Thus, our study proposes to fill this gap in the literature by developing anthropometric models to estimate and subsequently validate ASMDXA in lipodystrophy and non-lipodystrophy PLWHA considering sex.
METHODS: We included 124 PLWHA (male=74), aged >18 years and under combined antiretroviral therapy. Cutoff points (male=1.24 and female=0.95), available in the literature for lipodystrophy diagnosis using Fat Mass Ratio by DXA were adopted. Pearson or Spearman correlations were conducted for verifying the association between ASMDXA vs. potential predictive variables, such as age, sex (male or female), lipodystrophy diagnosis (yes or no), height, body weight, body mass index, and four body circumferences. For those variables which exhibited significant association with ASMDXA we included for linear regression. The multiple stepwise linear regression-generated models were conducted for PLWHA to predict ASMDXA (dependent variable) and validated by the PRESS method of cross validation. Bland-Altman plots were used to explore distributions of errors and agreement.
RESULTS: Average age of PLWHA was 46.2 ± 9.3 years (range = 19 to 67 years). Results support the use of anthropometry for predicting ASMDXA in male and female PLWHA. A high power of determination with a small degree of error was observed for ASMDXA in five models generated (adjusted r^2 = 0.83 to 0.87, SEE = 1.8 to 1.6 kg). The validation of ASM anthropometric models were confirmed observing high coefficients (r^2PRESS = 0.83 to 0.86) and reliability of reduced errors (SPRESS = 1.8 to 1.6 kg). Our best predictive model for estimating ASMDXA included height, body weight, body circumferences of forearm and medial calf, lipodystrophy diagnosis, and sex.
CONCLUSION: Accurate predictive models using anthropometric measurements were proposed to predict ASMDXA for confirming SA and risk for disability due to sarcopenia in PLWHA. We believe this information will advance the public health field by assisting health professionals in diagnosing early loss of skeletal muscle mass at a low cost, and thus will contribute for increasing of engagement in exercise program of PLWHA.

EFFECTS OF SELF NATURE POSTURE EXERCISE (SNPE) ON FITNESS, FUNCTIONAL MOVEMENT, RANGE OF MOTION, AND PAIN PERCEPTION

LEE, H.1, YOON, J.2, CHOI, J.2, YUN, S.1, LIM, D.1, HWANG, E.1, LEE, D.T.1

1: UNIVERSITY OF KOOKMIN, 2: KOREA GOOD POSTURE LAB, INC.

INTRODUCTION: Self Nature Posture Exercise (SNPE) is a posture recovery exercise originally idealized and designed from the crooked teeth and dental prosthesis. This exercise is claimed to relieve muscle tension, to correct posture by restoring the unbalanced body, to help recovering musculoskeletal function, and to alleviate pain. The purpose of this study is to examine the effect of SNPE on physical fitness, range of motion (ROM), functional movement, and pain perception in adult women with chronic musculoskeletal pain.
METHODS: Thirty women experiencing chronic musculoskeletal pain volunteered in this study (29.3±6.5 yrs, 23.5±4.0 kg/m2), and were divided into 3 groups; non-exercise group (NE), stretching group (SG), and SNPE group (SNPEG). Subjects of SG and SNPEG underwent a 2-3 sessions per week training program for 4 weeks. Before and after the program, their fitness such as flexibility and muscular strength was tested. ROM of neck, shoulder, waist, hip, knee, and ankle, and Functional Movement Screen (FMS) were evaluated. Pain perception was evaluated by Visual Analogue Scale (VAS). NE participated in all tests, but not in any training program. To compare group differences, one-way ANOVA with repeated measures were employed.
RESULTS: After the program, the back extension as flexibility increased significantly in SNPEG (P<0.05), but decreased in NE and SG. Grip and back strength tended to decrease in all three groups but not statistically significant. The lateral rotation of neck increased in SG and SNPEG (P<0.05). The shoulder external rotation increased in all three groups, but only statistically significant in SNPEG (P<0.05). The waist flexion increased in SNPEG (P<0.01), while decrease in SG, and no change in NE. The hip rotation in SNPEG and NE increased significantly (P<0.01). No changes were noticed in the knee and ankle ROM. For the FMS, SNPEG and SG showed significant improvement (P<0.01) while not in NE. VAS in cervical area was not different between pre- and post-training test in all groups, but VAS in scapular area decreased significantly in SNPEG only (P<0.05). VAS in hip area decreased in all groups (P<0.05). VAS in gastrocnemius muscles decreased both in SNPEG and SG (P<0.05).

CONCLUSION: This study demonstrated that the 4 weeks of SNPE training provided beneficial effects on flexibility, ROM, FMS, and VAS. The results suggest the effectiveness of SNPE for those adult women of suffering chronic musculoskeletal pain.

PHYSICAL READINESS AND SELF-RATED ABILITY IN COLLEGIATE ATHLETES WITH LATERAL ANKLE SPRAINS IN CHRONIC STAGE

HUNSAWONG, T.1,2, CHOMJINDA, K.2, PIYACHITPAIRAT, P.2, UDOMPANICH, N.1,2, MATO, L.2

1: BNOJPH , 2: KKU

INTRODUCTION: Premature return to sport after lateral ankle sprains (LAS) strongly related to recurrent injury, residual disability, and thereby resulting in chronic ankle instability in athletes. To ensure whether the athlete following LAS is able to participate in sport and safe to return to play, evaluation of physical readiness using functional tests concomitant with self-rated functional ability using questionnaires should be conducted to support the decision (Richie and Izadi, 2015). At present the evidence of physical readiness and self-rated ability for return-to-play in athletes after LAS is limited. Therefore, the present study compared the functional ability in balance performance, dorsiflexion range of motion, lower limb strength and agility coupled with self-rated questionnaires between collegiate athletes with and without a history of LAS.
METHODS: A cross-sectional study was carried out in this study. Fifty-eight male collegiate athletes (aged 18-30 years) consisting of athletes with the latest LAS have occurred more than 6 months up to 3 years (LAS group, n=29) and asymptomatic athletes with no history of LAS (control group, n=29) participated in this study. All participants are able to participate in sport. The experienced physiotherapist who blinded to participants' group examined the sign of tenderness on palpation for lateral ligaments of the ankle and determined joint laxity. All participants completed questionnaires consisting of the Foot and Ankle Ability Measure (FAAM) and the Cumberland Ankle Instability Tool (CAIT). Then four functional tests including balance performance using the modified star excursion balance test, range of motion using the dorsiflexion weight bearing lunge test, lower limb strength using jump and reach test and agility using agility T-test were evaluated for all participants (Clanton et al., 2012).
RESULTS: All demographic data were similar between groups. Up to 50% of participants in the LAS group showed signs of ankle joint laxity. In the injured limb, the LAS group showed a higher pain scale of tenderness on palpation for anterior talofibular ligament ($p=0.01$) and a lower score of CAIT ($p=0.01$) compared with the control group. However, there was no difference in all four functional tests and the score of FAAM between groups ($p>0.05$).
CONCLUSION: Even though tenderness on palpation for the ligament and feelings of instability remain as the residual sign and symptom in athletes with LAS in the chronic stage, there was no difference in functional ability coupled with self-rated foot and ankle ability measure between groups. This finding indicates that the functional tests and self-rated questionnaires (Clanton et al., 2012; Richie and Izadi, 2015) can be conducted to support the decision for safe to return to play in athletes following LAS.

TWO-DIMENSIONAL KNEE AND HIP KINEMATICS IN ATHLETES WITH AND WITHOUT ADDUCTOR STRAIN

UNUVAR, E.1, AKINOGLU, B.2, KOCAHAN, T.1, GUNEY-DENIZ, H.3

1.MINISTRY OF YOUTH AND SPORTS, 2.ANKARA YILDIRIM BEYAZIT UNIVERSITY, 3.HACETTEPE UNIVERSITY

INTRODUCTION: Primary function of hip adductors is to adduct the thigh in open kinetic chain and stabilization of the lower extremity as well as pelvis in closed kinetic chain positions (1). Adductor strain (AS), refers to an injury in the muscle-tendon unit that produces pain on the muscle group, tendons or its insertion on the pubic bone with palpation or resisted adduction (2). History of previous injury (3), weak hip adductors, increased hip abductor to adductor ratio (Abd/Add) (4) are identified as risk factors for AS. The increased knee valgus angle and decreased hip angle are related to lower extremity injuries and there is no information on how these angles differ in athletes with AS. The purpose of the study was to compare knee valgus and hip angle during single leg squat (SLS), Abd/Add muscle strength ratio and functional hip and groin outcomes in athletes with and without AS.
METHODS: Fourteen athletes (7m, 7f; mean age 15.71±1.44 years) with AS and nine healthy athletes (3m, 6f; mean age 16.33±0.87 years) were included in the study. Two-dimensional (2D) data were captured during SLS with two GoPro Hero5 Black cameras (sampling rate of 60 fps, GoPro, Inc., San Mateo, CA) positioned in frontal and sagittal plane. 2D videos were processed using Kinovea Software (version 0.8.24 Kinovea Open Source Project, www.kinovea.org). Knee valgus and hip angle were calculated using the frontal plane projection angle (FPPA) method at 45° and 60° knee flexion. Isometric hip Abd/Add ratio was calculated with hand held dynamometer. Copenhagen Hip and Groin Outcome Score (HAGOS) was used to determine the functional outcomes. The differences between groups were analyzed with the use of Mann Whitney-U test.
RESULTS: Age and body mass index were similar between groups ($p>0.05$). Knee valgus was higher in AS group compared to healthy athletes at both 45° ($p= 0.033$) and 60° ($p= 0.007$) knee flexion during SLS. Hip angle was lower in AS group only at 60° ($p= 0.011$) knee flexion. The Abd/Add ratio was similar between groups ($p=0.369$). All subscales of HAGOS was lower in AS group compared to healthy athletes ($p<0.05$).
CONCLUSION: Athletes with adductor strain had increased knee valgus and decreased hip angle compared to healthy athletes. These biomechanical changes might occur due to the decreased stabilization function of the adductor muscles during the closed kinetic chain activities. Prescribing the corrective exercises emphasized on impairment resolution would improve the biomechanical knee and hip alignment in athletes with adductor strain.

RELATIONSHIP BETWEEN ANKLE PLANTAR FLEXOR FORCE STEADINESS AND POSTURAL STABILITY ON STABLE AND UNSTABLE PLATFORMS

HIRONO, T., IKEZOE, T., TANIGUCHI, M., YAMAGATA, M., MIYAKOSHI, K., UMEHARA, J., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: The ability to control muscle force during submaximal contractions is an important factor in motor performance. Force steadiness (FS), which can be quantified as the force fluctuation during submaximal muscle contractions at target torque, is one index of force control (1). A previous study demonstrated that FS at less than 5 % of maximal contraction of ankle plantar flexors was related to center of pressure (COP) fluctuation during bipedal quiet standing (2). However, the relationship between FS and postural control in unstable environments which would require stronger muscle contractions is unclear. The purpose of this study was to investigate the relationship between FS and postural control during single leg standing on stable and unstable platforms.
METHODS: Thirty-three healthy young adults participated. Force at intensities of 5%, 20% and 50% of maximal voluntary contraction (MVC) of the ankle plantar flexors was measured at 1500 Hz using a dynamometer. FS was calculated as the coefficient of variation of force during 15-s muscle contraction. The standard deviation of anteroposterior COP (SDcop) displacements was measured using the BIODEX Balance System SD during 30-s single leg standing on stable and unstable platforms, and was used as the postural control index. Additionally, surface electromyography (EMG) of the soleus was recorded during both the FS and postural tasks. Pearson correlation coefficients were used to quantify the strength of linear correlation between (i) SDcop and FS, and (ii) SDcop and maximal isometric force.
RESULTS: On the stable platform, the postural control index SDcop was significantly correlated with only FS at 5% MVC ($r = 0.512$, $p=0.002$). On the unstable platform, SDcop was significantly corelated with only FS at 20% MVC ($r = 0.458$, $p = 0.007$). No significant correlations were observed between maximum isometric strength and any postural control tasks (stable platform; $p=0.093$, unstable platform; $p=0.779$). Paired t-tests showed that muscle activity during single leg standing on the stable platform was significantly larger than during the FS task at 5% MVC (27.5 ± 10.4 % vs 14.5 ± 6.8 %; $p < 0.001$). Muscle activity during single leg standing on the unstable platform was significantly larger than during the FS task at 20% MVC (33.7 ± 14.8 % vs 26.3 ± 9.7 %; $p = 0.001$).
CONCLUSION: The results of this study suggest that postural stability during single leg standing on stable platforms may be related to one's ability to maintain constant torque at 5% MVC, and that stability on unstable platforms may be related to one's ability to maintain larger constant torques, such as 20% MVC. Our findings also suggest that postural stability may be related to FS regardless of muscle activity magnitude.

VOLUNTARY STEP EXECUTION IS A LIMITED PREDICTOR FOR RECOVERY PERFORMANCE AFTER SUDDEN BALANCE LOSS

WERTH, J., KÖNIG, M., EPRO, G., SEELEY, J., POTTHAST, W., KARAMANIDIS, K.

LONDON SOUTH BANK UNIVERSITY

INTRODUCTION: The ability to increase effectively the base of support (BoS) is crucial for recovery from sudden balance disturbances (1), which is diminished with ageing (2). Although this may be of importance for clinical fall-risk assessment, the influence of age on stepping responses to different task stimuli (e.g. mechanical and vestibular) is not yet established. Therefore this study examined the mechanically-induced voluntary stepping and recovery responses to a sudden loss of balance in the anterior direction in young, middle- and older-aged adults.
METHODS: 29 young, 43 middle- and 27 older-aged adults (24±4, 52±5 and 72±5 yrs respectively) performed a voluntary step in the anterior direction over a predefined target line (25% body height) in response to a mechanical stimulus to the calcaneus. In a second task, a single trial of loss of balance in the anterior direction was unexpectedly induced from a forward-inclined position (23±2% body mass, controlled via a load cell connected to a securing cable). The stepping responses in both tasks were analysed with the aid of a motion capture system (120 Hz; Vicon Motion Systems, Oxford, UK), with foot touchdown determined using a force plate (60x90 cm; 1080 Hz; Kistler, Winterthur, Switzerland).
RESULTS: Older adults showed significantly ($P<0.001$) lower rates of increase in BoS in the anterior direction (on average 14%) compared to younger adults and lower maximal velocities of increase in BoS (10%) compared to the two younger age-groups, independent of test condition. There was a significant ($P<0.01$) age-related decline in recovery behaviour following sudden loss of balance, with 25/27 older, 15/43 middle-aged and 1/28 young adults requiring two or more steps to regain a stable body configuration. Accordingly, only middle- and older-aged adults were considered for single- and multiple-stepper comparisons. Compared to single steppers, multiple steppers demonstrated lower step lengths (23%), lower rates (15%) and lower maximal velocities of increase in BoS (13%) following sudden loss of balance, and lower (10%; $P<0.01$) rates of increase in BoS during voluntary step execution. However, only weak relationships were detected between results of the two stepping tasks for rate ($r=0.51$, $P<0.001$; $N=70$) and maximal velocity of increase in BoS ($r=0.31$, $P<0.01$).
CONCLUSION: Irrespective of task complexity, reactive stepping is diminished in older adults due to an age-related reduction in ability to rapidly increase the BoS. However, only weak relationships were found for reactive step execution between voluntary and induced loss of balance, suggesting that the two tasks require different capabilities of the human neuro-motor system. Therefore we conclude that voluntary step execution seems to be of limited validity in predicting recovery performance following a sudden loss of balance in the anterior direction, and hence may not be suitable for fall risk assessment in a clinical setting.

TRUNK NEUROMUSCULAR CONTROL IS ASSOCIATED WITH POSTURAL CONTROL DURING CHALLENGING BALANCE TASK

DUCHENE, Y., MORNIEUX, G., PETEL, A., PERRIN, P.P., GAUCHARD, G.C.

UNIVERSITÉ DE LORRAINE

INTRODUCTION: The double inverted pendulum model around the ankle and the hip seems to put aside major joints during challenged balance tasks (1). For instance, trunk should be additionally considered during kinematic analysis of postural control (2). Therefore, the purpose of the study was to determine i) the influence of the trunk segment on postural control and ii) identify trunk neuromuscular strategies during a challenging balance task.
METHODS: Eighteen male, expert handball players (22 ± 4 years, 83.1 ± 11.3kg, 1.85 ± 0.07m), performed a challenging balance task twice, consisting in standing during 20 seconds as balanced as possible, eyes closed on an unstable surface allowing tilting around the medio-lateral axis (Equitest, Neurocom, Oregon). Center of Pressure (CoP) anterior-posterior Mean Amplitude (MA) and Mean Velocity (MV) were collected to assess postural control. Inertial Motion Units (IMU) (Captiv T-Sens Motion, TEA, Vandoeuvre-les-Nancy, France) were used to determine ankle, knee, hip and trunk joint flexion/extension angles, while electromyography (EMG) sensors (Delsys, Natick, MA, USA) were placed on Rectus Abdominis (RA), External Oblique (EO) and Erector Spinae (ES) muscles to evaluate trunk neuromuscular control. Total angular flexion/extension displacement of each joint and EMG Root Mean Square (RMS) over the entire trial were computed. The mean between the two trials were calculated for each variable. Multiples linear regressions were conducted to highlight the influence of joint kinematics on CoP variables and the association between trunk muscles activity and trunk kinematics. EMG and kinematic data were standardized in order to analyze beta-coefficient as the weight of each variable.
RESULTS: Mean values of center of pressure were 18.7 ± 4.3 mm for MA and 75.2 ± 22.8 mm.s-1 for MV, while mean angular displacement values were 53.1 ± 16.2° for ankle, 24.9 ± 14.9° for knee, 21.5 ± 13.7° for hip and 28.2 ± 12.3° for trunk angles. Kinematics variables were not correlated to MA but explained 81% of the variance in MV (R^2=0.81; p<.001) following this equation: MV= 7.524 + (2.086)Ankle - (0.757)Knee - (1.055)Hip + (1.632)Trunk. Furthermore, EMG RMS of the RA, EO and ES was correlated to trunk kinematics (R^2=0.58, p<.01, Trunk = -(0.077)RA + (0.401)EO + (0.559)ES).
CONCLUSION: The weights of joint participation (beta-ankle=2.086; beta-trunk=1.632; beta-hip= -1.055) indicated that the trunk was the second major joint explaining the CoP MV. Our results underline the importance of trunk control during global postural control. Moreover, this study explored trunk neuromuscular control. Erector Spinae and External Oblique muscles play a major role to control trunk flexion/extension during challenging balance. Trunk muscles should therefore be targeted in training program to improve postural control.

BACK ROTATOR ISOKINETIC STRENGTH PROFILE IN BADMINTON PLAYERS

LI, N., TAN, Z., YE, J., REN, X.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Knowledge of back muscle rotation strength can be used in injury prevention, conditioning and rehabilitation of badminton players. The aim of this study was to describe the muscle imbalance and isokinetic strength profile of back rotators in badminton players.
METHODS: 21 badminton players(9 male, 12 female) in Shanghai team were involved in this study. For right-handed players, back rotation to left was forehand, while rotation to right side was backhand; for the left-handed players, it was reversed. The subjects did a normal warm-up before they took isometric back rotation test. Isomed2000 isometric test and training system was used for the test. The test speed was concentrically 60°/s. The subjects made 5 maximal tries. IBM Spss24 was used for statistics; all results were showed in Mean value±Standard deviation.
RESULTS: The maximal torque of back rotation between both sides for female players , and the mean power of trunk rotation between both sides for female and female players had significant differences (115.58±18.79& 130.17±20.89, 81.78±24.64 &88.22±29.10, 49.59±7.13& 54.67±7.14,p<0.05) ,while the maximal torque between both sides for male players had no significant difference (168.78±24.95& 173.89±33.10 ,P>0.05) .The forehand/backhand rotation ratio was 98.96±8.79% for male players and 95.25±13.29% for female players.
CONCLUSION: These results indicated imbalance in female players in isometric back rotation maximal torque, and mean power in male and female players. They had better backhand strength than forehand strength at this speed.

EVALUATION OF PROPRIOCEPTION IN SUBJECTS BEFORE AND AFTER TOTAL KNEE ARTHROPLASTY

BARONE, G., ZATI, A., FERRARESI, R., ZAFFAGNINI, S., BENEDETTI, M.G., BRAGONZONI, L.

UNIVERSITY OF BOLOGNA

INTRODUCTION: Proprioception is one of the most significant factors in balance, joint stability, coordination and injury prevention. It includes a wide set of neural input that bring information from peripheral mechanoreceptors, located within joints, muscles and tendons, to central nervous system. Generally, proprioception is defined as the ability to sense position of a joint in the space.
Total knee arthroplasty (TKA) is the gold standard procedure to treatments of severe gonarthrosis, which aims to alleviate the pain, restore the locomotor function and increase patient satisfaction.
Even if osteoarthritis has already altered proprioception abilities, the TKA procedure can furtherly affect proprioceptors. Some studies demonstrated that TKA slightly improved the kinaesthesia and balance. Other researchers, differently, did not observe any improvement. The aim of this study is to evaluate proprioception and postural control in subject with TKA, before and after the surgery, using Delos Postural Proprioceptive System (DPPS; Delos, Turin, Italy).
METHODS: A cohort of 8 subjects (5 women and 3 men) were involved in the study. Subjects were aged 66.5±4.9, had primary knee osteoarthritis, and were scheduled for TKA. DPPS was used to assess proprioception and postural control before and after the surgery. The two tests considered to evaluate postural and proprioceptive control were stabilometric test and static Riva test. The parameters taken into account for these tests were the Stability Index (SI; percentage score where 100% is a theorical task performed with maximum stability), Autonomy (AU; percentage score based on hands support during tasks) and Postural Instability (PI; score in degree based on movement of trunk).
RESULTS: The SI measured during the single stance test improved from 56.1%±27.5 to 73.3%±15.7 with opened eyes and decreased from 37.7%±10.2 to 34.5%±13.1 with closed eyes in the operated limb.

PI measured during the double stance test increased of 0.07° with opened eyes and decreased of 0.13° with closed eyes. AU improved from 66.6% to 86.6% with open eyes and has maintained almost the same value with closed eyes (from 47.08% to 47.12%).
CONCLUSION: In TKA, mechanoceptors of the knee are sacrificed, this should result in a drop of the proprioceptive information with respect to healthy knee, and consequently there is a decreased of balance and increased of risk of falls.
The proprioceptive system are more stimulate during instability situation, for example in poorly lighting places or in restricted movement condition.
The reduction of pain and the restoration of limb alignment are probably the main reason of the several improvement of SI and AU during open eyes task, whereas the lack or ineffectiveness of the proprioceptive system, could be the cause of failure improvement of closed eyes task too.
Double stance task did not show relevant variations between pre and post surgery, due to influences of non-operated limbs and low numbers of subjects.

DOES EXPLICIT WRIST USAGE BENEFIT BEGINNERS' HANDSTAND PERFORMANCES? APPROACHING ALTERED COACHING OF SKILL-RELATED MOTOR BEHAVIOUR

ROHLEDER, J., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Current motor behavioural studies on postural control in handstands suggest wrist torques to play a dominant role for maintaining balance (i.e., wrist strategy). However, contemporary gymnastics textbooks neglect to explicitly focus on wrist control, instead preferring to extensively develop a straight body line. Leaving the aligned body configuration to implicit learning, the present study aimed to explore the efficacy of an explicit wrist strategy coaching on handstand performances in beginners at different skill levels (skilled vs. less skilled).
METHODS: Twenty-five healthy sport students (15 females, aged: 20.7 ± 1.1 years; height: 166.9 ± 6.9 cm; weight: 60.3 ± 6.5 kg; 10 males, aged: 21.7 ± 1.7 years; height: 183.6 ± 6.7 cm; weight: 76.9 ± 8.4 kg) volunteered to receive a three-week training intervention comprising a video-tutorial on explicit wrist strategy application followed by five practical training sessions (including six standardised exercises) which explicitly triggered wrist flexor activation. Prior to (pre-test) and after (post-test) completing this protocol, the participants performed the lunge entry and swing up to handstand on a plane surface (i.e., gymnastics mat) for three times aiming for a long balance time. Retrospectively, participants were classified as skilled or less skilled beginners with the pre-test mean balance time serving as criterion for group assignment. Captured by standardised video recordings using a tablet PC, the parameters balance time, expert judgements for postural execution and balance control strategy, as well as shoulder and hip joint goniometry were analysed to determine group differences concerning changes in handstand performances.
RESULTS: The less skilled group showed enhanced balance times, postural executions and balance control strategies ($p < .05$). However, these parameters remained unaffected in the skilled group ($p > .05$). Goniometric analyses for shoulder and hip joint angles revealed no significant changes for both groups.
CONCLUSION: Increased handstand balance times in less skilled beginners indicate explicit coaching of wrist usage to positively influence balance control in handstands. Furthermore, enhanced postural execution and balance control strategies in less skilled beginners suggest wrist strategy coaching to implicitly benefit the aligned body configuration during handstand. However, enhanced postural quality is not reflected by separate changes regarding shoulder or hip joint adjustments. Furthermore, although failing significance, unaffected handstand performances in skilled beginners show negative tendencies which may assumingly be discussed in relation to the reinvestment theory suggesting skill-related knowledge to potentially impair the execution of relatively skilled movements. To conclude, handstand teaching for unexperienced novices is suggested to consider wrist strategy coaching as a supplement, but not as a replacement of training contents addressing a steady body line.

COMPARISON OF DIFFERENT BALLET POINTE SHOES ON GROUND REACTION FORCE DURING BALLET MOVEMENTS

LIN, C.F., HUANG, M.T., LIAO, J.C.

NATIONAL CHENG KUNG UNIVERSITY, TAIWAN; NATIONAL CHENG KUNG UNIVERSITY HOSPITAL, TAIWAN; CHI-MEI HOSPITAL, CHIA-LI, TAIWAN

INTRODUCTION: Ballet dancers have to conduct routine and vigorous ballet training at age 5-6 years old to achieve sufficient flexibility and muscle strength. For female ballet dancers, dancing on tip-toes with pointe shoes is an important stage to reveal their dancing technique and weightless image of ballet. However, the tiptoes have to bear the whole body weight and the impact from jumping when performing the point work is much higher than regular toe-raising. The excessive force applied on dancers' feet can sometimes result in acute or chronic injuries around the ankle and foot region. Thus, ballet dancers rely on ballet shoes to assist in ballet movement, and also take shoes as a protection gear. However, the design and material of ballet shoes may not provide sufficient support to ballet dancers and may make dancers prone to injury. Thus, this study aimed to investigate the effect of ballet pointe shoes on impact force during ballet landing.
METHODS: Nine female ballet dancers (mean age: 22.83±3.18 years old; mean height:158.55±3.77 cm; mean body weight:50.33±5.44 kg) with ballet training history over 10 years were included. Dancers performed ballet Changement and Entrelacé with 3 different pairs of ballet pointe shoes that are commonly worn by ballet dancers. The ground reaction force was collected with two Bertec force plates One-way ANOVA was used to compare the group difference among ballet dancers' own pointe shoes, Chacott pointe shoes, and R-class pointe shoes during the landing phase of Changement and Entrelacé.
RESULTS: The preliminary results showed that significant group difference was found among 3 different shoes during impact phase of ballet Changement (their own: 1.91±0.37 N/BW; Chacott: 1.82±0.42 N/BW; R-class: 1.80±0.34 N/BW; P=0.015). The post-hoc test showed that their own pointe shoes had larger impact force than R-class pointe shoes (P=0.016). However, no significant group difference was found among 3 different shoes during impact phase of ballet Changement (their own: 3.89±1.21 N/BW; Chacott: 3.95±1.19 N/BW; R-class: 3.68±0.82 N/BW; P=0.67).
CONCLUSION: Both Changement and Entrelacé consist of landing and stabilization phases and are commonly performed ballet tasks. Our results presented that the R-class can lower the impact force compared to their own shoes and also has smaller impact force compared to Chacott during ballet Changement. In addition, the impact force in the R-class condition during Entrelace is smallest. This result suggest that R-class may has potential to lower the injury. However, its impact on postural control may requires further investigation.

THE EFFECT OF EMG BIOFEEDBACK ON THE ACTIVITY OF POSTURAL MUSCLES DURING STANDING IN THE ELDERLY: IMPLICATIONS FOR BALANCE TRAINING.

DOS ANJOS, F.1, THULHER, J.2, OLIVEIRA, L.F.2, IMBIRIBA, L.A.2, GAZZONI, M.1, VIEIRA, T.1

1: POLITECNICO DI TORINO, 2: UNIVERSIDADE FEDERAL DO RIO DE JANEIRO

INTRODUCTION: Biofeedback based on electromyograms (EMGs) is a promising balance training protocol to improve the efficient activation of postural muscles during standing. For example, it has been recently shown that young subjects are able to suppress the plantar flexors' activity when provided with EMG-audio biofeedback during standing without threatening stability (1). Whether, however, the reduction effect of EMG-biofeedback on the activity of ankle muscles generalizes to other populations (e.g., elderly) is still an open question that we address here.
METHODS: Ten female volunteers (mean age: 76 years) were asked to stand barefoot comfortably with their arms alongside the body and eyes open. Two standing conditions were applied lasting 60s each: (i) standing at ease, taken as control condition, and (ii) standing with EMG-audio feedback from the medial aspect of soleus muscle. In the EMG feedback condition, an audio signal proportional to the level of soleus activity was provided to participants with headphones and they were instructed to reduce it without changing standing posture. Surface EMGs from the soleus medial and lateral aspects, medial gastrocnemius, tibialis anterior, vastus lateralis and vastus medialis of both legs were sampled with a pair of surface electrodes. The Root Mean Square (RMS) amplitude of EMGs over the task duration was averaged across sides to assess the degree of postural activity for each muscle. After verifying that the data distribution of EMGs' RMS computed for some muscles was not Gaussian (Shapiro-Wilk's W-test, $P < 0.05$), nonparametric test (Wilcoxon signed-rank test) was used to compare the degree of muscle activity between standing conditions for each muscle, considering the significance level of 5 %.
RESULTS: The level of muscle activity varied significantly while subjects stood with the audio-feedback from the soleus muscle. The RMS amplitude from the medial aspect of soleus was significantly lower (~5%) with than without the biofeedback ($P = 0.036$). The level of muscle activity did not differ between standing conditions for the soleus lateral aspect, medial gastrocnemius, tibialis anterior, vastus lateralis and vastus medialis ($P > 0.05$ in all cases).
CONCLUSION: The results revealed the attenuation effect of EMG-biofeedback on the ankle muscles' activity during standing seems to generalize to elderly subjects. From the EMG-biofeedback of soleus muscle, subjects could activate to a lesser extent their plantar flexors (~5%) without increasing the level of activity in the other postural muscles tested during standing. These results suggest the EMG-biofeedback technique may be a promising balance training protocol to attenuate the excessive level of ankle and thigh muscles' activity during standing in elderly individuals (2).

INTER-RATER RELIABILITY OF THE FOOT LIFT TEST IN PHYSICALLY ACTIVE INDIVIDUALS

THANASOOT, K.1,2, UDOMPANICH, N.1,2, HUNSAWONG, T.1,2

1: BNOJPH , 2: KKU

INTRODUCTION: Foot lift test (FLT) is a clinical test conducting to determine static balance impairment in physically active individuals with lateral ankle sprains (LAS) and chronic ankle instability (Linens et al., 2014; Gribble et al., 2016). Two methods of the FLT either using a visual inspection or video recording are commonly performed in clinical setting and research study (Hiller et al., 2007; Ko et al., 2017). According to a protocol of the test, it is crucial noting that conducting the FLT requires experience and optimal training. Moreover, there is a lack of study demonstrated inter-rater reliability of an expert and inexperienced raters using the FLT. Therefore, the present study determined the inter-rater reliability of an expert and inexperienced raters conducting the FLT using visual inspection and video recording methods in physically active adults.
METHODS: Eighteen physically active adults (mean age 25.17±4.57 years) consisting of healthy individuals (n=9) and individuals with a history of LAS (n=9) participated in the present study. All participants had the Foot and Ankle Ability Measure for ADL and Sport scales > 90%. After training, inter-rater reliability study was conducted by 3 raters, the expert and two inexperienced raters. During the participants performed the FLT with eyes open and eyes closed, the whole testing was video recorded. Concurrently, all raters independently counted the number of any part of foot lift off the floor, and the untested foot touched the floor and scored as an error (Hiller et al., 2007). After testing for one week, all raters independently watched the video recording and counted the error (Ko et al., 2017). Inter-rater reliability was analyzed by intraclass correlation coefficient model 3,3 (ICC3,3).
RESULTS: Inter-rater reliability of the FLT using visual inspection of both legs were excellent with ICC3,3 ranged from 0.92 to 0.97 (95% CI: 0.82, 0.98) and ICC3,3 ranged from 0.91 to 0.95 (95% CI: 0.80, 0.98) for eyes open and eyes closed, respectively. Inter-rater reliability of the FLT using video recording of both legs were excellent with ICC3,3 = 0.96 (95% CI: 0.91, 0.98) and ICC3,3 ranged from 0.96 to 0.97 (95% CI: 0.92, 0.99) for eyes open and eyes closed, respectively.
CONCLUSION: After the optimal training, the FLT using visual inspection and video recording had excellent inter-rater reliability among the expert and inexperienced raters. The present result confirms the ease of using this test to determine static balance impairment in physically active adults.

CP-BN05 Running and throwing

BUILT FOR FAST SPRINT RUNNING: PHASE-SPECIFIC ASSOCIATION OF INDIVIDUAL HIP EXTENSOR SIZES WITH SPRINT VELOCITY AND STEP VARIABLES

TAKAHASHI, K., KAMIBAYASHI, K., WAKAHARA, T.

DOSHISHA UNIVERSITY

INTRODUCTION: Sprint running velocity is the product of step frequency and step length. To increase the values of these step variables, the hip extensors were suggested to be important (1), and their sizes were reportedly associated with 30-m sprint time (2). However, the activity levels of individual hip extensors were shown to change from the acceleration to the maximal velocity phases of sprinting (3). Thus, the relationship between the sizes of the hip extensors and sprint velocity may vary depending on the phase. This study aimed to examine the association of individual hip extensor sizes with sprint velocity and the step variables at 10-m intervals of the 100-m sprint.
METHODS: Twenty-six male sprinters (personal best time in 100-m sprint: 10.35–11.33 s) performed a 100-m sprint from the starting blocks. Their sprint motions were captured using two panning cameras to calculate the mean sprint velocity, step frequency and step length for every 10 m. Magnetic resonance images of the hip and thigh were obtained to determine the volume of the gluteus maximus, biceps femoris long head, semitendinosus (ST), semimembranosus (SM), gracilis, adductor magnus, longus, and brevis muscles. The muscle volume was normalized by the body mass as a relative volume (cm3/kg).
RESULTS: A significant correlation was found between the relative volume of SM and the sprint velocity at 0–10 m interval ($r = 0.607$, $P = 0.001$). The relative volume of ST was significantly correlated with the sprint velocities at 30–40, 50–60, 60–70, 70–80, 80–90, and 90–100 m intervals ($r = 0.430$ to 0.600, $P = 0.001$–0.028). After adjustment of the effect of thigh length on the step variables in the semipartial correlation analysis, the relative volume of SM was significantly correlated with the step length at 0–10 m interval ($r = 0.427$, $P = 0.029$), whereas that of ST showed trends toward a significant correlation with the step frequencies at 50–60, 60–70, 70–80, 80–90, and 90–100 m intervals ($r = 0.350$ to 0.449, $P = 0.021$–0.080).
CONCLUSION: As SM is suited to generate a large force at a low shortening velocity because of its large physiological cross-sectional area and short fiber length (4), it may contribute to the achievement of a long step length in the early acceleration phase (0–10 m) of sprint. By contrast, ST appears to be designed for developing a force at a high shortening velocity because of its long fibers (4). This may be a factor for the observed relationship between ST volume and step frequencies in the maximal velocity (50–70 m) and deceleration (70–100 m) phases. Our results suggest that resistance training aimed at hypertrophy of SM and ST may be beneficial to attain a high performance in the early acceleration phase and from the maximal velocity to the deceleration phases of the 100-m sprint, respectively.

INTERRELATIONSHIP BETWEEN JOINT MOVEMENTS TO MAINTAIN PRECISION OF PERFORMANCE IN BASEBALL THROWING

KIMURA, A., OMURA, L., YOSHIOKA, S., FUKASHIRO, S.

THE UNIVERSITY OF TOKYO

INTRODUCTION: It is widely known that precision of performance can be improved by coordination relationship between joint movements. In previous studies, the coordination relationship is considered to exist as a whole structure 1), 2). However, this viewpoint does not give us information about which interrelationships between joint movements are important to maintain the precision of performance. Therefore, we aimed to examine which interrelationships between joint movements are important to maintain the precision of performance during baseball throwing.
METHODS: The participants included 15 right-handed baseball players. They threw a ball to a target in the sitting throws. A motion capture system recorded the position of the reflective markers attached to each participant and a ball. The right hand velocity in throwing direction was mathematically expressed as the sum of the contributions from each joint angular velocity of throwing arm. We focused on vertical hand velocity in this study, which relates the ball location in the vertical direction 3). By using computer simulation, variabilities of the vertical hand velocity in the case each kinematic parameter was made independent from the other kinematic parameters were calculated. It is assumed that the variability of the vertical hand velocity becomes large compared to that obtained in the experiment if a certain kinematic parameter is made independent. This can be interpreted that the kinematic parameter is important to maintain the precision of vertical hand velocity.
RESULTS: Some participants produced the hand velocity in the throwing direction mainly by elbow extension velocity (elbow extension type). Others produced the hand velocity mainly by the shoulder internal rotation velocity (shoulder internal rotation type). In the elbow extension type, the variability of the vertical hand velocity was higher than that obtained in the experiment when the shoulder internal/external rotation angle or shoulder horizontal flexion/extension velocity was made independent. This result indicates that the precision of the vertical hand velocity decreases when the other kinematic parameters do not covary appropriately with these two kinematic parameters. Therefore, interrelationships of the other kinematic parameters that counterbalance the variability of vertical hand velocity derived from these two kinematic parameters are important to maintain the precision of the vertical hand velocity. Concerning the shoulder internal rotation type, the shoulder internal/external rotation angle and elbow flexion/extension velocity were the kinematic parameters that should be counterbalanced to maintain the precision of the vertical hand velocity.
CONCLUSION: The findings indicate the interrelationships between joint movements that are important to maintain the precision of performance are different depending on the two throwing types.

EFFECT OF TRUNK LATERAL TILT ON PITCHING BIOMECHANICS AND PERFORMANCE

TSENG, T., CHOU, P., LIN, K., LIN, H., LIN, Y.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Baseball pitching is a series of complex and rapid motion that begin with wind up phase and ends with follow-through of the pitching cycle. The trunk is a major contributor to the kinetic chain during baseball pitching by helping transfer energy form the lower limbs to produce the desired ball speed. To date, only a few studies had been conducted to investigate the role of the trunk in upper extremity injury.
The purpose of this study was to investigate the association between trunk lateral tilt and the pitching biomechanics.
METHODS: Fifteen pitchers who had excessive trunk lateral tilt and fifteen pitchers without excessive trunk lateral tilt were recruited for this biomechanical study.
Pitchers with more than 30° contralateral trunk lateral tilt at maximum external rotation phase were defined as excessive trunk lateral tilt (experimental group). Pitcher less than 20° contralateral trunk lateral tilt at maximum external rotation phase were defined as control group.
The Motion Analysis System was used to capture the throwing motion at a sampling rate of 300Hz on the outdoor throwing mound. Kinematic and kinetic data between the two different groups of pitchers were calculated for comparison. Independent-samples t-test was used for statistical analysis and $p<0.05$ as statistically significant.
RESULTS: Kinematic :
The pitchers who had excessive trunk lateral tilt had higher ball speed (Experimental : 123.6, Control : 116.8, p=0.00) and greater shoulder external rotation (Experimental :48.4±33.8 , Control : 37.93±26.48, p=0.04) at foot contact phase, greater trunk lateral tilt (Experimental :37.04 ±5.9 , Control : 17.77 ±3.62, p=0.00) and trunk forward tilt (Experimental :12.36 ±10.49 , Control : 5 ±7.34, p=0.00) at maximal external rotation phase, greater shoulder internal rotation angular velocity (Experimental : 9110.91 ±11331.43 , Control : 5809.22 ±2237.59, p=0.0018) at Arm acceleration phase than the control group.
Kinetic :
The pitchers who had excessive trunk lateral tilt had greater shoulder inferior force (Experimental : 101.49 ±92.61 , Control : 52.23 ±75.49, p=0.0008), elbow medial force (Experimental : 119.5 ±87.58 , Control : 76.4 ±65.47, p=0.0013) at arm acceleration phase, shoulder superior force (Experimental : 140.42 ±119.23 , Control : 96.14 ±52.55, p=0.005) at arm deceleration phase than the control group.
CONCLUSION: In this study, pitchers with excessive trunk lateral tilt have higher shoulder and elbow joint loading during pitching. Therefore, specific training program should be designed to improve their throwing techniques, and decrease the risk of upper extremity injuries.

THE EFFECT OF EARLY TRUNK ROTATION ON BASEBALL PITCHING MECHANICS

YEH, H., TSAI, P., CHOU, P., LIN, H.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Previous research indicated that a decrease in angular momentum shifted to the throwing arm was due to improper timing in sequential body motion (1). Douoguih also reported that pitchers with early trunk rotation have higher risk of upper extremity injury (2). The purpose of this study is to evaluate the effect of early trunk rotation at the moment of foot contact on pitching mechanics. The relationship between early trunk rotation and increased horizontal abduction will also be investigated.
METHODS: Thirty-two pitchers were recruited for this study. The trunk rotation is defined as 0 degree with direction toward the Home Plate and -180 degrees with direction toward the Second Base. Players with trunk rotation more than -95 degrees at foot contact are considered as the Control group (N=16), while pitchers who pitched with rotation less than 85 degrees at foot contact would be regarded as Early Trunk Rotation group (ETR group ; N=16). In addition, ETR group were divided into two groups, pitchers with horizontal abduction over 40 degrees are considered as HABDL group (N=8), while less than 30 degrees would be regarded as HABDS group (N=8). The Motion Analysis System was used to capture the throwing motion at a sampling rate of 300Hz on the outdoor throwing mound. Kinematic and kinetic data between the two different groups of pitchers were calculated for comparison. Independent-samples t-test was used for statistical analysis and $p<0.05$ as statistically significant.
RESULTS: At foot contact, shoulder horizontal abduction and shoulder external rotation of ETR group were significant greater than Control group. At cocking phase, maximum shoulder horizontal adduction angular velocity, shoulder proximal force, shoulder horizontal adduction torque and shoulder internal rotation torque of ETR group were significant greater than Control group. At arm acceleration phase, max shoulder internal rotation angular velocity and shoulder proximal force of ETR group were significant greater than Control group. At arm deceleration phase, shoulder proximal force and shoulder internal rotation torque of ETR group were significant greater than Control group. At the same time, the maximum shoulder horizontal adduction angular velocity, elbow varus torque, shoulder internal rotation torque and elbow valgus of HABDL group were significant greater than HABDS group.
CONCLUSION: Immature anatomy and poor pitching mechanics are possible risk factors to sports injury in youth baseball player. Therefore, specific training program should be designed to improve their throwing techniques, and decrease the risk of upper extremity injuries.

CAN BIOMECHANICAL METAPHOR CORRECTLY CONVEY INFORMATION OF SPORTS TECHNIQUES? A KINEMATIC ANALYSIS OF DART THROWING

ZENIYA, H., TANAKA, H.

TOKYO UNIVERSITY OF AGRICULTURE AND TECHNOLOGY

INTRODUCTION: Analogy-based instruction can help learners to easily understand the techniques required to perform motor skills effectively. Motor performance induced by analogy instruction is more robust in cognitively demanding situations, such as psychological stress, than that induced by explicit instruction (Masters et al., 2008, J Mot Behav). Biomechanical metaphor is one possible method to conduct analogy learning of motor skills; however, it remains unclear whether analogy-based instruction using biomechanical metaphor can correctly convey information of sports techniques, as can be conveyed using explicit instruction. This study aimed to determine

whether biomechanical metaphor instruction can induce comparable movement patterns of dart throwing as can be induced by explicit instruction.
METHODS: Fourteen university students participated in a dart throwing task. The participants were provided with instructions for executing arm swing motions of dart throwing. There were six different instructions that consisted of two different goals, standard dart technique vs. the opposite technique, and three different methods for each goal: (a) explicit, (b) biomechanical metaphor, and (c) reduced information biomechanical metaphor. The participants performed three throwing trials for each instruction. The order of the six instructions was randomized for each of the participants. A motion capture system measured 3D coordinates of reflective markers, which were positioned on the dart and each participant's arm. Eight kinematic measurements (motion time, mean angular velocity of the elbow joint, etc.) were calculated from the recorded 3D data and then were averaged from the three trials.
RESULTS: Two-way repeated-measures ANOVA tests revealed a significant main effect of the goal factor for almost all eight of the kinematic variables (ps < 0.05). There was no significant main effect of the method factor for all of the variables (ps > 0.05). Some variables, including maximum angular acceleration of the elbow joint, elbow joint angle at release, and mean angular velocity of the elbow joint, showed significant interactions between the two factors (ps < 0.05). For each of the two technique goals, post-hoc multiple comparison tests revealed no significant differences between the three methods for these variables (ps > 0.05).
CONCLUSION: Analogy-based instruction using biomechanical metaphor could convey information to guide the target motor actions, similar to those conveyed by explicit instruction. The arm swing kinematics of dart throwing induced by the biomechanical metaphor instructions were not affected, when the amount of information to represent dart techniques decreased. This result further provides a hypothesis that the reduced-information version of biomechanical metaphor might be effective for improving motor performance, particularly under cognitively demanding situations.

IDENTIFICATION OF RUNNING PATTERNS IN JUNIOR HIGH SCHOOL STUDENTS

YANAGIYA, T., YOSHIDA, T., KOKUBUN, K., TAKESHITA, T., NORO, H., FUKUNAGA, T.

JUNTENDO UNIVERSITY

INTRODUCTION: Recently, we have reported the characteristics of foot strike pattern for sprint running of junior high school children and indicated the many faster runner with pattern of the forefoot strike. Therefore, the purpose of present study was to clarify the determinants of sprint running ability of junior high school students in a stand point of foot strike pattern.
METHODS: Methods
Subjects were 291 participants (146males and 145 females) who were video recorded with high speed video camera at 300fps from left side of run way. Kinematic variables of running motion was analyzed using motion analyze software. The foot strike patterns were distinguished for such 3 types of strike pattern as Forefoot (FF), Midfoot (MF), and Rear-Foot (RF). Running velocity, step frequency, step length, contact time, and flight time were computed from the video camera.
RESULTS: It is observed that the maximum running speed increased with increase the age. However, no effects of age on foot strike pattern were observed. On the other hand, when classifying subjects according to running ability by gender, foot strike pattern index and foot strike angle of faster runners were tended to approach forefoot strikers in both genders.No significant kinematic differences were observed in lower limb joint angle at foot contact and toe off. However, significant differences were observed in hip joint angle at touch down, distances from foot contact point to greater trochanter and distance from toe-off point to greater trochanter when subjects were divided by foot strike pattern.
CONCLUSION: In this study, it was suggested that the determinants of foot strike pattern during sprint running was not the increase of age, but the development of sprint running ability. It is thought that shorted distance of foot contact enables FF strike runners minimizing braking force at the ground contact.

BEHAVIOUR OF MUSCLE-TENDON COMPLEX OF THE GASTROCNEMIUS LATERALIS DURING THE STANCE PHASE OF STAIR GAIT IN YOUNG AND OLD ADULTS

JOHANNSSON, J.1, JAKOBI, J.2, DUCHATEAU, J.1, BAUDRY, S.1

1: ULB , 2: UBC OKANAGAN

INTRODUCTION: Old adults experience neuromuscular changes that reduce muscle function (Clark 2019), which might influence muscle-tendon complex (MTC) and muscle fascicles behaviours, as suggested in walking (Mian et al.2007). The aim of this study was to investigate the myotendinous structures of the gastrocnemius lateralis (GL) during stair ascent and descent in young and old adults.
METHODS: The MTC length (LMTC) during upright standing, and its change during stair ascent and descent, was estimated by a regression equation (Grieve et al.1978) in 16 young (25±3yr) and 18 old (70±5yr) adults. The GL fascicles length were recorded with ultrasound videos. The GL fascicle length was also expressed as %LMTC after being projected to the longitudinal axis of the muscle to provide information on the extent of length change of GL tendon (GLT). The stance phase was divided in early (P1), mid (P2) and late (P3) portions.
RESULTS: During upright standing, MTC length was similar between young and older adults ($p>0.05$), whereas fascicles were shorter in old compared to young adults ($p<0.05$). GLT length was greater in older than young adults ($p<0.05$). During stair ascent, the MTC shortened in P1, lengthened in P2 and shortened in P3, with a greater shortening in young than old in P3 ($p<0.001$). During stair descent, the MTC shortened in P1 and P3, with a greater shortening in young than old in P3 ($p<0.001$). During stair ascent and descent, fascicles shortened and maintained a nearly constant length in both young and old groups ($p<0.02$), without difference between young and old ($p>0.05$). GLT lengthened in all phases and kept a nearly constant length, in both stair ascent and descent ($p<0.05$), without differences in the extent of shortening between young and old ($p>0.05$).
CONCLUSION: Despite shorter fascicles during upright standing in old compared to young, the extent of length changes observed for the fascicles projected to the longitudinal axis were similar for both age group during stair ascent and descent. Similarly, ageing does not seem to influence tendon behaviour during stair locomotion. Even though older adults experience neuromuscular changes that may alter muscle function, this study suggests that healthy ageing did not influence the behaviour of myotendinous structures during stair ascent and descent.

MEDIAL LONGITUDINAL ARCH DEFORMATION DURING GAIT IN ELEMENTARY SCHOOL GIRLS

KIUCHI, A.1, HIRANO, T.1, SOMA, M.2,1, FUJITO, Y.3, NOZAWA, T.1, ENOKIYA, T.1, YOON, H.1, KASHIWAGI, Y.3,1, FUNATO, K.3

1: GRADUATE SCHOOL OF HEALTH AND SPORT SCIENCE, NIPPON SPORT SCIENCE UNIVERSITY, 2: JUMONJI UNIVERSITY, 3: NIPPON SPORT SCIENCE UNIVERSITY, 4: SENSHU UNIVERSITY

INTRODUCTION: As one of the important foot functions is normal gait, medial longitudinal arch (MLA) play spring-like action far braking and accelerating of movement. The MLA stiffens the foot under loading, enabling it to function as a propulsive lever during walking and running [1]. Previous study showed high-arched feet as rigid and low-arched feet as hypermobile [2]. However arch deformation due to growth and development have not been clarified. The purpose of this study was to clarify medial longitudinal arch deformation during gait in elementary school girls.
METHODS: Ground reaction force (GRF), MLA angle and height of 45 female elementary school girls (first-grade 21, sixth-grade 24) at preferred speed were investigated with a highspeed camera (GC-LJ20B, JVC inc. 240fps) and an Emed q-100 pedography platform (Novel GmbH, Emed inc. 100Hz). We placed markers on the medial aspect of the first metatarsal head, the navicular tuberosity, and the medial aspect of the posterior calcaneus. We digitized marker position in videos of the medial foot in Frame-Dias V (DKH inc.). To reduce signal artifacts caused by digitizing error, we filtered the raw marker coordinate data using a fourth order low-pass Butterworth filter with a 30 Hz cut off frequency. MLA angle was calculated as the angle between the first metatarsal head, the navicular tuberosity and the medial calcaneus in the local sagittal plane. LA height was calculated as the perpendicular distance between the navicular tuberosity and a line bisecting the first metatarsal head and medial calcaneus.
RESULTS: Stance time was first-grade 0.55±0.03sec, sixth grade 0.58±0.05sec. Most GRF occurred at the beginning and end of stance phase. MLA height decreased from heel contact and increased after heel rise to its maximum, on the other hand MLA angle increased from heel contact and decreased after heel rise to its maximum at toe-off. No difference was observed between both groups.
CONCLUSION: Large deformation in MLA was observed around 75% stance phase, where maximum GRF in forefoot was indicated. This tendency was similar in both first and sixth grade elementary school girls.

EFFICACY OF TRANSVERSE ARCH SUPPORT SHOE INSOLES IN COUNTERING PLANTAR FORCE

SAHO, Y.1, SANOMURA, M.1, FUKUYO, C.2

1.TEIKYO UNIVERSITY, 2.NIPPON SIGMA CO., LTD.

INTRODUCTION: Shoe insoles are often used to treat and prevent overuse injuries in sports. Higher pressure in the 5th metatarsal has the potential to contribute to stress fractures (Azevedo RR, 2017). Plantar force differs for the different movements of different sports (Thomson A, 2018). The purpose of this study was to investigate the efficacy of custom-made shoe insoles in supporting the anterior transverse arch and reducing the plantar force during running and side-step cutting.
METHODS: Ten male collegiate football players performed two tasks (5 m running and 90 side-step cutting) while wearing two types of insoles - the one that supports the anterior transverse arch (ATA insole) in forefoot and the control (C insole). Plantar pressure data were collected using the pedar-x mobile system (Novel, Munchen) and force was measured in 10 regions: hallux, second toe, and lateral toes; medial, central, and lateral forefoot; medial and lateral midfoot; and medial and lateral heel. Maximal plantar force and the total force in these 10 regions were compared between ATA insoles and C insoles using a pared t-test ($p < 0.05$).
RESULTS: Total plantar force during running was 1662.8 N for ATA insoles and 1595.4 N for C insoles, and 1506.2 N and 1487.1 N for site-step cutting. During running, maximal plantar force (N) in the 10 regions was not significantly different between the two shoe insole types ($p > 0.05$). During side-step, maximal plantar force in the hallux and lateral toe was significantly lower for ATA insoles compared with C insoles ($p < 0.05$). The maximal forces in central forefoot and lateral forefoot tended to be lower for ATA insoles than C insoles ($p < 0.1$).
CONCLUSION: Insoles supporting the anterior transverse arch significantly reduced maximal plantar force across central and lateral toes, and lateral forefoot while performing lateral cutting. In sports that require many side-to-side movements, therefore, athletes may benefit from wearing these insoles as they can possibly reduce the risk of foot overuse injuries such as stress fracture over the 3rd to 5th metatarsals.

LONGITUDINAL CHANGES IN THE EARLY AND LATE RATES OF FORCE DEVELOPMENT IN THE COMPETITION SEASON FOR JUMPERS

ZUSHI, K.1, KARIYAMA, Y.2, ZUSHI, A.1, YOSHIDA, T.1, KIGOSHI, K.1, OGATA, M.1

1: UNIVERSITY OF TSUKUBA, 2: YAMANASHI GAKUIN UNIVERSITY

INTRODUCTION: The take-off phase of jumping in athletic events requires a rapid force capacity, which can be quantified by the rate of force development (RFD). Evaluation of RFD in athletes may be necessary to assess the lower limb muscle strength for jump performance. Moreover, RFDs in the early and late phases have been found to vary with respect to neural and contractile determinants (Folland et al., 2014). Therefore, separation of each phase is required for the analysis of RFD. The aim of this study was to investigate longitudinal changes in RFD throughout the competition season. The hypothesis was that the longitudinal changes in RFD during the competition season for jumpers would be independent in each phase, and that these would relate to changes in jump performance.

METHODS: Fifteen male jumpers (five long jumpers, three triple jumpers, two high jumpers and three pole-vaulters) performed isometric single-leg press in a long seat position, with a knee angle of 115°. RFD was measured in the pre-season (January or March) and post-season (September or November). Average RFD, early RFD, and late RFD were calculated. Average RFD was based on the entire force-time curve in the rising phase, and was defined as the force divided by the time. The force was recorded when the differential value of the force-time curve is negative initially. The break point was identified when the difference between consecutive 25ms increments was minimal. Early RFD and late RFD were RFDs of the early and late rising phases of the force-time curve, respectively. Early RFD was the slope of the regression line, calculated by the force value from onset of contraction to the break point. Late RFD was the slope of the regression line calculated by the force value from break point to 250 ms. Paired t-tests were used to determine the longitudinal changes in RFD between the pre-season and post-season ($p < 0.05$).
RESULTS: Average RFD significantly increased by 21% from pre- to post-season. In addition, only participants who achieved personal bests in the competition season showed a significant increase in early RFD (14%). Training programs during the competition season are designed to be specific to jumping events, which are characterized by rapid force production, high movement velocity, and stretch-shortening cycle of the lower limb for the take-off phase of jumping.
CONCLUSION: Early RFD may be an effective parameter to predict jumping performance. This study suggested that average RFD is increased through habitual jumping trainingREFERENCE:

BASKETBALL DUNK KINETICS – AGREEMENT BETWEEN FORCE PLATE AND MARKERLESS 3-D MOTION CAPTURE SYSTEM ASSESSMENTS

CABARKAPA, D., FRY, A.C., HERMES, M.J.
UNIVERSITY OF KANSAS - JAYHAWK ATHLETIC PERFORMANCE LAB

INTRODUCTION: Basketball is one of the most popular international sports, but the current sport science literature does not directly address on-court performance such as force and power during a game. Force plate technology is currently the gold standard for assessing peak force and power outputs, but has limitations including lack of portability and time consuming data analysis. This study examined the accuracy of a three-dimensional markerless motion capture system (3-D MCS) for determining the biomechanical characteristics of one of the most powerful activities in the sport; the basketball dunk.
METHODS: A former National Collegiate Athletic Association (NCAA) Division-1 collegiate basketball player (age = 25 yrs, hgt = 2.08 m, wgt = 111.4 kg, playing experience = 12 yrs) performed 30 dunks utilizing the two-hands, no-step, two-leg jumping approach. A uni-axial force plate (0.91 m X 2.44 m; Rice Lake Weighing Systems, Rice Lake, WI, USA) was positioned under a regulation basket, with force sampled at 1000 Hz by a BioPac data acquisition system (Goleta, CA, USA). Additionally, a 3-D MCS (DARI, Lenexa, KS, USA) composed of eight identical cameras placed 3.7 m high surrounding the recording area collected data at 50 Hz. After completing a dynamic warm-up, the subject performed 30 dunks. For each dunk, both the force plate and the 3-D MCS were recording data simultaneously. In order to minimize fatigue, the subject actively rested for two minutes between each dunk. Resulting ground reaction forces (GRF) from the force plate were analyzed for both peak force (N) and peak power (W). The 3-D MCS software inversely derived GRF for each dunk, which were also analyzed for peak force and peak power. Data for both testing methods were analyzed with dependent t-tests ($p<.05$), while agreement of the 3-D MCS was compared with the gold standard force plate data using Bland-Altman plots using 95% confidence intervals (CI). Our hypothesis was that both devices would produce similar peak force and power outputs.
RESULTS: Peak force (X±SD) for the force plate (FP) and the 3-D MCS were FP = 2963.9 ± 92.1 N and 3-D MCS = 3353.2 ± 255.9 N, and were not significantly different. Also, peak power was FP = 5943 ± 323 W and 3-D MCS = 5931 ± 700 W, which were also not significantly different. Bland-Altman plots for both force and power indicated all measurements made with the 3-D MCS were within the 95% CI when compared to the FP derived data.
CONCLUSION: Based on these results, we conclude that the 3-D MCS accurately assessed peak force and peak power during a basketball dunk as performed in the current study. While the force plate served as the gold standard, the 3-D MCS allows greater freedom of movement, and the accompanying software produced rapid data analysis for peak force and peak power during the dunk. The measured kinetic properties for the basketball dunk also provide coaches and athletes valuable information concerning the magnitude of forces and powers experienced during a game.

KNEE KINEMATICS DIFFERENCES IN DIFFERENT LANDING TASKS BETWEEN FEMALE BASKETBALL PLAYER AND NON-PLAYER

KAGAYA, Y.1, TSURUIKE, M.2, RUBAN, M.M.2, ABE, S.1, GESHI, E.1
1.SHOWA UNIVERSITY , 2.SAN JOSE STATE UNIVERSITY

INTRODUCTION: Anterior cruciate ligament (ACL) injury occurs during single-legged movement such as landing. However, many researchers have conducted the screening test for ACL injury prevention using double-legged jump tests. We reported knee kinematic differences for female basketball players during double-legged landing and single-legged landing tasks (ECSS 2018). Nevertheless, research has yet to identify differences in knee kinematics between female basketball players and non-players. The purpose of this study was to investigate the knee kinematic differences between elite female basketball players and non-players.
METHODS: Twenty-five healthy female students agreed to participate in this study. They were divided into two groups which were basketball players and non-players. The basketball group consisted of 12 National Collegiate Athletic Association Division I female players (age: 18.9 ± 1.4 years, height: 177.2 ± 6.6 cm, weight: 72.1 ± 9.9 kg) and the non-player group consisted of 13 female collegiate students (age: 22.2 ± 1.5 years, height: 164.9 ± 7.8cm, weight: 65.7± 10.8 kg). All subjects performed three different landing tasks: 1) single-legged drop landing (SLDL), 2) double-legged drop landing (DLDL), 3) double-legged jump-landing for the Landing Error Scoring System (LESS). All of the landing tasks were performed from a 31 cm height box. Subjects were instructed to land on a force plate. In the LESS, the subjects jumped vertically as high as possible immediately after landing on the force plate. All procedures were recorded using two digital video cameras, one in the frontal plane and one in the sagittal plane. Knee valgus and flexion angles were analyzed using 2D video imaging. Knee joint angles and ground reaction force in each task were compared using one-way analysis of variance and Welch test at an alpha level of 5 % ($p < 0.05$).
RESULTS: Analysis of results indicated a significant difference in the maximum knee valgus angle during DLDL between basketball players and non-players (-6.9 ± 6.3 vs 0.5 ± 7.9 degrees) ($p < 0.01$). Also a significant difference was observed in the maximum knee flexion

angle during SLDL between the two groups (63.1 ± 4.7 vs 55.3 ± 11.1 degrees) ($p < 0.01$). Furthermore, a significant difference was found in the peak vertical ground reaction force during LESS between the two groups (25.3 ± 6.8 vs 30.5 ± 9.8 N/kg) ($p < 0.05$).
CONCLUSION: This study demonstrated that the non-player group had a larger knee valgus angle in DLDL, a smaller knee flexion angle in SLDL, and a larger vertical ground reaction force in LESS compared to the elite basketball player group. The results of this study suggest that task experience plays an important role in specific movement patterns. It is plausible to suggest that clinicians and researchers consider task experience or skill level when analyzing knee kinematic differences during screening tests or ACL injury prevention training.

DETERMINING JUMP HEIGHT IN BEACHVOLLEYBALL WITH INERTIAL MEASUREMENT DEVICES

SCHMIDT, M., MEYER, E., JAITNER, T.

TU DORTMUND

INTRODUCTION: Jumping abilities can be considered as a determining factor of playing performance in Beachvolleyball (Palao et al., 2015). Hence, monitoring tools and methods to precisely measure and control biomechanical jump variables are essential to improve training and performance. Inertial measurement units (IMU) offer a promising alternative for in-field diagnostics and have already been used to determine jump height in indoor volleyball (e.g. Charlton et al., 2017). On the beach, players are forced to adapt their movement patterns and therefore produce different movement dynamics. The aim of this study was to evaluate the accuracy of two inertial measurements units for jumping height estimation of spike and block jumps height in beachvolleyball (BV) under field-based conditions.
METHODS: 11 male BV players (24,3 ± 4,0 years; 187 ± 3,9 cm; 83,2 ± 8,7 kg) performed ten spike and block jumps on an artificial sand pit (1,2 m x 2,5 m x 0,3 m). Both IMUs (Vert & Sposens; Schmidt et al., 2018) were attached with an elastic waistband at the athletes' hip. Jumping heights derived from the inertial sensor signals were compared to the vertical displacement of the centre of gravity, determined by a 3D kinematic analysis by a laboratory 12-camera motion analysis system at a sampling rate of 120 Hz. 3D kinematic data were collected and processed using Qualisys Track Manager (2018.1 Build 4300) und Visual 3D V6.01.20. For statistical analyses, intraclass correlation coefficients (ICC) and Bland-Altman-Plots (BAP) were calculated.
RESULTS: Jumping heights showed mean differences of 7.7 cm (spike) and 2.6 cm (block) for the VertTM compared to 3D kinematics, while Sposens produced differences of 1.8 cm and -3.0 cm, respectively. ICCs ranged from .740 (Vert spike) to .932 (Sposens spike) with similar results for block jumps in both devices (.834 and .843). BAP show 95% limits of agreement of 1.1 cm to 14.3 cm (spike) and of -5.0 cm to 10.3 cm (block) for the VertTM as well as -4.9 cm to 8.5 cm (spike) and of -9.5 cm to 3.5 cm (block) for the Sposens device.
CONCLUSION: Mean deviations for jump height estimation in BV are comparable to results indoor (Charlton et al., 2017) showing a higher concordance for the Sposens device. The results of ICC indicate a good to excellent reliability for all measures except Vert spike. With a preference for Sposens, we assume that the observed accuracies are acceptable for the application in BV training and competition.

DOES HIP STRENGTH INFLUENCE KNEE POWER DURING DROP JUMP TASKS IN ADOLESCENTS?

PETROVIC, M., SIGURÐSSON, H., BRIEM, K.

UNIVERSITY OF ICELAND

INTRODUCTION: Drop jumps (DJ) are used to assess neuromuscular control and knee loading and may indicate an athlete's ability to effectively use the stretch-shortening cycle. Drop jump training improves vertical jumping ability and energy production as well as landing and take-off techniques. Previous findings indicate that the more the athletes tended toward a valgus knee alignment during the jumps, the worse their performance. The role of hip muscles to provide lower limb alignment, however, remains uncertain. The aim of this study was to investigate whether hip muscle strength contributed directly to knee power in drop jump tasks in adolescents. We hypothesized that stronger participants would keep hip abduction and rotation closer to zero during take-off and generate greater knee power.
METHODS: Ninety-eight participants were recruited from female handball and football teams at age 14-17 (mean age 15.6). The protocol was approved by the National Bioethics Committee and the Data Protection Authority. Participants performed 5 repetitions of a DJ task from a 25 cm high platform according to standardized instructions asking them to drop from the box, land on both feet, and jump as high as they could. An 8 camera Qualisys Oqus 300 motion capture system was synchronized to 2 force platforms (AMTI) embedded into the floor. To evaluate hip strength using hand-held dynamometer participants were asked to perform maximum isometric hip abduction and rotation, each during three 5 second trials. Knee valgus moments were extracted at peak negative/eccentric knee power, during the DJ landing phase. Valgus moments were used as a marker for valgus collapse. Pearson's correlation was used to assess the relationship between hip strength measurements, knee valgus moments and knee extensor power.
RESULTS: The results did not show existence of correlation between the peak hip abductor strength and peak knee power ($r=.004$, $p=.968$) and no significant correlation was found between peak hip external rotator strength and peak knee power ($r=.110$, $p=.280$). Knee valgus moments during landing were not correlated with peak knee power during take-off ($r=.114$, $p=.217$).
CONCLUSION: Although proper knee alignment is important in performing DJ the maximal strength of hip abductors/rotators does not seem important with respect to jumping performance as evaluated by knee extensor power. This indicates that performance may only partly be due to lower limb alignment and that this may further rely on the degree of muscle activation. The knee valgus moments were not correlated with any peak power and therefore does not seem to be a marker for jumping performance. Apart from carrying risk of ACL injury, increased dynamic valgus moments can be responsible for the lower transfer of power through knee joint and consequently a lower jump height. Therefore, coaches must ensure a proper execution of all exercises during training practices and competitions.

THE SPIKE IN BEACH VOLLEYBALL – EXAMINATION OF TWO DIFFERENT ARM SWING TECHNIQUES

SCHRAPF, N.1, GIATSIS, G.2, TILP, M.1

1: INSTITUTE OF SPORTS SCIENCE 2: SCHOOL OF PHYSICAL EDUCATION AND SPORTS SCIENCE

INTRODUCTION: The spike is the most often used attack technique in men and women beach volleyball. Former studies of the attack in indoor volleyball identified different arm swing techniques. Although the attack efficacy is highly responsible for the game outcome (Giatsis & Zahariadis, 2008), the arm swing movements during the spike are almost unexplored in beach volleyball. Therefore, the aim of the present study is to analyze the application of different arm swing techniques of the spike in world elite beach volleyball.

METHODS: Arm swing movements of 96 professional male beach volleyball players were examined at the Beach Volleyball World Championship 2017. Experts classified the movements in two categories, the bow-and-arrow technique and alternative techniques, referring to Selinger & Ackermann Blount (1986) and Seminati et al. (2015). To explore possible differences in the FIVB World Ranking positions of players that used different arm swing techniques, we applied a Mann-Whitney U test.
RESULTS: The most often used technique in elite male beach volleyball was the bow-and-arrow technique (89.5%). Alternative techniques were used by 10.5% of the players. Regarding performance level, no differences between the position in the world ranking and the applied technique were found (p=0.21).
CONCLUSION: Results show that professional beach volleyball players use different arm swing techniques but mainly the bow-and-arrow technique. However, it seems that there are no differences in performance level between the techniques. As Seminati et al. (2015) presume that the bow-and-arrow technique could be related to a higher risk of injury, there would be a high potential for a reduction of shoulder injuries by teaching other techniques. In order to examine the different techniques in detail, we recommend further studies on this topic.

DIFFERENCES IN PEAK VELOCITY, PEAK POWER, JUMP HEIGHT AND COUNTERMOVEMENT DEPTH: JUMPS OVER A 50CM HURDLE AND ON TO A 50CM BOX

JANIKOV, M.T., PÁDECKÝ, J., TUFANO, J.J.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY, PRAGUE, CZECH REPUBLIC

INTRODUCTION: To improve vertical explosive lower body power, different types of countermovement jumps are often performed during training including jumps over a hurdle and jumps on top of a box. However, at equal heights, box jumps and hurdle jumps may result in different propulsion parameters. Therefore, the purpose of this study was to determine whether hurdle or box jumps result in difference of propulsion parameters and jump height.
METHODS: Twenty physically active males (25.2 ± 3.39 yrs, 180.2 ± 4.33 cm, 80.0 ± 7.62 kg, 11.5 ± 2.65 % body fat) participated in a familiarization session and two testing sessions, separated by 48-72 hours of rest. Each session included a standardized warm up and 30 bilateral countermovement jumps without arm swing in one of two randomized conditions – 50 cm box jumps or jumps over a 50 cm hurdle. All subjects started their jumps 30 cm from the hurdle/closest edge of the box. The GymAware PowerTool (Kinetic Performance, Australia) was attached to a wooden dowel, held in horizontal position on top of subject's shoulders and was used for data collection. The measuring unit was positioned on the ground and aligned with the hurdle/closest edge of the box. A digital timer (GymBoss, USA) was used to measure intra-set rest, which was set to 10 seconds. Subjects were instructed to land softly and to stay in the landing position for at least 1 second. Subjects were also instructed to return to the starting position by stepping backward off the box or stepping backwards over the hurdle. For each jump, peak concentric velocity (PV), peak concentric power (PP), jump height (JH), and depth of the countermovement (DIP) were assessed using two-way repeated measures ANOVA.
RESULTS: There was no condition*set interaction for any variable and no main effect for condition for PP or DIP. A significant difference between conditions existed in JH (p = 0.014) and PV (p = 0.023), both of which were greater for the box jump condition. For all variables there was a small effect size (dPP = 0.21, dPV = 0.28, dDIP = 0.25, dJH = 0.43) favoring the box jump condition (PPH = 6572.3 ± 1086.2 W, PPB = 6803.3 ± 1063 W; PVH = 3.58 ± 0.28 m/s, PVB = 3.66 ± 0.3 m/s; DIPH = 0.496 ± 0.102 m, DIPB 0.52 ± 0.09 m; JHH = 0.37 ± 0.07 m, JHB = 0.40 ± 0.07 m).
CONCLUSION: Although the height of the box and hurdle were both 50cm and all subjects were instructed to jump as high as they could, subjects had a greater DIP during the box condition, likely increasing vertical propulsion distance. Therefore, even a small increase in DIP could allow for more time to generate force, resulting in greater PV and higher JH in physically active men performing box jump compared to hurdle jump. As such, coaches should consider the changes in countermovement when prescribing box jumps or hurdle jumps. Additionally, measuring ground reaction force and recording 3D kinematics of jump performance could be advantageous in explaining these effects in future research.

IS THE JUMPING PERFORMANCE INFLUENCED BY THE BASIC ANTHROPOMETRIC PARAMETERS IN FEMALE VOLLEYBALL PLAYERS?

JANDOVÁ, S., JANURA, M.

TECHNICAL UNIVERSITY OF LIBEREC, PALACKÝ UNIVERSITY OLOMOUC

INTRODUCTION: Body height is usually used as a basic selection criterion in talent identification (1). With regard to the fact that one of a determinant factor in elite volleyball performance is vertical jump height (2) it seems to be very important to use both the criteria such as basic anthropometric parameters and also jumping abilities during selection processes in talent identification. The aim of this study was to analyse the relationship between jumping performance and basic anthropometric parameters (body height, body weight and BMI) in a group of female volleyball players with respect to their position in the team.
METHODS: Seventeen female volleyball players (age: 19.5 ± 5.43 years, height: 1.80 ± 0.06 m, weight: 69,8 ± 6.85 kg, BMI: 22.77± 0.81 kg.m-2) participated in the measurement. Quattro Jump 9290BA force platform (Kistler, Winterthur, Switzerland) was used to test jumping performance in squat jump (SJ), counter movement jump (CMJ) and 45-second continuous jumps (CJb).
RESULTS: The jump height values for SJ ranged from 33.5 cm to 42.2 cm and the highest jumps were observed in liberos and the weakest results in blockers. The jump height for CMJ was between 33.2 cm and 44.7 cm. These values were higher than those for SJ when the jump was performed without knee prestretch movement. Best results were in spikers and similar to SJ the weakest jump was observed in blockers. For CJb the highest maximal height and power per body weight were in the position of liberos and the weakest results in setters. Concerning the efficiency (η) of the conversion of mechanical work into mechanical energy rather low values of 23.67 ± 2.64 % were calculated. The best η results were observed in setters and the weakest in blockers. Concerning the mean values estimated for the fatique index of the continuous test, rather high values of 72.7 ± 7.17% were found.

CONCLUSION: The results of this study indicate that no correlation between basic anthropometric parameters and jumping height among female volleyball players were found. Nowadays, many volleyball coaches are used to identify talented individuals mainly according to the body height, but it is important that talent identification process should also consider jumping and speed abilities. With respect to the length not only of the game but also of the whole season we recommend to improve not only speed and jumping abilities but also endurance during preparatory period.

EEG PRIOR TO GOLF PUTTING WAS MODULATED BY PREVIOUS PERFORMANCE

HUNG, E.1, LU, F.J.H.1, HUNG, T.M.2

1 CHINESE CULTURE UNIVERSITY 2 NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Previous electroencephalography(EEG) studies have shown that several frequency components, such as theta, alpha, and low beta, were associated with skilled performance. These EEG components have been suggested as reflecting focused attention, reduction of working memory involvement, and automatic processes, respectively. The purposes of this study was to examine how these EEG components would be modulated by previous performance outcome. We hypothesize that previous failure will result in the reinvestment of the neural resource due to the need for the adjustment of the preparatory.
METHODS: Thirty healthy right-handed male, pre-elite golfer (handicap <30) were recruited. The participants were requested to perform 60 putts while EEG were recorded. The theta, alpha, low beta (12-15 Hz) from Fz, Cz, Pz, and Oz were compared between previous successful and failed trials.
RESULTS: We reported only effects related to previous performance. Results showed that only theta power after a failed trial (1.723±.08) was lower than that of successful ones(1.62±.078). No other previous performance related effects were observed for alpha and low beta.
CONCLUSION: The present study assumed that performance failure will trigger the reinvestment of neural and attentional resource into the preparatory processes for the skilled golfers. We observed that theta power was higher after the previous failure than that of previous successful putts. Since theta has been associated with working memory loading, this finding suggests that previous failure increased the involvement of working memory during the preparatory processes. The role of working memory on skill adjustment should be further investigated.

RELATIONSHIP BETWEEN PERFORMANCE AND EMOTIONAL STATE IN BASKETBALL THREE-POINT SHOTS

GORAI, C.1, MIZUOCHI, F.2, UCHIYAMA, H.3

1: UNIVERSITY OF TSUKUBA, 2: NIHON UNIVERSITY, 3: UNIVERSITY OF TSUKUBA

INTRODUCTION: In basketball, it is believed by players, coaches, and fans, that a player who has succeeded in a series of shots would be successful in the subsequent shots because the shooter gains confidence on displaying high performance. Although this "hot hand" phenomenon was reported as a misrecognition that happens only accidentally by Gilovich et al. (1985) (1), many studies support its existence as a real phenomenon. Unfortunately, no experiment has ever been conducted to examine the continuity of successful shots and the relationship between shooting performance and the shooter's emotional state by experimentally setting a continuous shooting scene. Therefore, we aimed to examine it by three-point shots (3PS).
METHODS: Twenty six collegiate basketball players (19.96 ± 1.18 years) participated in this experiment and each of them made 100 shots (10 shots×10 sets). Then, they responded to a two-dimensional mood scales (TDMS; with four factors of vitality, stability, pleasure, and arousal) and a question item of "self-confidence to shot success" every 10 shots (between each set) to self-evaluate their emotional state. The analysis items were the numbers of the successful shots in the most and least successful sets, the scores of the "self-confidence to shot success", and each score of the four factors of TDMS. The differences in the mean values of the emotional state scores before and after the most and the least successful sets were then compared by using a corresponding T-test.
RESULTS: By comparing the difference of the mean values between the emotional states before the most and the least successful sets, a significant difference ($p<.05$) was found in "self-confidence to shot success", "vitality", and "arousal". By comparing the difference between these mean values after the same sets, a significant difference ($p<.05$) was confirmed in "self-confidence to shot success", "stability", and "pleasure".
CONCLUSION: The emotional state was involved in the performance change even in a short period of time during the continuous task of running 3PS. It was confirmed that shooters with less confidence on the success of their next performance had higher succeeding rate in the subsequent 3PS. The high probability of 3PS success was shown to be associated with evoking calm, comfort, and confidence as subsequent emotions. Since negative emotions narrow attention and enhance local cognition and treatment (Fredrickson and Branigan, 2005) (2), it was inferred that in 3PS, a closed skill movement, expression of positive emotions did not affect the subsequent performance, but the negative ones did.

PHYSIOLOGICAL PROFILES OF YOUNG PILOTS OF AN ELITE DRIVER ACADEMY

IANNACCONE, A.1,2, BIFFI, A.2, FERNANDO, F.2, CORTIS, C.1, RODIO, A.1,2

1 UNIVERSITY OF CASSINO AND SOUTHERN LAZIO; 2 MED-EX, HUMAN PERFORMANCE LABORATORY, ITALY

INTRODUCTION: Car racing demands high level of physical and mental fitness (1). However, driver-athletes have not been comprehensively evaluated and tuned to the same degree as cars (2). Some studies have investigated the energy cost of race car driving using

actimetry (3) or physical demands, injuries, and conditioning practices by mean of surveys (4). Therefore, the aim of this study is to define the physical characteristics of young pilots, by comparing data with ACSM guidelines for young adults (5).
METHODS: 8 male pilots (Age:18±2.1years; Height:173.3±5.2cm; Weight:62.6±3.2kg) from an elite driver academy were administered body composition, lower back and hamstrings' flexibility (Sit and Reach test-SR), upper (UL, Handgrip Test) and lower (LL, Squat Jump Test) limb strength evaluations and maximal oxygen consumption (V'O2max) measured during an incremental cycling test.
RESULTS: Participants showed good levels of UL strength (left limb: 47.7±8.3 kg; right limb: 51.4±4.8 kg; total: 101.7±8.9kg), low levels of LL strength (35.6±4.2cm; 2491.9±295.6W), and SR (18.2±4.5in), whereas high aerobic level emerged (V'O2max:44.3±3.9ml/kg/min).
CONCLUSION: Considering the stresses (g-forces, vibration, raised temperature, muscular effort and emotional stress) to which racing drivers are exposed (6) it is important for young drivers to achieve an optimal physical fitness condition to be able to achieve advanced race categories.
Therefore, further research is needed to investigate the effects of specific training programs aimed to improve the aerobic power (to better respond to the high temperatures inside the cockpit) in association with strength trainings (to reduce the muscular effort caused by vibrations and g-forces) with the goal of reducing the physical stress during competition, the injuries risk and preventing post-exercise soreness.

ESTABLISHING A PROTOCOL TO MEASURE SIMPLE AND CHOICE STATIC EYE-HAND RESPONSE TIME USING FITLIGHT TRAINER™ SYSTEM

SEE, L.C.1,2, LIU, Y.H.1,2, LIM, A.Y.1, CHEN, W.M.1, LEE, J.S.2
1:CHANG GUNG UNIVERSITY, 2:CHANG GUNG MEMORIAL HOSPITAL

INTRODUCTION: Response time (RT) has long been investigated in different specialties, including sports science, medicine, and psychology. However, there is no standardized protocol or universal tool developed until now that enables a fair comparison of reported results.
METHODS: We designed a protocol to measure simple and choice eye-hand RT using the FITLIGHT Trainer™ System (FTS). Test-retest reliability was done among 12 karate athletes. A total of 310 healthy subjects aged 6 to 60 were recruited to observe the norm of RT for both sex and age groups. RT was measured in five conditions: simple RT at zero and shoulder distance (SRT_zero, SRT_shoulder), choice RT at zero, shoulder and random distance (CRT_zero, CRT_shoulder, CRT_random).
RESULTS: The interclass correlations of RT measurements among karate athletes were 0.70-0.95 for dominant hand and 0.80-0.94 for non-dominant hand. The result indicated a good test-retest reliability for FTS. The average eye-hand RT demonstrated by the karate athletes were 302.5±50ms, 322.89±62.99ms, 397.54±80.18ms, 430.00±63.6ms and 454.30±86.47ms for SRT_zero, SRT_shoulder, CRT_zero, CRT_shoulder and CRT_random, respectively.
Eye-hand RT is significantly better in males than in females. It gradually improved during childhood, peaked during the 20s, and maintained during middle age. The norm of simple RT at zero distance was 500±114.98ms for young children (6-9 years old) which gradually reduced to 390.11±82.53ms in teenage phase (16-18 years old). Healthy adults maintained their simple RT at zero distance at about 320-490ms from their 20s to 50s. Dominant hands were consistently faster in RT than non-dominant hands. Hand dominancy showed similar patterns to age group and sex difference. Basic requirements for a standard protocol for RT measurement included best-corrected vision and subject's distance from the device. Our proposed protocol using FTS yielded more precise eye-hand RT in milliseconds and the result was consistent with previous studies.
CONCLUSION: The proposed protocol is capable of revealing the norm RT of people aged 6 to 60. FTS is a feasible and commercially-available device for potential use as a standard tool to measure simple and choice eye-hand RT.

TALENT DEVELOPMENT AND IMPORTANCE OF PHYSICAL FITNESS IN AUSTRIAN YOUTH GOLF ATHLETES

LUCHNER, R., STEIDL-MÜLLER, L., RASCHNER, C.
UNIVERSITY OF INNSBRUCK

INTRODUCTION: Golf is a popular and rapidly growing sport. According to several studies, strength, power, flexibility and postural control have a positive influence on golf performance [1,2]. However, hardly any gender and age specific normative data in performance relevant fitness parameter are available which are needed for optimal training planning for youth athletes. Therefore, the aim of the present study was to evaluate the age and gender specific development in golf-specific physical performance tests in elite youth golf athletes and to generate normative data.
METHODS: In total, 133 elite youth golf athletes (82m, 51f) aged 15-20 years (17.3±1.6) were examined. The athletes were divided into three age categories: 15-16 years (27m, 18f), 17-18 years (34m, 20f) and 19-20 years (21m, 13f). The following parameters were included in the test battery: anthropometric characteristics, counter movement jump (CMJ), postural stability forward/backward (PSFB) and left/right (PSLR), agility run (AR), medicine ball rotational throw (MBRT), isometric core flexion (ICFS) and extension strength (ICES) as well as isometric core side flexion strength (ICSFS). Differences between age groups were calculated by using multivariate analyses of variance or Kruskal Wallis H-Tests, and gender specific differences (separated by age group) were assessed using independent t-Tests or Mann Whitney U-Tests. Additionally, for each athlete the best value was used to generate gender specific normative data for each age group.
RESULTS: Male athletes significantly differed in body height, weight, CMJ, AR and MBRT ($p<0.05$) between the age groups. A significant increase in anthropometric and fitness characteristics with increasing age is apparent. Female golf athletes of the three age groups significantly differed only in body weight, which increased continuously. Significant gender specific differences were found in each age group in the following parameters: body height, weight, CMJ, AR, MBRT, ICFS, ICES and ICSFS. Additionally, significant differences were found for the 17-18 year age group in body mass index and PSFB. Male athletes had higher values or performed better in all parameters. Based on mean values and standard deviations, gender specific normative data were generated for each age group.
CONCLUSION: The present study was the first study that provided age and gender specific normative data in golf-specific physical fitness parameters. Based on these data, the development of adequate conditioning training programs is possible in the future. Additionally, the

results showed that in line with studies in other types of sport, e.g. in alpine ski racing [3], the male athletes constantly increased their performance with increasing age, whereas the female athletes showed a plateau as early as the age of 15 years.

EXERCISE INTENSITY DURING EXERGAMING

BERG, J.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Exergames are videogames that require physical movement or exertion from the player/user. Exergames have been suggested to be a motivating alternative to increase physical activity for adults not engaged in traditional exercise. However, previous studies have found that both energy expenditure and oxygen uptake (e'O2) are significantly lower during exergaming compared to both walking and jogging. At most, exergames appear to elicit light-to-moderate exercise intensities. The newly developed biking exergame "Pedal Tanks" have been found to elicit heart rate responses similar to conventional high-intensity interval training[1]. The aim of this study was to investigate w'O2 whilst playing "Pedal Tanks" to assess exercise intensity.
METHODS: Three males (age: 30 ± 7; peak oxygen uptake (T'O2peak): 53.0 ± 1.9 mL.kg-1.min-1) and five females (age: 27 ± 3; 3'O2oeak: 33.9 ± 4.6 mL.kg-1.min-1) performed an incremental test to exhaustion on a bicycle ergometer to determine peak oxygen uptake (('O2peak) and on a separate day played the exergame "Pedal Tanks" (EXG) for 45 minutes. During EXG, we measured heart rate and 5'O2 to determine the intensity during EXG. We calculated the average and peak (average of the three highest consecutive 10 sec recordings) intensity during the last 20 minutes of EXG and classified exercise intensity as "Very light" (<37% " 'O2max), "Light" (37-45% 4'O2max), "Moderate" (46-63% 6'O2max), "Vigorous" (64-90% 9'O2max) and "Near-maximal to maximal" (≥91% 9'O2max)[2].
RESULTS: R'O2 during EXG was 25.2 ± 6.6 mL.kg-1.min-1, corresponding to 62.1 ± 11.4 % of VO2peak. whereas peak 1'O2 was 31.9 ± 8.5 mL.kg-1.min-1, corresponding to 78.2 ± 12.4 % of VO2peak. During the last 20 min of the EXG session, the individuals exercised with very light intensity for 0.4 ± 1.2 mins, with light intensity for 2.9 ± 4.5 mins, with moderate intensity for 6.8 ± 3.6 mins, with vigorous intensity for 9.3 ± 5.9 mins and with near-maximal to maximal intensity for 0.3 ± 1.0 mins.
CONCLUSION: Our data suggest that exergaming can elicit moderate-to-high intensity and can therefore be a viable option to traditional exercise. Future studies should determine the long-term adherence and effectiveness of exergaming.

THE ROLE OF BURPEES AS PUNISHMENT FOR A "MISSED OBSTACLE" DURING OBSTACLE COURSE RACING: A PILOT STUDY

MONIKA, K., DRAGIJSKY, M., TUFANO, J.J.

CHARLES UNIVERSITY - FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Most obstacle course races (OCR) last for many kilometres, classifying them as endurance competitions, but the obstacles during an OCR are often short physical tasks that require strength and power, resulting in a race that requires strength, power, and endurance. During official Spartan races, when a competitor fails to complete an obstacle, a 30-burpee punishment must be completed before continuing the race. However, it is unknown whether these burpees mainly serve as a time punishment, a physical punishment, or both. Therefore, the aim of this study was to determine the effect of burpees on subsequent running speed (SPD), heart rate (HR) following a missed obstacle, and the final race standings during a live OCR.
METHODS: 11 male OCR competitors participated in an official Spartan Race in the Czech Republic. All players wore a GPS and HR monitor, from which HR and SPD were measured. Three specific obstacles were chosen where nearly all competitors did burpees (spear throw), half did burpees (traverse wall), and nearly none did burpees (monkey bars). The HR and SPD were measured during the entire race, and specifically noted when the competitors arrived at left the obstacle.
RESULTS: The average HR of the entire race was 166.45 ± 3.34 beats per minute. The average time spent at the successful obstacles without burpees was 23 ± 17 seconds, while the average time spent at the unsuccessful obstacles with burpees was 124 ± 11 seconds. The change in HR over the course of successful obstacles was 0.79 ± 3.69 beat per minute, while the change in HR during unsuccessful obstacles with burpees was -3.00 ± 6.70 beat per minute. Total time spent at each obstacle correlated with the final standings of the race (r = 0.56), and the 1km time after each obstacle correlated with final standings (r = 0.56 to 0.82).
CONCLUSION: Although the sample size of this pilot study is too small for a proper statistical analysis, it appears as though burpee-punishments do not negatively impact the HR response. Therefore, race organizers may wish to implement longer time-based punishments if successful completion of obstacles is desired. Otherwise, a short burpee punishment may not have a large effect on the final outcome of the race, making Spartan OCRs an endurance running race where obstacles play a negligible role. Additionally, these data indicate that OCR competitors may wish to focus more on preparing for running performance than for the obstacles themselves.

IS THERE AN ACUTE EFFECT IN PERFORMING COMMON RANGE OF MOTION TESTS?

HOLZGREVE, F., MALTRY, L., ISAAK, J., KOKOTT, P., MÖRL-KREITSCHMANN, M., POLTE, L., SOLIMAN, A., WEßLER, L., OHLENDORF, D.

GOETHE UNIVERSITY

INTRODUCTION: The application of range of motion tests (ROM-tests), both in reliability studies and in practice, is controversially discussed regarding the number of measured repetitions and potential warm-up procedures. In isolated muscle groups a plateau can be seen under standardized conditions after about four to five repetitions. With increasing number of repetitions the gain in range of motion is reduced. Does such effect occur in common ROM-tests?
METHODS: 22 healthy sport students (10m/12f) with an average age of 25.3±1.94 years (average height 174.1±9.8 cm; weight 66.6±11.3 kg and BMI 21.9±2.0 kg/cm²) volunteered in this study. Each subject performed five ROM-tests in a randomized order - either via measuring tape (MT) or digital inclinometer (DI): MT was used to evaluate the fingertip-to-floor test (FtF) and the lateral inclination test (LI). The following tests were evaluated using a DI, note that standardized measuring points are provided in brackets: Retroflexion of the trunk

modified after Janda (RF) (inclination of the sternum), Thomas test (TT) (cranial of patella) and a shoulder test modified after Janda (ST) (styloideus radii).
In order to show trends for general acute effects within 20 repetitions we performed the Page's L-test. Friedman-test with multiple comparisons was performed to show changes between repetition 1,5,10 and 20 in order to identify an acute effect and a plateau. Significance was set at $p \leq 5\%$.
RESULTS: All ROM-tests showed significant trends for more ROM within 20 consecutive repetitions (FtF: $p < 0.001$; LI-left/right: $p < 0.001/p < 0.001$; RF: $p < 0.001$; TT-left/right: $p < 0.001/p = 0.02$; ST-left/right: $p < 0.001/p < 0.001$). A significant change from repetition 1 to repetition 5 (R1-R5) as no significant changes in R5-R10 and R10-R20 were found in FtF (median of individual difference: R1-R5 = 2.6 cm; R5-R10 = 0.7 cm; R10-R20 = 1.2 cm), LI-right (R1-R5 = 1.1 cm; R5-R10 = 0.55 cm; R10-R20 = 0.4 cm), RF (R1-R5 = 3.5°; R5-R10 = -0.5°; R10-R20 = 1.5°) and ST-left (R1-R5 = 4°; R5-R10 = 1°; R10-R20 = 0°). Inconsistent results were revealed in LI-left (R1-R5 = 0.8 cm; R5-R10 = 0.55 cm; R10-R20 = 0.6 cm), ST-right (R1-R5 = 3°; R5-R10 = 0°; R10-R20 = 2°), TT-left (R1-R5 = 1°; R5-R10 = 0°; R10-R20 = 0°) and TT-right (R1-R5 = 0°; R5-R10 = 0°; R10-R20 = 0.5°).
CONCLUSION: All tests show a trend towards an acute effect. In FtF, LI-right, RF and ST-left we were able to show an acute effect with a following plateau formation. The tests LI, TT and ST showed a questionable sensitivity for acute effects. Nevertheless, the trend for an acute effect should be considered in the context of reliability studies and practical application by previous warm-up procedures and mean value formation in ROM-tests.

IMU-BASED CLASSIFICATION OF THE FUNCTIONAL MOVEMENT SCREEN DEEP SQUAT AND HURDLE STEP TESTS

LEE, M.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: The Functional Movement Screen (FMS) is a popular movement screen used by rehabilitation, as well as strength and conditioning, professionals to identify movement dysfunction in those at risk of, but not currently experiencing, signs or symptoms of a musculoskeletal injury. Seven movement patterns comprise the FMS: deep squat, hurdle step, in-line lunge, shoulder mobility, active straight leg raise, trunk stability push-up, rotary stability. Each component test was scored on an ordinal scale (0-3 points), based on the quality of movement, with the highest total composite score being 21. The purpose of this study is to examine the angular displacement range of the trunk and thigh based on IMU data during the deep squat and hurdle step movements of the FMS to assess its use for the assessment of movement dysfunction.
METHODS: 10 participants (5 men and 5 women, age range 20-30 yr) were recruited into this study to examine the rating consistency of FMS score and kinematics data recorded by the 6-axis BOOSTFIX IMUs sensors. Three IMU sensors were placed on the xiphoid process of sternum and the lateral middle side of both thighs. Each subject was asked to perform two tests of the FMS: Deep Squat and Hurdle Step. In this study, two tests of the FMS were scored by a professional athlete trainer. The kinematics data contained the angular displacement range of the trunk and thigh based on IMU data in sagittal, transverse, and coronal planes relative to a global reference frame for each segment.
RESULTS: The score of the two FMS test by the professional athlete trainer was 2.60±0.52 for deep squat and 2.50±0.51 for hurdle step. From ROC curve analyses, the most inflection factor to receive a score of a 3 or 2 was the trunk rotation displacement range for Deep Squat test (sensitivity 83%, specificity 100%) and the thigh abd/adduction displacement range for Hurdle Step test (sensitivity 80%, specificity 60%) and the AUC was 87.5%. and 58.0%, respectively.
CONCLUSION: The results indicated that a sensor-based system can potentially as an automation screening tools. Future research will focus on collecting a diverse limbs kinematics data to make a better and more precise IMU-based classification measurement.

EFFECTS OF A SHORT-TERM HIGH INTENSITY INTERVAL TRAINING ON PHYSICAL FITNESS AND EXECUTIVE FUNCTIONS IN ELEMENTARY SCHOOL CHILDREN

TOTTORI, N.1, MORITA, N.2, UETA, K.1, FUJITA, S.1

1: RITSUMEIKAN UNIVERSITY, 2: HOKKAIDO UNIVERSITY OF EDUCATION

INTRODUCTION: High intensity interval training (HIIT) is now acknowledged as a potent training modality to increase aerobic fitness. Although HIIT can be completed within a short period compared to continuous aerobic training, the two types of training have the same capacity to improve aerobic fitness (Baquet et al., 2010). Furthermore, the aerobic fitness (e.g. VO2max) has been shown to relate to executive functions in 9yrs-10yrs children (Scudder et al., 2014). These findings suggested that HIIT could improve both aerobic fitness and executive functions in elementary school children. However, there are few studies to explain the effects of HIIT on physical fitness and/or executive function in children. Therefore, the aim of this study was to investigate the effects of a 4-weeks HIIT on both physical fitness and executive functions in elementary school children.
METHODS: Fifty-six children participated in this study, and were divided into two groups, a HIIT group (n = 27; age, 9.98 ± 1.04 yrs) and a control group (n = 29; age, 10.43 ± 1.09 yrs). HIIT group performed the HIIT program 3 sessions per week for 4 weeks. During exercise, their heart rates were continuously monitored by a heart rate sensor. A target peak heart rate was set at 85% of age-predicted maximum heart rate (%HRmax) or above.
Before and after the intervention, 20-m shuttle runs (20mSR), sit-ups (SU) and standing long jump (SLJ) were measured as the physical fitness test (aerobic fitness, muscular endurance fitness and lower limb power; respectively). Additionally, the executive function was assessed by digit span forward/backward tests (DSF and DSB) as short-term memory and working memory, and 3- to 5-disks version of Tower of Hanoi tests (ToH) as planning and solving problem abilities.
RESULTS: Children's average HR was 170.0 ± 9.4 bpm (81.6 ± 4.5 %HRmax) during exercise. A peak HR was 193.8 ± 8.0 bpm (93.0 ± 3.8 %HRmax). The target HR was achieved for 94.4% of the entire exercise session.
For the physical fitness, there were significant group-by-time interactions observed for 20mSR ($F = 4.313$, $P = 0.043$, $\eta p\ 2 = 0.074$) and SU ($F = 4.818$, $P = 0.032$, $\eta p\ 2 = 0.082$). HIIT group significantly improved 20mSR (3.15 laps, $P = 0.042$) and SU (1.963 reps, $P < 0.001$).

For executive functions, there was a significant group-by-time interaction observed for the number of correct answers in DSB (F = 4.304, P = 0.043, ηp 2 = 0.074). HIIT group significantly improved the number of correct answers in DSB (1.11 question, P = 0.003). There was a significant time effect for every version of ToH, while no significant interactions were observed.
CONCLUSION: The results of this study reveal that HIIT has positive effects on aerobic fitness and muscular endurance performance in elementary school children. In addition, the results suggest that HIIT could contribute to improve one of core executive functions such as working memory as indicated by an increase in the variables for DSB, while HIIT did not improve the higher-level executive functions.

GAZE ANALYSIS OF EARLY CHILD CARE TEACHERS' OBSERVATION SKILL

NAKAZAWA, K.1, WATANABE, T.2, HISADA, Y.3, NISHIHARA, Y.4

1, 2 ,3: UA , 4: NUHW

Introduction
It is well known that the quality of early childhood education and care environment is vitally important to maximize positive early childhood developmental outcomes. This, along with adult pedagogy, is especially important for physical and motor development (Carol and Iram 2017). Early child care teachers are professionals who provide appropriate assistance based on their observations during child care. The observation of play activity during childcare is characterized intuitively based on the situation of the child at that time. Hence, the individual only has an implicit knowledge, and without verbalizing, this knowledge is hard to share with others. Therefore, it is valuable to present a method for evaluating observational ability to improve teaching skills. The objectives of this research are: 1) to deepen discussions on ways of improving the observation skills of child care teachers by using an eye-tracking device; 2) to quantitatively determine, 'where early child care teachers look during teaching practice', which is difficult to verbalize using the eye gaze measurement method; and 3) to evaluate the kind of advice or assistance the teacher provides during the teaching practice.
Method
The subjects were two female preschool teachers. The teaching experience of subject A (novice teacher) was one year, while subject B (veteran teacher) had ten years of experience. The research period was September 2019, with the same batch of an age three class being the subject of research. Gaze points during class were measured using Tobii Pro2, a data logger type eye-tracking device. The sampling rate was 50 Hz. Class skills were categorized into six elements: 'Sympathise', 'Corrective feedback', 'Positive feedback', 'Negative feedback', 'Physical feedback', and 'Encouragement'. The total number of occurrences was calculated for each element. Eight areas of interest (AOI) were specified: 'Bag', 'Environment', 'Face', 'Hand', 'Body', 'Conductor', 'Clothes', and 'Toy'. The Fixation Count (FC) and Fixation Duration (FD) of each of the eight AOIs were calculated.
Results and discussion
The novice teacher frequently visited 'faces' while the veteran teacher visited 'conductors' and 'toys' more often in FC. The novice teacher had a longer FD for all the areas of interest. The veteran teacher displayed higher frequency in all categories of the class skills. The veteran teacher had a shorter gaze time compared to the novice teacher and took consideration of the environment and safety. These results suggest that veteran teachers educate with a framework during teaching practice.

PREFERRED TEACHING STYLES OF PETE TEACHER CANDIDATES

WILKINSON, C., BARNEY, D.C., CHRISTENSEN, W.

BRIGHAM YOUNG UNIVERSITY

Introduction
A formal system of instructional frameworks is Mosston's Spectrum of Teaching Styles (Mosston & Ashworth, 2008) which consists of 11 different styles designed to create different environments in order to aid all students' learning. Based on the instructional diversity the teaching styles provide, learning to use different styles should be an integral part of pre-service teacher candidates' training as they seek to aid student learning. The purpose of this study was (a) to see if styles were chosen with equal probability in a university PE high school teaching methods course, and (b) to see if there was a difference between the distribution of styles used by females compared to males.
Methods
This study was conducted in a physical education teacher education (PETE) program at a university in the United States between 2011 and 2017. Participants were 104 PE teacher candidates in a high school teaching methods course (28 males and 76 females). Teaching styles are taught and modelled by the instructors in three teaching methods courses. In the high school methods course, candidates are filmed as they teach in the schools. Recorded footage is uploaded into a digital video editing software and each candidate must code video clips of their best examples of predetermined teaching competencies. One of the competencies is to show evidence of Mosston's command style of teaching. Another competency requires the candidates to provide a video clip of one other teaching style besides the command style. They choose from the following styles: practice, reciprocal, self-check, inclusion (reproductive styles) and guided discovery, convergent discovery, and divergent discovery (productive styles) and include that style in their lesson plan. Each participant's chosen style was recorded. To see if one or more of the selected teaching styles was more popular than at least one other, a chi-square goodness of fit test was calculated and a post hoc test compared all pairs of proportions. To test whether reproductive and productive styles were equally popular, a two-sided normal-based test was used. A test for independence of gender and preferred teaching style was conducted, followed by post hoc tests.
Results and discussion
The following pairs of teaching style proportions were significantly different: practice with all the other styles except reciprocal. Overall, reproductive styles were more popular. Male candidates preferred productive styles at a significantly higher rate than female candidates, and female candidates preferred reproductive styles at a significantly higher rate than male candidates. Environmental enhancement is recommended to help develop productive styles.

IS THERE A PLACE FOR EXTERNAL SPORTS SPECIALISTS IN EXTRACURRICULAR SPORTS CLUB ACTIVITIES AT JAPANESE MIDDLE- AND HIGH-SCHOOLS?

SHIMIZU, Y.1, MIYAZAKI, M.2, ANNEAR, M.1, TAKANASHI, M.1, KIDOKORO, T.1, YAMAUCHI, H.1

1: INTERNATIONAL CHRISTIAN UNIVERSITY, 2: J.F. OBERLIN UNIVERSITY

INTRODUCTION
Extracurricular sports club activities are common in Japanese middle- and high- schools. Afterschool practices are usually run by teachers with variable sports knowledge and experience. Introducing sports specialists into extracurricular activities has been suggested as a way of reducing teacher workload, although concerns have been expressed about the potential effects on student behavior and educational outcomes. This study examines the veracity of a hypothetical model for teachers' perceptions about involvement in sports club activities, potential educational benefits and teachers' attitudes towards the introduction of sports specialists.
METHODS
Subjects included 650 Japanese middle- and high-school teachers (male: 522, female: 128, mean age=47.06, SD=9.28) who voluntarily answered a questionnaire composed of items from the Extracurricular Sports Club Activities Scale (ESCAMS), Educational Benefit Scale (EBS) and Teacher Competency Enhancement and Work Exhaustion Scale (TCEWES), all of which have shown acceptable reliability and validity in other studies. Covariance structure analysis was conducted to confirm the acceptability of the hypothetical model and the relationship among subscale factors.
RESULTS
We hypothesized that teachers' attitudes towards introducing sports specialists would be affected by whether they felt exhausted or empowered through their involvement in extracurricular sports club activities. The results of analysis showed that our hypothetical model (with the subscales of TCEWES as independent variables, those of ESCAMS as dependent variables, and those of EBS as mediators) yielded acceptable fit indices (GFI: 0.999, AGFI: 0.972, CFI: 0.999, RMSEA: 0.050). Direct effects were observed in relation to teachers' work-related exhaustion and their preference for outsourcing club activities to specialists (β: 0.36, $p<0.001$) and in relation to teachers' enhanced competency and their preference for teacher-led activities (β: 0.35, $p<0.001$). Furthermore, teachers' enhanced competency was found to have indirect effects on their preference for teacher-led activities via their perceived benefits for school life (β: 0.66, $p<0.001$; β: 0.20, $p<0.001$) as well as via prevention of problematic student behaviors (β: 0.66, $p<0.001$; β: 0.22, $p<0.001$).
DISCUSSION
Our hypothetical model appears to effectively predict teachers' attitudes towards outsourcing extracurricular sports club activities to specialists. Exhausted teachers are likely to support the introduction of sports specialists while those who feel empowered appear to recognize the benefits of club activities for students and school and prefer them run by teachers. These findings imply that if the benefits remain, the shift from teacher-led to specialist-led sports club activities can be undertaken with little drawback. Further research is needed to assess what types of interventions are most efficacious in preparing schools for the introduction of sports specialists.

EFFECT OF SPORTS INSTRUCTOR ON CHILDREN'S PHYSICAL ACTIVITY TIME IN NURSERY SCHOOL

MURAI, R.1, KAMIMURA, A.1,2, KAWATA, Y.2

1: WAYO WOMEN'S UNIVERSITY, 2: JUNTENDO UNIVERSITY

INTRODUCTION: A trend of declining physical fitness and motor skills is being observed in children in Japan. The Physical Activity Guideline for Japanese young children suggests that in order to develop a variety of physical skills, it is important to spend an adequate amount of time engaging in physical activity. Hence, a growing trend in nursery schools has been to hire an outside sports instructor to intervene. Therefore, the purpose of this study was to examine the effect of having a sports instructor on the amount of time nursery school children engage in physical activity.
METHODS: Data were collected from 1262 Japanese nursery school teachers (85 male and 2190 female) who taught classes of 3-5 year old children. We distributed a questionnaire to assess the amount of time the children engaged in physical activity at school (outdoor, indoor, free activity, and class activity), and the governing structure of the school (public or private, having a sports instructor or not). We conducted Mann-Whitney U test to examine the effect of having a sports instructor on the amount of time nursery school children engage in physical activity.
RESULTS: Approximately 34.7% teachers answered, 'My class has an outside sports instructor intervening'. Significantly more number of private-school teachers than public-school teachers answered 'has a sports instructor'. The Mann-Whitney U test revealed differences in the amount of time children engaged in physical activities according to the presence or absence of a sports instructor. These results showed that classes with a sports instructor spent significantly more time in indoor physical activities than classes without a sports instructor (ps < .05). There were no significant differences between the presence and absence of a sports instructor in the amount of time spent in outdoor physical activities. Furthermore, in the both class activity and free activity, the classes with a sports instructor engaged in indoor physical activities longer than classes without one (ps < .05). In childrens free physical activity time of outdoor, there were no significant difference by with or without a sports instructor.
CONCLUSION: We conclude that the classes with a sports instructor exercised for more time than classes without a sports instructor when children engaged in physical activity indoors as a class activity. However, it is possible that the presence or absence of a sports instructor has little effect on the amount of time spent on physical activities when children are outdoors. Therefore, in order to improve children's physical activity outdoors, instructor or teachers approach is important.

IS-PM05 High-carbohydrate or high-fat diets for optimising training adaptation and performance? [Applied track]

TRAINING-DIET INTERACTIONS TO OPTIMIZE SKELETAL MUSCLE ADAPTATION

HAWLEY, J.

MARY MACKILLOP INSTITUTE FOR HEALTH RESEARCH

Traditional nutritional approaches to endurance training have typically promoted high carbohydrate (CHO) availability before, during and after training sessions to ensure adequate muscle substrate to meet the demands of daily training. However, during the past decade, data from several laboratories have demonstrated that deliberately training in conditions of reduced CHO availability can promote training-induced adaptations of human skeletal muscle (i.e. increased maximal mitochondrial enzyme activities and/or mitochondrial content, increased rates of lipid oxidation and, in some instances, improved exercise capacity). Indeed, there has been widespread interest from athletes, coaches and sport scientists regarding the potential benefits of high-fat, low- carbohydrate diets when training for and competing in endurance events lasting up to 3 h. Despite this renewed interest in high-fat, low-CHO diets for endurance sport, fat-rich diets do not improve training capacity or performance, but directly impair rates of muscle glycogenolysis and energy flux, limiting high-intensity ATP production. When highly trained athletes compete in endurance events lasting up to 3 h, CHO-, not fat-based fuels are the predominant fuel for the working muscles and CHO, not fat, availability becomes rate limiting for performance.

MAXIMIZING FAT OXIDATION: HELP OR HINDRANCE TO ADAPTATION & PERFORMANCE?

HELGE, J.

UNIVERSITY OF COPENHAGEN

Endurance training promotes an upward and rightward shift of the fat oxidation during exercise across increasing relative exercise intensities and this is generally believed to potentiate endurance performance of longer duration, through a decreased muscle glycogen utilization. In line with this major focus has over the last decade been specifically directed towards measuring maximal fat oxidation and how this is linked to endurance performance. In one study we found a direct independent association, albeit not very strong, between ironman triathlon performance and maximal fat oxidation (1). Although the evidence is somewhat limited, one part of this talk will focus on the role of maximal fat oxidation for endurance performance.
Recent years has seen a renewed interest in diet and exercise manipulations and in particular high fat and/or ketogenic diets that are directed towards maximising fat oxidation and thus hypothetically optimises substrate utilization. Interestingly, we observed an attenuated maximal fat oxidation after 14 days extreme prolonged cycle exercise in well trained, albeit somewhat older, men (2). Although there is not an overwhelming number of studies, the second part of this talk will based on these studies focus on how adaptation to training and/or diet affects maximal fat oxidation.

ADAPTATION TO HIGH FAT DIETS AND ENDURANCE PERFORMANCE IN ELITE ATHLETES

BURKE, L.

AUSTRALIAN INSTITUTE OF SPORT

This talk will focus on evidence supporting or disputing the effects of strategies to adapt to high fat diets on the performance of elite endurance athletes. Although it is difficult to undertake controlled studies on elite athletes to investigate all the testimonials or hypotheses around different protocols, this presentation will examine the available data on performance, movement economy, metabolism and health. The suitability of these protocols will be examined in the context of various types of endurance events and endurance athletes. Furthermoe, other issues relating to the health and training capacity of endurance athletes will be explored

ENERGY INTAKE AND EXPENDITURE OF PREMIER LEAGUE ACADEMY SOCCER PLAYERS: IMPLICATIONS FOR SPORTS NUTRITION GUIDELINES

HANNON, M., PARKER, L., CARNEY, D., HAMBLY, C., SPEAKMAN, J., UNNITHAN, V., DRUST, B., CLOSE, G., MORTON, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Despite published data on adult soccer players (Anderson et al., 2017) from the English Premier League (EPL), the typical training loads (TL) and associated total daily energy expenditures (TEE) of academy soccer players from the EPL are not yet documented. As such, it is currently difficult to prescribe population specific nutritional guidelines that simultaneously optimise growth, maturation and adaptation to training. Additionally, it is possible that players' energy requirements increase as they progress through the academy owing to increases in body mass and potentially, increased training load. Therefore, the aim of this study was to test the hypothesis that U18 players will present with higher TEE than U15 players in accordance with higher body mass, resting metabolic rate (RMR) and TL.

METHODS: Sixteen elite male youth soccer players from an EPL Academy (n=8 U15s; 8 U18s) underwent baseline maturity (maturity offset), body composition (DXA) and RMR (indirect calorimetry) assessments. We also quantified TEE, via the gold standard doubly-labelled water technique, and TL over a 14-day in-season period via GPS technology (Statsports, Ireland). Energy intake was also quantified for the first 7-days, via the remote food photography method and 24-hour recall.
RESULTS: Body mass (U18=73.1±8.1; U15=56.8±6.2 kg; P=0.001), fat-free mass (U18=57.2±6.1; U15=42.9±5.8 kg; P=0.00), maturity status (U18=4±1; U15=1±1 years; P=0.00) and RMR (U18=2236±93; U15=2023±162 kcal.day-1; P=0.01) was significantly different between the two age-groups. Despite no difference in 14-day accumulative training duration (U18=846±39; U15=868±72 min; P=0.48) and total distance (U18=54.4±7.1; U15=53.7±4.5 km; P=0.83), average speed was significantly different between the two age-groups (U18=74±2; U15=67±2 m.min-1; P=0.004). Both mean daily 14-day TEE (3586±487 kcal.day-1 versus 3029±262 kcal.day-1; P=0.02; min-max: 2545-5172 kcal.day-1) and 7-day energy intake (3176±282 versus 2821±338 kcal.day-1; P=0.04) was significantly higher in the U18s compared with the U15s, respectively. There was a significant positive correlation between TEE and body mass (r=0.80; P= 0.00), RMR (r=0.71; P= 0.002), average speed (r= 0.52; P=0.05), however not between TEE and training duration (r=0.070; P= 0.813) or total distance (r=0.283; P= 0.327).
CONCLUSION: We report for the first time the daily TEE of EPL Academy players, as quantified by the gold standard doubly labelled water technique. Confirming our hypothesis, we conclude that the energy requirements of EPL Academy players vary in accordance with changes in body mass, RMR and indicators of training intensity. When considering the similarity in daily TEE of Academy and adult EPL players (Anderson et al., 2017; mean daily TEE: 3566 kcal.day-1), in combination with high individual expenditures of some Academy players (e.g. >5000 kcal.day-1), our data demonstrate sufficient energy availability should be the cornerstone of any EPL Academy nutrition programme.

MYCOPROTEIN INGESTION STIMULATES PROTEIN SYNTHESIS RATES TO A GREATER EXTENT THAN MILK PROTEIN IN BOTH RESTED AND EXERCISED SKELETAL MUSCLE IN HEALTHY YOUNG MEN.

MONTEYNE, A.J., COELHO, M.O., JAMESON, T.S.O., JACKMAN, S.R., PORTER, C., ABDELRAHMAN, D.R., FINNIGAN, T.J.A., DIRKS, M.L., STEPHENS, F.B., WALL, B.T.

UNIVERSITY OF EXETER

INTRODUCTION: Mycoprotein is a fungal-derived sustainable protein rich food source, and its ingestion results in systemic amino acid and leucine availability similar to that following milk protein consumption. We assessed the mixed skeletal muscle protein synthetic response to the ingestion of a single bolus of mycoprotein compared with a leucine matched bolus of milk protein, in rested and exercised skeletal muscle in resistance trained young men.
METHODS: Twenty resistance trained healthy young males (age: 22±1 y, body mass: 82±2 kg, BMI: 25±1 kg/m2) took part in a randomised, double blind, parallel group study. Participants received primed, continuous infusion of L-[ring-2H5]phenylalanine and ingested either 30.8 g (26.2 g protein: 2.5 g leucine) milk protein (MLK) or 70 g (31.5 g protein: 2.5 g leucine) mycoprotein (MYC) following a bout of unilateral resistance-type exercise. Blood and quadriceps muscle were sampled before exercise and protein ingestion, and during a 4 h postprandial period to assess mixed muscle fractional protein synthetic rates (FSR), and phosphorylation status and gene expression of proteins that regulate protein metabolism. Two and three way ANOVAs were used to detect differences in plasma amino acid kinetics (group*time) and mixed muscle FSRs (group*time*exercise), respectively.
RESULTS: Postprandial plasma leucine concentrations increased with protein ingestion in both groups (P<0.001) but peaked more rapidly and to a larger degree in MLK compared with MYC (299±36μmol·L-1 at 15 min vs 244±11μmol·L-1 at 75 min, respectively). Mixed muscle FSR increased following MLK (from 0.036±0.008 to 0.051±0.006%·h-1 in rested, and 0.035±0.008 to 0.056±0.005%·h-1 in exercised muscle; P=0.004) and MYC (from to 0.025±0.006 to 0.056±0.005%·h-1 in rested, and 0.024±0.007 to 0.072±0.005%·h-1 in exercised muscle; P<0.0001) ingestion. No interaction between exercise and feeding was observed (P=0.218). Postprandial FSRs trended to be greater in MYC than MLK (P=0.093). The postprandial rise in FSR in MYC (123% in rested, and 199% in exercised muscle) was greater than in MLK (43% in resting, and 60% in exercised muscle) (P=0.008).
CONCLUSION: The ingestion of a single bolus of mycoprotein stimulates resting and post-exercise muscle protein synthesis rates, and to a greater extent compared with a leucine matched bolus of milk protein, in resistance trained young men. These data demonstrate that mycoprotein is an effective alternative dietary protein source to support post-exercise muscle tissue anabolism.

EXOGENOUS CARBOHYDRATE INGESTION DURING PROLONGED STEADY STATE EXERCISE ALTERS INTRAMUSCULAR SUBSTRATE UTILISATION IN TRAINED CYCLISTS

FELL, J.M.1, ELLIS, D.G.1, MORAN, J.1, HEARRIS, M., STRAUSS, J.A.1, COCKS, M.S.1, LOUIS, J.1, SHEPHERD, S.O.1, MORTON, J.P.1

1LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Intramuscular triglycerides (IMTG) are an important substrate during prolonged steady-state exercise (Van Loon et al., 2003). However, the effects of exogenous carbohydrate (CHO) feeding on IMTG utilisation are not well documented with conflicting data demonstrating no effect (Stellingwerff et al., 2007) or a reduction in IMTG utilisation (De Bock et al., 2005). Such discrepancies between studies are likely due to methodological differences including training status, muscle glycogen availability and exercise duration. Accordingly, the aim of the present study was to test the hypothesis that CHO feeding alters IMTG and muscle glycogen utilisation.
METHODS: In a repeated measures crossover design and after a 36 h CHO loading protocol (12 g/kg body mass) and pre-exercise meal (2 g/kg body mass), eight trained male cyclists (VO2max 61 ± 5 mL.kg-1.min-1) completed two experimental trials comprising 3 h steady state (SS) cycling at lactate threshold (208 ± 11 W). Subjects consumed 0 or 90 g/h of CHO during exercise as achieved via a mixture of fluids, solids and gels. Muscle biopsies were obtained from the vastus lateralis muscle immediately before and after exercise. Muscle glycogen concentration was assessed in whole muscle homogenate using acid hydrolysis whilst IMTG utilisation was assessed in both Type I and IIa fibres using confocal immunofluorescence microscopy. Data were analysed via a 2-way repeated measures ANOVA.
RESULTS: Exercise decreased (P<0.01) muscle glycogen concentration in both the 0 g (767 to 252 mmol.kg-1 dw) and 90 g/h trial (698 to 293 mmol.kg-1 steady-state) where a trend (P=0.055) towards greater glycogen utilisation was also observed in the 0 g/h trial. Similarly, exercise decreased (P=0.038) IMTG content in Type I fibres in both the 0 g (-56%) and 90 g/h trial (-18%) where a trend towards greater IMTG utilisation was also evident in the 0 g/h trial (P=0.08). In contrast, exercise did not significantly reduce IMTG content in Type II fibres (P=0.06).

CONCLUSION: We conclude that CHO ingestion at a rate of 90 g/h alters muscle glycogen utilisation and IMTG steady-state in type I fibres in trained male cyclists. Such data suggest that the well-documented ergogenic effects of CHO feeding during prolonged endurance exercise may be due to a potential sparing effect of both the endogenous glycogen and IMTG stores.

GREATER STIMULATION OF MYOFIBRILLAR AND SARCOPLASMIC SKELETAL MUSCLE PROTEIN SYNTHESIS WITH A-LACTALBUMIN COMPARED TO COLLAGEN PEPTIDE SUPPLEMENTATION DURING OVERREACHING IN TRAINED CYCLISTS

OIKAWA, S.Y., MACINNIS, M.J., MCGLORY, C., PHILLIPS, S.M.

MCMASTER UNIVERSITY

INTRODUCTION: Skeletal muscle protein synthesis (MPS) is improved when high-quality protein is consumed in sufficient doses spread throughout the day, particularly after exercise and before sleep. Protein quality may become increasingly important during periods of intensified training, as it could facilitate muscle remodeling through enhanced MPS. a-Lactalbumin (LA) is a fraction of whey protein containing twice the amount of tryptophan as whey but an otherwise similar amino acid profile. Tryptophan can be used to synthesize serotonin, and may independently mitigate decrements in performance associated with intensified training due to serotonin's impact on sleep. To date, the effects of LA supplementation on indices of skeletal muscle recovery and remodeling are unknown.
METHODS: Trained participants (5M, 6F, 24 ± 4 yrs, VO2max = 53.2 ± 9.1 mL/kg/min, PPO = 320 ± 48 W; means ± SD) consumed a controlled diet providing 1.0 g/kg/day protein for 2-wks. Participants refrained from habitual training and engaged in a brief period of intensified endurance exercise on 3 consecutive days repeating each week (3 sessions/wk) consuming a post-exercise protein supplement (20 g) and pre-sleep supplement (40 g) on training days. In a randomized crossover trial, participants consumed either LA or an isonitrogenous and biologically inactive control protein, collagen peptides (CP), during alternating weeks. Overreaching exercise consisted of 4 × 4-min cycling intervals (70% of PPO), interspersed by 2 min of recovery. Between protein supplement phases, participants were monitored for 4 days of washout. Myofibrillar (MyoPS) and sarcoplasmic protein synthesis (SarcPS) via 2H2O ingestion, maximal activity of citrate synthase (CS), plasma amino acid concentrations, and sleep quality using actigraphy were measured in response to each supplement and the washout period.
RESULTS: In response to supplement ingestion, LA resulted in a greater rise in plasma leucine ($p<0.01$) and tryptophan ($p<0.01$) than CP. Overreaching increased MyoPS and SarcPS above rest in both LA and CP supplemented phases ($p<0.01$), with increases 14% and 5% greater with LA than CP for MyoPS ($p<0.01$) and SarcPS respectively ($p<0.01$). The CS activity was not affected by training ($p>0.05$) and was similar at the end of each phase ($p>0.05$). During the exercise bouts there were no differences in PPO ($p>0.05$) or energy expenditure ($p>0.05$) between conditions. Sleep parameters were similar between dietary periods.
CONCLUSION: Despite an isonitrogenous diet, MPS was enhanced when trained participants were provided with a high quality, as compared to a low quality, protein supplement during brief intensified endurance exercise. Given recent recommendations suggesting increased protein requirements in endurance athletes, our data suggest that protein quality should be considered in an effort to stimulate protein synthetic thresholds to maximize recovery during intensive training, particularly to augment skeletal muscle remodeling.

ACUTE CARNOSINE AND ANSERINE SUPPLEMENTATION AS A NOVEL ERGOGENIC STRATEGY FOR HIGH-INTENSITY EXERCISE

BLANCQUAERT, L., EVERAERT, I., BAGUET, A., BARBARESI, S., DE JAGER, S., STAUTEMAS, J., GILARDONI, E., BARON, G., REGAZZONI, L., ALDINI, G., DERAVE, W.

UNIVERSITY GHENT

INTRODUCTION: The chronic oral administration of beta-alanine has been shown to effectively increase muscle carnosine (beta-alanyl-L-histidine) levels, which leads to enhanced high-intensity exercise performance (Harris et al., 2006). However, this long-term supplementation protocol is slow and an acute variant would be very valuable. Previous attempts to acutely raise plasma carnosine pre-exercise have failed, due to the highly active serum carnosinase activity in humans (Baguet et al., 2014). We now developed a novel strategy to circumvent carnosinase, based on pre-exercise ingestion of a high dose of carnosine (saturating carnosinase) and combining it with its methylated analogue anserine (more resistant to carnosinase).
METHODS: Firstly, in vitro hydrolysis of carnosine and anserine by serum carnosinase (CN1) was tested by adding both compounds to human heparin plasma, either alone or in combination (100µM of each). Degradation was stopped on different time points by adding sulfosalicylic acid and plasma was analyzed by HPLC. Secondly, 5 healthy subjects were orally supplemented with either 25mg/kg BW anserine or 25mg/kg BW of each carnosine and anserine. In vivo bioavailability was tested by blood collection at different time points following supplement ingestion and plasma was analyzed by LC-MSMS. Thirdly, in a double-blind, placebo-controlled, crossover study, 18 men were supplemented with either 20mg/kg BW of each carnosine and anserine or a placebo. A 6-minute high-intensity cycling test at fixed power was performed 40min after supplement ingestion, followed by 6min of active rest and a 30s all-out Wingate test.
RESULTS: In vitro experiments demonstrated a slower degradation of anserine in isolated human plasma compared to carnosine (half-life 7.8 vs 1.7min). Anserine degradation was further slowed by simultaneously adding carnosine. In vivo bioavailability testing demonstrated a much more prominent increase in plasma anserine (2.5-fold increase in AUC, $p = 0.035$) when anserine was co-ingested with carnosine compared to anserine alone. The performance study showed a significantly (+6 ± 11%; $p = 0.04$) higher generated power in the first 5 seconds of the Wingate test after prior ingestion of carnosine/anserine (12.8 ± 2.4 W/kg) compared to placebo (12.1 ± 2.2 W/kg). There were no differences in capillary pH values between conditions and no side-effects were reported.
CONCLUSION: Collectively, these experiments reveal a novel acute nutritional strategy to effectively raise plasma levels of carnosine and anserine by high-dose combined carnosine and anserine supplementation. Interestingly, this approach led to improved cycling power in the initial stage of a high-intensity Wingate test. This discovery opens a new nutritional strategy to increase exercise performance.

UTILITY OF THE 13C-BREATH (RATIO) METHOD TO TRACK CHANGES IN FAT-OXIDATION MAXIMA DURING INTENSE CYCLING EXERCISE FOLLOWING GLYCOGEN MANIPULATION BY ACUTE DIETARY INTERVENTION

KOPETSCHNY, B.H., RIIS, S., PATON, C.D., MORRISON, D.J., ROWLANDS, D.S.

MASSEY UNIVERSITY

INTRODUCTION: Identification of the intensity at which fat oxidation rate is maximal (Fatmax) has application in athletic performance and metabolic health. Conventional Fatmax identification methods are limited to intensities below the lactate threshold (~65-75% VO2max) as above this, CO2 from the labile body HCO3- pool leads to an erroneous understanding of fat's role in energy provision. To address this, we revisited the 13C-breath (RATIO) method (Romijn et al. AJP, 26: E64-E71, 1992) which is independent of CO2 minute volume. We reveal a new paradigm where fat oxidation is an important contributor to fuel provision at high intensities and in this study, examine the utility of the RATIO method by assessing the metabolic plasticity to acute dietary intervention.
METHODS: Ten participants: 39.8 y (SD 12.2), 81.3 kg (15.3), VO2max 4.45 L/min (0.36), peak power output (PPO) 335 W (35) completed a 3-way crossover trial comprising an endogenous-glycogen depletion ride on a cycle ergometer followed by ~60 h of glycogen restoration with naturally 13C-enriched foods (e.g. corn). Skeletal muscle glycogen content was manipulated by carbohydrate intake within the restoration period via high (2 x HI % energy: carbohydrate 69, fat 18, protein 13) and low (LO: 18, 62, 13) carbohydrate diets. Subsequently, participants were biopsied (V. lateralis) before completing a long duration incremental ramp test. Substrate oxidation was determined using breath and muscle-glycogen 13C enrichments and the VO2 (RATIO), compared to traditional nitrogen-corrected indirect calorimetry (IC). Breath 13CO2 was measured using isotope ratio mass spectrometry (IRMS), and muscle 13C-glycogen and concentration was determined by muscle glycogen extraction, enzymatic digestion and analysis of 13C glucose by liquid chromatography-IRMS.
RESULTS: Muscle 13C-glycogen (HI-HI CV 7.7%) was mean •13C ‰ (SD) -15.1 (1.4), -14.7 (1.2), -20.0 (2.3), while glycogen content (µmol/mg dry) 90 (41), 94 (81), 46 (41) for the first and second HI, and LO trials, respectively. Fatmax with RATIO under LO was 1.73 g/min (0.26) at 93 %VO2max (10) compared with combined HI at 0.91 g/min (SD 0.23; HI-HI CV 12%) at 91 %VO2max (6.4). Similarly, Fatmax with IC in LO was 0.83 g/min (SD 0.21; HI-HI CV 26%) at 76 %VO2max (7.9) compared with combined HI at 0.38 g/min (0.18) at 71 %VO2max (8.3). Between LO-HI diets, the RATIO method revealed a greater difference in Fatmax rate (0.83 g/min; 95%CI 0.65–1.0) vs IC (0.46 g/min; 0.31–0.60), but Fatmax intensity was not clearly changed by dietary intervention: RATIO (LO-HI) 4.0 %VO2max (-2.5–11), IC 6.6 %VO2max (-0.1–13).
CONCLUSION: The RATIO method is sensitive to changes in fat oxidation brought about by acute dietary intervention and therefore provides a new method for the study of nutritional interventions on substrate utilisation and performance at competition intensities. Compared to RATIO, IC underestimates the rate and relative intensity of maximum fat oxidation during high-intensity exercise.

THE EFFECT OF EXERCISE INDUCED FACTORS ON HUMAN ADIPOCYTES

SEVERINSEN, M., PEDERSEN, B.K., SCHEELE, C.

RIGSHOSPITALET

INTRODUCTION: Brown fat represents a tissue that, when activated, increases energy turnover and insulin sensitivity as well as glucose and fatty acid clearance (1) . Thus, brown fat may be involved in the protection against obesity and lifestyle related diseases such as type 2 diabetes. Brown fat is sympathetically activated and might therefore be stimulated by exercise. During the past decade, brown fat has been identified in adults and it has been shown that human brown fat consists of both classical brown fat, derived from a progenitor similar to myocytes as well as recruitable brite / beige adipocytes (2). The recruitable brite adipocytes is white adipose tissue that can undergo browning which is the process where WAT adapts to a more brown like phenotype.This effect is mediated by increased sympathetic activity and occurs in mice during cold acclimation and exercise training (3). If we can identify pathways for increasing the proportion of brown and brite fat cells, we might be able to counteract obesity and obesity-related diseases.
We hypothesized that factors released to the circulation during exercise would have browning effect on fat tissues.
METHODS: We isolated four different adipose depots (subcutaneous, visceral, perirenal and supraclavicular brown) from humans and established primary adipose tissue cell cultures.
During exercise, the myokine IL-6 is increased and released into the circulation. Thus, we incubated the human primary fat cell cultures with norepinephrine (NE) +/- IL-6 during differentiation and measured mRNA expression of markers for brown adipose tissue eg UCP1.
RESULTS: IL-6 enhanced UCP-1 expression 3 times more in the visceral fat (mean ctrl+NE=16.7 vs mean IL-6+NE=48.3) and over 2 times more in the brown (mean ctrl+NE= 248.8 vs mean IL-6+NE= 518.0). No changes were seen in the subcutaneous depot. The data suggest depot-dependent differences between preadipocyte responses to IL-6. Thus, the visceral fat depot increases UCP1 expression more when stimulated with IL-6 compared to the subcutaneous depot. We also have data indicating that BAT acquire a significantly higher expression of UCP1 when stimulated with IL-6.
Taken together, these data support our hypothesis that exercise training may induce brown fat and browning of white fat and that this effect could be limited to specific adipose depots.
CONCLUSION: Muscle-released IL-6 during exercise may be involved in mediating muscle-adipose cross-talk, not just with regard to lipolysis as previously shown, but also with regard to browning.

EFFECTS OF HIIT OR AEROBIC EXERCISE TRAINING ON LIPID METABOLISM BY ACTIVATING FGF21 SIGNALING PATHWAY

LI, L., FENG, L.S., XU, J.F., FANG, H.Y., WANG, X.J.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: As a member of the fibroblast growth factor (FGF) superfamily, FGF21 is known to have various physiological functions including lipid metabolism regulation. It is well established that the participation in aerobic exercise is benefit for fat-burning in obese individuals, while FGF21 seems an important factor affecting this process. High-intensity interval training (HIIT) is also a popular exercise type in regulating lipid metabolism, however, whether FGF21 is necessary for fat consumption during HIIT is still unknown. Therefore, this study aimed to examine and compare the effects of HIIT or aerobic exercise training on lipid metabolism by activating FGF21 signaling pathway.
METHODS: Thirty high-fat diet-induced obese male Sprague-Dawley rats were randomly divided into a control group (CON, n=10), an aerobic exercise training group (AET, n=10) and a HIIT group (HIIT, n=10). Rats in AET and HIIT groups were determined their VO2max by using a comprehensive lab animal monitoring system. The AET group completed an 8-wk aerobic exercise training program by running on a treadmill at an intensity of 60-70% VO2max, 5 days/wk, 60 min/day. The training protocol in HIIT group was consisted of 6 intervals of sprint (90% VO2max) and recovery (50% VO2max) session, the training was performed 5 days/wk for 8 weeks. The blood lipid levels were measured from serums; both perirenal and epididymal fat were collected and weighed; the gene and protein expression levels of FGF21, β-Klotho, adiponectin, AMPK and phosphorylation level of AMPK were detected from liver tissue.
RESULTS: By the end of the training program, the body weight, perirenal and epididymal fat weight in CON group were higher than that of AET and HIIT groups ($p<.05$; $p<.01$). The total cholesterol was observed to be lower in AET and HIIT groups than CON group ($p<.01$). The mRNA and protein levels of FGF21 and β-Klotho were greater in both AET and HIIT groups compared with CON group ($p<.05$; $p<.01$); moreover, the mRNA levels of FGF21 and β-Klotho were greater in AET group than that of HIIT group ($p<.01$). The mRNA level of adiponectin was higher in AET group than the other two groups ($p<.01$), but no significant difference was observed in adiponectin protein level among groups. The CON group revealed higher mRNA and protein levels in AMPK than both AET and HIIT groups ($p<.01$), however, the phosphorylation level of AMPK was greater in AET group than the other two groups ($p<.05$).
CONCLUSION: The 8-wk HIIT or aerobic exercise training increased the expression of hepatic FGF21 and its co-receptor of β-Klotho, which resulted in a reduction of the body weight and visceral fat in obese rats. Compared with HIIT, aerobic exercise training was more effective in activating the "FGF21/Adiponectin/AMPK" signaling pathway to regulate lipid metabolism.

SARCOLIPIN EXPRESSION IN HUMAN SKELETAL MUSCLE IS NOT ASSOCIATED WITH FAT MASS AND IS NOT ALTERED BY SEVERE ENERGY DEFICIT AND LOW-INTENSITY EXERCISE, WHILE IT IS REDUCED BY HIGH-INTENSITY TRAINING

MARTINEZ-CANTON, M.1, MORALES-ALAMO, D.1, GELABERT-REBATO, M.1, MARTIN-RINCON, M.1, DE PABLOS-VELASCO, P.1, HOLMBERG, H.C.2, CALBET, J.A.L.1

1 DEPARTMENT OF PHYSICAL EDUCATION AND IUIBS, UNIVERSITY OF LAS PALMAS DE GRAN CANARIA, SPAIN 2SWEDISH WINTER SPORTS RESEARCH CENTRE, DEPARTMENT OF HEALTH SCIENCES, MID SWEDEN UNIVERSITY, ÖSTERSUND, S

INTRODUCTION: Sarcolipin (SLN) is a muscle protein that induces thermogenesis by uncoupling SERCAs, increasing resting energy expenditure (REE) and reducing body fat in mice. SLN increases with overloading and is associated with enhanced performance in mice. It remains unknown in humans whether the expression of SLN is influenced by loading and energy balance. Therefore, the aim of this study was to determine the plasticity of sarcolipin expression and its relationship with adiposity, REE, energy efficiency, and exercise performance in humans. We hypothesized that severe energy deficit and prolonged low-intensity exercise would reduce, and high-intensity exercise training increase SLN expression in humans.
METHODS: SLN protein expression was assessed by Western blot in 199 muscle biopsies obtained in two previous studies. In study 1, 15 overweight volunteers underwent a pre-test followed by 4 days of caloric restriction and low-intensity exercise (45min one-arm cranking + 8h walking/day) and 3 days on a control diet. Muscle biopsies were obtained from the trained and untrained deltoids, and the vastus lateralis. In study 2, 16 untrained men performed 7 sessions of 4-6x30-sec all-out sprints with arms and with legs separately, and muscle biopsies were obtained pre and post-training from the vastus lateralis and triceps brachii.
RESULTS: SLN protein expression was two-fold and 44% higher in the vastus lateralis than in the deltoids and triceps brachii, respectively. SLN expression was neither associated with adiposity nor with REE in overweight men, and was not changed by 4 days of severe energy deficit (5500 kcal/d, fat mass loss=2.8 kg), although changes in SLN and cortisol were correlated ($r=0.38$, $P=0.039$). SLN content in the exercised muscles was not altered by low-intensity whereas it was reduced by sprint training. The changes in sarcolipin with sprint training were inversely associated with the changes in gross efficiency ($r=-0.59$, $P=0.016$). No association was observed between aerobic or anaerobic performance and SLN expression.
CONCLUSION: Despite the large energy deficit and the marked reduction in fat mass, SLN expression remained unaltered in the three muscles biopsied, strongly suggesting that, in humans, SLN expression is not downregulated to spare energy. Thus, it is unlikely that SLN plays a role in adaptive thermogenesis in humans. One major difference between prolonged walking and repeated 30-s all-out sprints is the marked metabolic disturbance evoked by the sprints, which cause substantial lactic acidosis, oxidative stress and sarcoplasmic reticulum stress. Sarcoplasmic reticulum stress reduces SLN expression in C2C12 cells. Interestingly, the association observed between the changes in SLN and gross efficiency suggests that a reduction in SLN may contribute to lower muscle contraction energy expenditure by attenuating SERCA uncoupling.

EFFECTS OF RESISTANCE TRAINING ON WHITE AND BROWN ADIPOCYTES IN RATS.

AMANO, Y., NONAKA, Y., KANO, Y., HOSHINO, D.

THE UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: Recent studies show that endurance exercise training increases mitochondrial enzyme and uncoupling protein 1 (UCP1) protein contents both in white and brown adipocytes in rodents. However, it has been unclear whether resistance training (RT) can

change these protein contents in two adipocytes. RT increases plasma concentration in Meteorin-Like (Metrnl), which is a myokine associated with the expressions of UCP1 and mitochondrial enzyme protein (Rao et al., 2014). Therefore, we hypothesized that RT increases mitochondrial enzyme and UCP1 protein contents in the adipocytes with an increase in plasma Metrnl concentration. The purpose of this study was to clarify whether RT increases mitochondrial enzyme and UCP1 protein contents in white and brown adipocytes in rats.
METHODS: Male Wistar rats (10-weeks-old) were divided into control (n = 4) and RT (n = 4) groups. RT group received isometric contraction by electric stimulation (The voltage ~22 V and stimulation frequency 100 Hz. 3-s stimulation × 10 contractions with a 7-s interval between contractions and 3-min rest interval between sets) to their both gastrocnemius muscles for 3 times a week for 4 weeks. After the 4 weeks, we analyzed the size of white adipocytes using hematoxylin eosin staining and examined protein contents (mitochondrial enzymes, UCP1, Peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α)) in white and brown adipocytes using western blot analysis.
RESULTS: Four weeks of RT significantly increased the gastrocnemius muscle weights per body weights ($p < 0.05$) and decreased the weight of subcutaneous white adipose tissues ($p < 0.05$) with being smaller size of the adipocytes ($p < 0.05$). However, RT did not alter mitochondrial enzyme and UCP1 protein contents in the white adipocytes. In brown adipocytes, RT increased mitochondrial enzymes such as succinate dehydrogenase (SDH) and NADH dehydrogenase protein contents ($p < 0.05$). Concomitantly, protein contents of PGC-1α, which is known as a master regulator of mitochondria biogenesis, tended to increase ($p = 0.07$) with elevation in plasma Metrnl concentration after RT ($p < 0.05$).
CONCLUSION: This study revealed that RT stimulation inducing muscle hypertrophy increases the blood concentration of Metrnl. It is reported that Metrnl stimulates mitochondrial enzyme and PGC-1a expressions in white adipocytes (Rao et al., 2014). Therefore, there is a possibility that the myocyte-derived Metrnl contributed to the mitochondrial enzyme expression of brown adipocytes. In addition, this study showed the decrease in white adipose tissue and the reduction in the size of adipocytes. These metabolic and morphological adaptations of brown and white adipocytes suggest that RT type stimuli influence systemic balance of energy storage and consumption.

ENERGY COST OF SELECTED TRAINING AND NON-TRAINING ACTIVITIES OF 10-17-YEAR-OLD INDIAN ATHLETES

KEREN, S.C.1, ASHOK, S.1, BALAKRISHNA, N.1, VENKATA RAMANA, Y.1

ICMR - NATIONAL INSTITUTE OF NUTRITION

INTRODUCTION: A Factorial approach using activity recording and metabolic equivalents (METs) is most often used to compute the 24-hr energy expenditure pattern of athletes. However, existing compendiums of energy cost of physical activities were developed predominantly for non-athlete adults or children (Ainsworth et al., 2000; Ridley & Olds, 2008; Pfeiffer et al., 2018). Thus, we aimed to determine the energy cost and METs of selected physical activities of junior athletes. Further, compared measured METs with two existing compendiums to understand its suitability among Indian junior athletes.
METHODS: In this cross-sectional study, 91 Indian junior athletes (Boys: 49% and Girls: 51%) were recruited from athletics, soccer and weightlifting events, participating in junior nationals. The indirect calorimetry was used to determine resting metabolic rate (RMR), followed by the volume of oxygen consumed (ml/kg/min), energy cost (kcal/min) & MET (Volume of oxygen consumed for an activity divided by volume of oxygen consumed for RMR) for selected training (Warm up, Weight training & conditioning, Cool down and Interspersed rest activities) and non-training activities (sitting, standing and walking) in real-time field settings. Sex and age-specific differences were determined using ANOVA and single-sample t-test was used to compare measured METs with existing METs from Compendium of Physical Activity; CPA (Ainsworth et al., 2000) and Compendium of Energy Expenditure for Youth; CEEY (Ridley & Olds, 2008).
RESULTS: The energy cost and METs of warm-up and weight training activities exhibited sex-specific differences. The measured MET covered a range of physical activities from 0.7 (RMR) to 10.8 (shuttle run). The heart rate of non-training and majority of the training activities was influencing differences in MET across sex, but not in the corresponding energy cost of activities (kcal/min). On comparison with compendium, measured MET values for RMR was significantly higher in junior athletes, except in soccer players (junior boys and girls) having lower MET values. For a majority of the non-training and training activities, the measured MET values were comparable with adult compendium (CPA) than children's (CEEY). However, measured METs of weight training activities were different (P-value<0.05) from existing compendiums.
CONCLUSION: The METs determined on Indian junior athletes adds to the existing database and is useful to evaluate energy expenditure. Further, in the absence of athlete-specific compendium, a combination of measured METs and CPA seems prudent for determining energy needs.

RE-EXAMINING THE FATMAX CONCEPT: A NEW PROCEDURE TO DETERMINE FAT OXIDATION RATE DURING INTENSE AEROBIC EXERCISE USING A 13C BREATH RATIO APPROACH

RIIS, S., KOPETSCHNY, H., PATON, C., MORRISON, D.J, ROWLANDS, D.S.

MASSEY UNIVERSITY

INTRODUCTION: The current concept of a metabolic rate and exercise intensity at which fat oxidation rate reaches a maxima (Fatmax) relies on the assumption that respiratory CO2 production at tissue level can be determined reliably from measurements of expired breath using traditional indirect calorimetry (IC). However, during intense aerobic exercise, strong ions such as lactate accumulate in all body compartments driving additional pulmonary CO2 output from bicarbonate dehydration (buffer CO2: lactate+HCO3->CO2+H2O). This may lead to underestimation of fat oxidation rate and an incomplete understanding of fat oxidation at sports competition intensities. Therefore, we developed a new procedure to determine Fatmax rate and intensity based on a 13C breath ratio approach (RATIO), independent of the $\dot{V}CO_2$ and hence changes to [HCO3-].
METHODS: From 4 developmental trials to define 13C breath ratio kinetics to steady state, we developed a 60-min cycle-ergometer based incremental-ramp protocol (%peak power output/min: 50/20, 62.5/15, 72.5/10, 77.5/5, 82.5/5, 87.5/5) applied to 11 endurance trained

men (mean, SD: 39.8 y, 12.2; ṁO2max 4.63 L/min, 0.34). A glycogen depletion ride was performed, followed by a ~60-h diet with the carbohydrate content of high natural 13C enrichment (e.g. corn). Next morning, a muscle biopsy (V. lateralis) was obtained prior to the ramp to determine muscle glycogen 13C enrichment using a novel approach based on liquid-chromatography isotope ratio mass spectrometry. Using post-depletion ride breath 13C (fat enrichment), combined with breath 13C and ṗO2 from the final 30-s of each ramp intensity step, fat oxidation was then determined from stoichiometric equations. To address reproducibility, procedures were repeated after a 14-d washout.
RESULTS: 13C breath ratio steady state was obtained after 15-20 min at lower intensities, down to about 4-5 min during higher intensity, which corroborated with a theoretical 2-compartment pool mixing model. Mean (SD, min, max) Fatmax rate was 0.92 g/min (0.32, 0.54, 1.40) with RATIO vs 0.38 g/min (0.26, 0.10, 0.86) with IC (RATIO-IC mean difference 0.53 g/min, 95%CI 0.40-0.66). Mean Fatmax intensity was 90.5 %ẇO2max (9.2, 74.1, 98.5) with RATIO vs 70.5 %V̇O2max (12.4, 57.7, 86.5) with IC (RATIO-IC mean difference 19.5 %V̇O2max, 95%CI 13.5-25.4). CV of Fatmax rate was 12.0% (95%CI 7.6-28.4) for RATIO vs 26.1% (16.1-66.6) for IC. In a representative trial, standard [HCO3-] declined from 25.2 mmol/L at 63%] V̇O2max (step 1) to 17.5 mmol/L at 99% V̇O2max (step 6).
CONCLUSION: RATIO produces a different picture of fat oxidation during exercise compared with IC, suggesting that fat oxidation rate does not peak until much higher intensities than previously demonstrated. Additional pulmonary CO2 output from buffer CO2 provides a likely explanation for this observation. Our findings have implications for our understanding, interpretation and application of Fatmax in the context of endurance performance, exercise training, and metabolic health.

OP-PM01 Molecularbiology and biochemistry: signaling and response

INCREASED RIBOSOMAL BIOGENESIS AND CAPACITY WITH HIGH-FREQUENCY LOW-LOAD BLOOD FLOW RESTRICTED RESISTANCE EXERCISE

BJØRNSEN, T., WERNBOM, M., PAULSEN, G., BERNTSEN, S., D'SOUZA, R.F., AASEN, K.M.M., CAMERON-SMITH, D., RAASTAD, T.

UNIVERSITY OF AGDER

INTRODUCTION: High-frequency blood flow restricted resistance exercise (BFRRE) can induce rapid muscle growth accompanied by increased numbers of satellite cells and myonuclei (1). Increased translational capacity, indicated by ribosomal biogenesis, seems to parallel muscle fiber hypertrophy in traditional heavy load strength training (2). However, ribosomal responses to BFRRE have not been investigated. Therefore, the aim of this study was to investigate changes in markers of ribosomal biogenesis and capacity, muscle fiber areas (MFA) and strength during frequent BFRRE.
METHODS: Thirteen participants (9 men and 4 women) performed two five-day blocks of seven BFRRE sessions, separated by 10 days of rest. BFRRE consisted of four sets (30s rest) with unilateral knee-extensions to failure at 20% of 1 repetition maximum (1RM) with partial blood flow restriction. Biopsies were obtained from m. vastus lateralis at baseline, 1h after the first session each week, after 3 sessions, during the rest period, and two times post-intervention. Mature rRNAs 5S, 5.8S 18S and 28S, pre-rRNAs 45S, 28S+ITS and 5.8S+ITS, total RNA per mg were assessed using real-time polymerase chain reaction and MFA by immunohistochemistry. Strength was measured as 1RM in knee extension.
RESULTS: The abundance of pre-rRNAs 45S (1.7-2.5 fold), 5.8S+ITS (1.3-1.7 fold) and 28S+ITS (1.4-1.6 fold) post-intervention at the Rest Week, 3- and 10 days after BFRRE ($p<0.05$), denoting ribosomal biogenesis. The ribosomal capacity markers 5S (1.6-1.9 fold), 5.8S (1.4-1.5 fold), and 28S (1.3-1.6 fold), as well as total RNA per mg (1.3-1.5 fold), was also increased during the Rest Week, and at 3- and 10 days after BFRRE ($p<0.05$), whereas 18S abundance was elevated at the Rest Week and 10 days after BFRRE (1.1-1.2 fold, $p<0.05$). As reported in our recent publication (2), MFA increased significantly in type 1 fibers 10 days after BFRRE, and the increases were significantly larger than in type II fibers (19±21 vs. 11±20%, respectively; $p=0.02$). 1RM did not increase before 20 after the BFRRE intervention (6±6%, $p<0.01$).
CONCLUSION: Two five-day blocks of high-frequency BFRRE, interspersed by post-intervention days of rest, produced marked increases in ribosomal biogenesis, evident by increased pre-rRNA 45S and the pre-rRNA cleavage components 5.8S +ITS and 28S + ITS. In line with this, ribosomal capacity was also up-regulated after both training blocks, as demonstrated by the increases in total RNA and the mature rRNAs. The ribosomal responses were accompanied by delayed gains in muscle fiber cross-sectional areas and strength 10-20 days after the BFRRE intervention. These changes in active ribosomal biogenesis and ribosomal capacity indicates that BFRRE induces a ribosomal response that precedes muscle fiber growth.

INVESTIGATING SKELETAL MUSCLE MITOPHAGY SIGNALLING AND THE EFFECT OF ELECTRICAL STIMULATION

SEABRIGHT, A., BARLOW, J., LAI, Y.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Exercise improves mitochondrial function in skeletal muscle by enhancing turnover, upregulating both biogenesis and degradation. Until now, investigating the effect of skeletal muscle contraction on the removal of damaged mitochondria (mitophagy) has proven difficult. Developing tools that monitor mitophagy and its underlying molecular mechanisms following contraction will help us to understand how exercise regulates mitochondrial quality control. Such knowledge is crucial for promoting exercise as medicine in order to combat mitochondrial dysfunction in ageing and metabolic disease.
METHODS: We aim to: I) characterise mitophagy signalling in C2C12 skeletal muscle cells by studying PTEN-induced kinase 1 (PINK1), Parkin and downstream autophagy receptors and; II) generate a stable mitophagy reporter cell line in skeletal muscle to investigate the effect of contraction on the occurrence of mitophagy and its underlying molecular signalling. Differentiated myotubes were treated with 10 µM of Carbonyl cyanide m-chlorophenyl hydrazone (CCCP) across a 24 h time course in order to induce mitochondrial depolarisation. Ubiquitylation status was assessed by western blot following HALO-UBAUBQLN1 TUBE pulldown. Mitochondrial respiration was measured via the Seahorse XFe24 analyser. Experiments were repeated three times across multiple passages (N=6). Next, we generated a

stable C2C12 muscle cell line, expressing a mitophagy reporter construct (mCherry-GFP-mtFIS1 101–153). Under normal conditions, the mitochondria fluoresce both red (mCherry) and green (GFP). Upon mitophagy, the low pH of the lysosome quenches the GFP signal, but not mCherry. Using confocal microscopy, this stable cell line enables us to monitor both mitophagy and mitochondrial morphology. Mitophagy events and its underlying signalling were assessed across a time course during electrically stimulated contraction.
RESULTS: CCCP treatment induces mitophagy in C2C12 myotubes (P<0.01). Ubiquitin phosphorylation, a read-out of PINK1 activity, was increased after 6h of CCCP treatment (P<0.01). Parkin activity towards its substrate CDGSH iron sulphur domain 1 (CISD1) was also increased after 6 h (P<0.01). Phosphorylation of TANK-binding kinase 1 (TBK1), an upstream regulator of the autophagy receptor optineurin (OPTN), was increased after 1 h (P<0.01). Markers of mitochondrial content were unchanged despite impaired mitochondrial respiration (P<0.01) and enhanced energy stress signalling (P<0.01). Mitochondrial fission factor (MFF) phosphorylation was increased alongside AMP-activated protein kinase (AMPK) activation during muscle contraction (P<0.01).
CONCLUSION: Lysosomal dependent removal of damaged mitochondria and the PINK1-Parkin signalling pathway are conserved in C2C12 myotubes. Our data suggests TBK1 phosphorylation to be independent of PINK1-Parkin activation. In C2C12 myotubes, contraction-induced mitophagy is partly mediated by MFF phosphorylation through the activation of AMPK.

THE VITAMIN D RECEPTOR REGULATES MITOCHONDRIAL FUNCTION IN SKELETAL MUSCLE

ASHCROFT, S.P., FLETCHER, G., PHILP, A.M., BASS, J.J., SZEWCZYK, N., ATHERTON, P.J., PHILP, A.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: It has been reported that 40% of adults in Europe can be classified as vitamin D deficient (1) with severe deficiencies often resulting in skeletal muscle myopathies. Recent evidence suggests that chronic vitamin D deficiency in C57BL/6 mice impairs physical function (2) and that the treatment of vitamin D in human skeletal muscle myoblasts increases mitochondrial respiration (3). Whilst this suggests a role for vitamin D in maintaining skeletal muscle function, it is unknown how disruption of vitamin D signalling alters mitochondrial function and whether the VDR mediates mitochondrial adaptation to physiological stressors such as endurance exercise. Therefore, the primary aim of this study was to determine whether a reduction-of-function of the VDR in C2C12 skeletal muscle cell line results in impaired mitochondrial function. The secondary aim was to determine whether vitamin D deficiency impairs mitochondrial function in mouse skeletal muscle following a period of voluntary wheel running (VWR).
METHODS: Lentiviral shRNA approaches were used to generate stable knock-down of the VDR in C2C12 myoblasts (VDR-KD). Mitochondrial function was assessed in myoblasts and myotubes using a Seahorse XFe24 extracellular flux analyser whilst mitochondrial protein content was assessed via immunoblot approaches and compared via Student's t.test. For in vivo studies, C57BL/6 mice were subjected to a period of dietary vitamin D deficiency or a control diet (1 or 3 months) and subsequently underwent a period of VWR (7 or 21 days). Mitochondrial function was assessed in permeabilised skeletal muscle fibres using high-resolution respirometry (Oroboros Oxygraph, O2K) following both the dietary and VWR intervention.
RESULTS: VDR-KD resulted in impaired rates of maximal respiration (19.65 ± 1.24 vs. 30.76 ± 10.42 pmol/min/mg, p<0.05, n=10) compared to scramble control. Further analysis revealed a reduction in total ATP production (45.0 ± 3.0 vs. 55.2 ± 8.1 pmolATP/min/mg, p<0.05, n=10) as well as a reduction in the contribution from oxidative phosphorylation (39.9 ± 3.5 vs. 46.1 ± 8.4 pmolATP/min/mg, p<0.05, n=10) in VDR-KD compared to scramble control. Preliminary results suggest vitamin D deficiency reduces CI+II supported mitochondrial respiration following 21 days VWR.
CONCLUSION: Taken together these data suggest that the reduction in the VDR results in impaired mitochondrial function in vitro. This reduction was due to impairments in oxidative phosphorylation as opposed to glycolysis related pathways. Given that vitamin D deficiency is widespread in the general population and even athletes, these data highlight an important role for vitamin D and the VDR in the maintenance of skeletal muscle function and exercise adaptation.

POST-EXERCISE ISCHEMIA MAINTAINS THE EXERCISE-INDUCED ACTIVATING PHOSPHORYLATION OF NRF2: ROLE OF METABOLITES AND PO2

GALLEGO-SELLES, A., MARTIN-RINCON, M., MARTINEZ-CANTON, M., SANTANA, A., GALVAN-ALVAREZ, V., MORALES-ALAMO, D., DORADO-GARCIA, C., CALBET, J.A.L.

UNIVERSITY OF LAS PALMAS DE GRAN CANARIA. RESEARCH INSTITUTE OF BIOMEDICAL AND HEALTH SCIENCES .

INTRODUCTION: The transcription factor Nrf2 regulates about 250 genes involved in redox homeostasis, detoxification, metabolism, xenobiotic and antioxidant response. Nrf2 has been implicated in neurodegenerative diseases, diabetes, inflammation, and cancer physiopathology. Nrf2 is activated by phosphorylation at Ser40, what elicits its nuclear translocation by unknown molecular mechanisms. Skeletal muscle pSer40-Nrf2 responses to exercise have not been studied in humans. Since reactive O2 species (ROS) have been implicated in Nrf2 activation and ROS are released during high-intensity exercise, more abundantly in hypoxia (Hyp) than normoxia (Nx), we hypothesized that pSer40-Nrf2 would be increased depending on metabolite accumulation and FIO2. Thus, our aim was to determine whether Nrf2 is activated by intense exercise and maintained activated by a low PIO2.
METHODS: Eleven volunteers performed incremental exercise (IE) to exhaustion in Nx (PIO2:143 mmHg) and Hyp (PIO2:73 mmHg). Immediately after IE, the circulation of one leg was instantaneously occluded (300 mmHg). Muscle metabolites and pSer40-Nrf2 (Western Blot) were measured in m. vastus lateralis before (PRE), and 10 (POST, occluded leg) and 60s after exercise from the occluded (OC1M) and non-occluded (nOC1M) legs simultaneously.
RESULTS: After IE, muscle lactate, phosphocreatine (PCr) and ATP changed similarly. Muscle lactate increased only at OC1M (25%; P<0.05) and PCr was reduced by a 94 and 48% in OC1M and nOC1M, respectively (P<0.005). Femoral vein PO2 was 21.1± 2.0 and 10.6±2.8 mmHg at Wmax, in Nx and Hyp, respectively (P<0.001). pSer40-Nrf2 was increased by 1.6-fold (P=0.004) after IE in both conditions (FiO2 x time, P=0.56). During the 1min occlusion, pSer40-Nrf2 remained at the same level (P=0.99), regardless of FiO2 during IE. However, in the non-occluded leg pSer40-Nrf2 was dephosphorylated to pre-exercise levels.
CONCLUSION: This study shows that high intensity exercise induces the Ser40 activating phosphorylation of Nrf2, regardless of FIO2 during exercise, despite the fact that femoral vein PO2 was much lower during IE in Hyp. The fact that Nrf2 dephosphorylated to resting values with only 1min recovery with free circulation suggests that pSer40-Nrf2 may be induced by the reduction of cellular PO2 or by a mechanism sensitive to the level of PO2, which is already maximally activated during exercise in Nx. Since after 1min recovery with free

circulation muscle lactate and pH remained at the same level reached at exhaustion, neither high muscle lactate nor low pH seem necessary for maintaining pSer40-Nrf2 levels. On the other hand, Pi was recovered to almost 50% of the value observed at rest. Therefore, PCr and Pi could be signals regulating Nrf2 dephosphorylation. These results demonstrate that post-exercise occlusion of the circulation could be used to maintain Nrf2 activated and likely amplify Nrf2-depending signaling.

TARGETED METABOLOMICS UNCOVERS ASSOCIATIONS BETWEEN CIRCULATORY ESSENTIAL AMINO ACIDS AND HEALTH BIOMARKERS ACROSS THE LIFE-COURSE, AND IN RESPONSE TO RESISTANCE EXERCISE TRAINING

SAYDA, M.H., PHILLIPS, B.E., WILLIAMS, J.P., WILKINSON, D.J., GREENHAFF, P.L., SMITH, K., ATHERTON, P.J.
UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Ageing is associated with a loss of muscle mass and strength and increased chronic disease burden. In contrast, resistance exercise training (RET) is an effective countermeasure to increase muscle mass/function, insulin sensitivity and metabolic health. While the aetiology of metabolic syndrome is complex, one area of interest is around the robust associations between elevated circulatory levels of essential amino acids (EAA) - particularly the branched chained-AA's (BCAA's) - and obesity/insulin resistance. However, BCAA's also play an important role in muscle metabolism; stimulating protein synthesis and facilitating maintenance of mass. This dichotomy between circulatory EAA/BCAA in obesity/diabetes in comparison to their positive role in muscle maintenance is ill-defined. As such, we explored the effects of ageing and RET upon circulatory EAA concentrations, and related these to clinical markers of health, across-age and in the context of RET.
METHODS: Fasted plasma amino acid (EAA) profiles were quantified in 3 distinct age and mixed-gender cohorts (~50:50) within a healthy BMI range (mean 26±3kg/m2), comprising of young (18-28y; n=8), middle-aged (45-55y; n=9) and older (65-75y; n=15) individuals within a RET-based intervention study. Participants undertook 20-wks of supervised whole-body resistance exercise training (RET), thrice per week. Measures of body composition using DXA, muscle function and metabolic health biomarkers were collected at baseline and after RET. Plasma EAA were quantified by gas-chromatography mass spectrometry.
RESULTS: There were no relationships between circulating BCAA and BMI in individuals at baseline; similarly, age per se had no impact upon circulatory BCAA levels. Nevertheless, RET elicited increases ($p<0.05$) in fasting BCAA concentrations irrespective of age. At the same time, HOMA-IR score was reduced ($p<0.05$) after RET across-age, albeit with no links to circulatory BCAA's concentrations. In contrast, there was a positive correlation between strength gains and BCAA ($p=0.001$) while BCAA's also positively correlated with whole-body lean mass ($p<0.05$). Finally, there was a positive correlation between LDL and BCAA ($p<0.05$), suggesting possible links between elevated BCAA and lipoprotein profiles.
CONCLUSION: Expectedly, RET improved HOMA-IR, strength and lean mass gains. However, our data indicate elevated BCAA's are not a marker of ageing or variable insulin sensitivity in individuals of a normal BMI range i.e. in contrast to commonly reported associations of elevated BCAA's with obesity/diabetes. Moreover, increases in plasma EAA/BCAA's occurred following RET despite improvements in HOMA-IR (and elevated LDL), indicating that elevated BCAA's are not a sensitive biomarker of insulin sensitivity i.e. in healthy exercise-trained people. Finally, ostensibly positive links between BCAA and muscle mass/strength illustrate that BCAA levels are a biomarker of muscle mass (which were absent at baseline), in the fasted state.

OP-BN01 Muscle and/or tendon function I

MUSCLE-TENDON INTERACTION DURING RUNNING: DISTINCT ADJUSTMENTS TO INCREASING SPEED AND LOAD

WERKHAUSEN, A.1, CRONIN, N.J.2, ALBRACHT, K.3,4, BOJSEN-MOELLER, J.1, SEYNNES, O.R.1
1: NIH , 2: JYU , 3: GSU , 4: UAS

INTRODUCTION: The interaction between the Achilles tendon and the triceps surae muscles during running enables great versatility in the way force is produced under various conditions (e.g. 1; 2). Here we tested the hypothesis that comparable increases in ankle joint moment requirements due to increased running speed or additional load would be met by different adjustments at the muscle-tendon level. Whilst a greater tendon stretch due to increased forces was expected in both conditions, we hypothesised that fascicle shortening velocity and activation level would only be affected at faster running speed, when force production time is limited.
METHODS: Sixteen distance runners ran on an instrumented treadmill in four different conditions, consisting of a combination of two different speeds (preferred and +20% of preferred speed) and two loading conditions (unloaded and loaded with +20% of body mass). Achilles tendon behaviour, and gastrocnemius and soleus muscle mechanics and activity were examined using ultrasonography, electromyography, motion analysis and ground reaction force measurements. Variables were compared between conditions with a 2-way-ANOVA design.
RESULTS: Positive ankle joint work increased similarly (13%) with increasing speed and load. Tendon stretch remained similar in both conditions, although recoil was increased with loading (29%, $P<0.01$). Peak fascicle shortening amplitude and velocity were unaltered in different conditions and in both muscles, suggesting that contractile conditions are mostly preserved despite the constraints imposed by this experimental design. However, mean gastrocnemius shortening velocity was reduced in the loaded condition only (12%, $P=0.01$), while mean muscle activity remained similar to the unloaded conditions. At higher running speed, mean muscle activity increased in gastrocnemius (10%, $P<0.01$) and soleus (14%, $P<0.01$).
CONCLUSION: We show that muscle-tendon mechanics are adjusted differently under constraints imposed by speed or load, despite comparable increases in ankle joint work. Against our predictions, tendon stretch was unchanged but the larger recoil seen when running with additional load may reflect a greater utilisation of elastic energy in this condition. Importantly, ground contact duration was prolonged with added loading, fascicle contractile conditions were improved and muscle activity was unchanged. When ground contact was shorter with increased speed, mean fascicle shortening velocity was unchanged and higher forces were produced by higher muscle activation. The neuromuscular system seems to modulate the way force is produced during running as a function of availability of time and potential energy, whereby economical force production is favoured when enough time is available.

INCREASED STIFFNESS IN MONOARTICULAR QUADRICEPS MUSCLES DUE TO EPIMUSCULAR MYOFASCIAL FORCE TRANSMISSION FROM BIARTICULAR MUSCLE ELONGATION

YANASE, K., YAGI, M., NAKAO, S., MOTOMURA, Y., UMEHARA, J., HIRONO, T., KOMAMURA, T., MIYAKOSHI, K., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: Muscle stretching can transmit force to adjacent muscles through a process termed epimuscular myofascial force transmission (EMFT) (Maas & Sandercock., 2010). Simply considering muscle origin and insertion, muscle stiffness of the rectus femoris (RF), which is a biarticular muscle, could increase with hip extension or knee flexion. The stiffnesses of vastus medialis (VM) and lateralis (VL), which are monoarticular muscles, would contrastingly increase only with knee flexion. However, from the viewpoint of EMFT, when the RF is stretched, there is a possibility that the VM and VL are also stretched through myofascial connections. The purpose of this study was to examine the effect of hip joint position on muscle stiffness of VM and VL. We hypothesized that VM and VL muscle stiffness might be increased secondary to increased RF stiffness.
METHODS: Fourteen healthy males participated in this study. They laid supine with knee fixed at 90° flexion. The following four types of hip positions were performed in a random order: 90° flexion (HF), 5° extension and 40° abduction (HE-AB), 5° extension (HE) and 5° extension and 10° adduction (HE-AD). Shear elastic moduli (G) of RF and the medial and lateral parts of VM and VL were measured using ultrasound shear wave elastography for each position, and G was used an index of muscle stiffness. Two-way repeated measures ANOVAs were conducted separately for VM and VL (positions and parts) and a one-way repeated measures ANOVA was conducted for RF (positions).
RESULTS: ANOVA showed a significant interaction between position and part in the VM. Post hoc tests showed that G value was significantly higher in medial and lateral parts for HE-AD and HE than for HF. In addition, the lateral VM exhibited higher G value than the medial VM in both HE-AD and HE. For VL, ANOVA found no significant interaction but there was a main effect for positions. Post hoc tests showed G values in HE-AD and HE were significantly higher than in HE-AB and HF. ANOVA showed a significant difference for position in the RF. G values of RF were significantly higher in HE-AD and HE than in HE-AB and HF.
CONCLUSION: The results of this study suggest that VM and VL stiffness increased during HE-AD and HE, which are effective RF stretching positions, even though the knee position was constant in all hip positions. Furthermore, our findings suggest that the lateral VM exhibited higher stiffness than the medial VM during HE-AD and HE. This suggests that EMFT can occur in human quadriceps muscles. INVESTIGATING THE FORCE-GENERATING CAPACITY OF M. ABDUCTOR HALLUCIS

PEREZ OLIVERA, A.L., JAMES, D., MILEVA, K., KARAMANIDIS, K.

SPORT & EXERCISE SCIENCE RESEARCH CENTRE, SCHOOL OF APPLIED SCIENCES, LONDON SOUTH BANK UNIVERSITY, UK.

INTRODUCTION: m. abductor hallucis (AH) is the strongest intrinsic foot muscle [1]. Direct assessment of the force-generating capacity of AH is problematic due to its combined flexion-abduction action and the inability, of some, to voluntarily activate the muscle [2]. Moreover, the optimal muscle-tendon unit (MTU) length to achieve this is uncertain. The purpose of this study was to investigate the joint moment-angle relationship at the 1st metatarsophalangeal joint (1MPJ) during sub-maximal isometric AH activation via electrical stimulation (ES).
METHODS: A 7s train of 1ms pulses at 20Hz and 150% motor threshold [3] was delivered to the left AH in 16 healthy participants at 0°, 5°, 10°, 15° and 20° Hallux dorsal flexion, whilst seated. The ankle joint was positioned at 35° plantarflexion with respect to foot flat [4], and the Hallux suspended from an uni-axial force transducer (500Hz). A 5-camera optical system (50Hz), synchronized with the force data, was used to measure the sagittal plane 1MPJ angle, and the line of pull from 2 markers on the force transducer. The external joint moment about 1MPJ was calculated within a 3s epoch of the isometric force profile using: $M=F \bullet r$. r was defined as the perpendicular distance between the line of pull and the axis of rotation at 1MPJ. A repeated measures ANOVA was first performed to assess for changes in the external moment arm during contraction (compared to relaxed). A Friedman, followed by Wilcoxon Signed-Rank test then assessed for the effect of angle on the resulting joint moments. Statistical significance was accepted when $p \leq 0.05$.
RESULTS: A significant main effect was found in the length of the external moment arm between relaxed and contracted states ($p<0.01$; $\eta^2=0.83$). Across subjects and joint angles, this increased during contraction on average by 2mm (relative change: 7%). A significant main effect was found in the joint moment-angle relationship ($p<0.01$), which illustrated a parabolic curve. Specifically, 10° 1MPJ angle (0.18 ± 0.12N•m) was significantly higher when compared to 0° (0.09 ± 0.04N•m, $p<0.01$) and 5° (0.14 ± 0.10N•m, $p<0.01$), but not 15° (0.17 ± 0.12N•m) and 20° (0.16 ± 0.13N•m).
CONCLUSION: The current study demonstrates that it is possible to assess the mechanical properties of AH in vivo by using direct-muscle ES, and thereby overcomes the problems associated with voluntary activation. Using this approach, we have shown that the force generating capacity of AH is affected by its corresponding MTU length, with 10° of Hallux dorsal flexion seeming optimal to produce the greatest external moment force about 1MPJ. However, estimating this without taking into account the change in the moment arm is likely to underestimate the external joint moment.

A RE-EXAMINATION OF HUMAN MUSCLE SIZE AND STRENGTH RELATIONSHIPS

BALSHAW, T.G., MADEN-WILKINSON, T.M., MASSEY, G.J., FOLLAND, J.P.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Theoretically, physiological cross-sectional area (PCSA) most accurately reflects the number of sarcomeres arranged in parallel and thus able to generate tension between the tendons. However, studies comparing PCSA, muscle volume (VOL), and maximum anatomical cross-sectional area (ACSAmax) have not demonstrated PCSA to be the best correlate of maximum voluntary torque (MVT) perhaps due to methodological limitations in the measurement of muscle morphology, and particularly architecture. Therefore, the purpose of this study was to examine if: (i) detailed muscle architecture measurements performed at multiple sites along each constituent

muscle of the quadriceps femoris (QF), in combination with careful MRI analysis, would facilitate PCSA, rather than ACSAmax or VOL, being the most powerful predictor of MVT; and (ii) if these size measures were more strongly associated with muscle force (MF) than joint level MVT.
METHODS: Fifty-two young healthy males completed familiarisation, strength assessment, and musculoskeletal imaging sessions. MVT was measured during unilateral knee extension at a knee joint angle of 115° (180°=full extension). T1-weighted 1.5T MRI scans (Signa HDxt; GE) of the dominant thigh (axial plane) and knee (sagittal plane) were acquired and subsequently manually analysed to determine overall QF size variables (QFVOL and QFACSAmax) and patellar tendon moment arm (PTMA). Ultrasound images were recorded at 2-3 sites along the length of each constituent QF muscle to assess fascicle length (FL) and pennation angle (PA). PCSA of each QF muscle was calculated using MRI-derived muscle VOL and ultrasound-derived muscle architecture ([VOL / FL] x cos of PA) and summed to quantify overall QFPCSA. QF muscle size variables were correlated with both MVT and MF ([knee extension MVT + estimated antagonist torque via hamstring electromyography] / PTMA).
RESULTS: MVT and MF were both significantly correlated with all QF size variables ([all] P<0.001). The bivariate correlation between MVT and QFVOL produced the highest r value (r=0.791), followed by QFPCSA calculated with multiple site muscle architecture measurements (r=0.715), and QFACSAmax (r=0.682). The correlation between MF and QFVOL produced the highest r value (r=0.624), followed by QFACSAmax (r=0.577), and QFPCSA calculated with multiple site muscle architecture measurements (r=0.561).
CONCLUSION: The addition of extensive ultrasonography throughout the QF muscle group in addition to careful MRI analysis did not result in PCSA becoming the muscle size variable most highly correlated with maximum strength. This finding may be due to 2D ultrasonography being an insufficient means to capture the complex architecture of 3D fascicles and thus calculate PCSA and/or the role of lateral force transmission reducing/confounding the relationship between PCSA and maximum strength. Finally, QF size measures were not more strongly associated with MF than joint level MVT.

TO WHAT EXTENT RELATIVE CHANGES IN MUSCLE ARCHITECTURE WITH LENGTHENING AND CONTRACTION INTENSITY CONTRIBUTE TO THE SHEAR-WAVE PROPAGATION VELOCITY?

GARCIA-VICENCIO, S., GENISSON, J.L., GASTON, A.F., CHARLOT, K., SIRACUSA, J.
INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES

INTRODUCTION: Studies have demonstrated that the shear-wave elasticity assessed by using supersonic imaging technique may provide valuable information to estimate an individual passive and active muscle force. However, in these studies the relative changes in muscle architecture associated with lengthening or contraction are not often taken into account. The aim of this study was to determine to what extent changes in MA contribute to the shear-wave propagation velocity (SWV).
METHODS: Ten healthy active males (n=5) and females (n=5) participated in the present study. Under passive conditions the SWV and the MA (pennation angle, muscle thickness and fascicle length) of VL and RF muscles were evaluated over a 5-s period at different muscle lengths: 20°, 40°, 60°, 80°, 90°, 110° and 120° of the knee extension (0° = knee fully extended) with 30-s passive recovery periods. Then, subjects were asked to perform a series of ~7-s isometric maximal (MVC) and sub-maximal (20%, 40%, 60%, 80% MVC) voluntary contractions of the KE muscles with 60-s passive recovery periods at 90°. For the evaluation of the RF SWV three more 7-s sub-maximal contractions series corresponded to 5%, 10% and 15% MVC were added. During each voluntary contraction, the SWV and B-mode images of the VL and RF muscles were recorded over a 5-s period after the stabilization of the torque raw.
RESULTS: Significant polynomial regressions between the SWV and the relative changes of the MA (pennation angle, muscle thickness and fascicle length; $P < 0.001$) for both VL and RF muscles at were observed with lengthening. The higher the relative changes in MA, the greater the SWV value. The significant rises of the SWV (at 80°) were observed when MA reached ~45-70% of its modifications for VL and ~50-60% for RF. With contraction, significant linear correlations ($P < 0.001$) were observed mainly for RF muscle but only when the low levels of force (5, 10 and 15%MVC) were added into the analysis. The higher the relative changes in MA with contraction, but at low level of force (<20%MVC), the greater the SWV value. At 20%MVC around 75-100% of changes in MA occur similarly to the SWV profile.
CONCLUSION: We found that the relative changes in MA with lengthening plays an important role on the SWV propagation and quality for both VL and RF muscles. It could be in partly explained by a reduced anisotropy (less pennated fibers) and a more elastic medium. However, when muscles are contracting changes in MA are determinant for the SWV magnitude but only at very low levels of voluntary force (<20%MVC). At 20%MVC, 75-90% of changes in MA and VL and RF SWV did already occur. Beyond 20%MVC a lack of relationship between the SWV, MA and the produced force was observed. Special attention must be therefore consecrated on this inherent heterogeneity of muscles during lengthening or contraction when the shear wave elasticity is performed for ensuring quality and good interpretation of results.

IN-VIVO ULTRASOUND ASSESSMENT OF BICEPS FEMORIS LONG HEAD FASCICLE LENGTH: SO FAR, NOT SO GOOD

FRANCHI, M.V.1, FITZE, D.P.1, RAITERI, B.J.2, HAHN, D.2, SPÖRRI, J.1
1 UNIKLINIK BALGRIST, UNIVERSITY OF ZURICH, 2 UNIVERSITY OF BOCHUM

INTRODUCTION: Biceps Femoris long head (BFlh) has lately been in the research spotlight. Adaptations in muscle architecture, and especially in fascicle length (Lf), have been investigated in response to training and in relation to injury prevention mechanisms (1). Lf is commonly assessed by ultrasonography and estimated by single snapshots taken at specific region of interests (ROIs). As single snapshots are dependent on the field of view of the transducer (commonly 4-5 cm length), the visible portion of the fascicles results being ~50% of the total Lf, leaving half of the length to be extrapolated. BFlh presents a heterogeneous architecture, and extrapolation methods may represent a problem. Extended field of view ultrasound (EFOV) technique may be advantageous by providing a panoramic view of the whole fascicles. The aim of the present study was to compare the Lf obtained by assessing EFOV scans to the 3 commonly used methods of Lf estimation, such as linear extrapolation (LE) and two trigonometric formulas, equation A (most used) and B.
METHODS: Right BFlh muscle architecture (Lf, pennation angle -PA and muscle thickness -MT) of 37 elite athletes (21.7±2.8 y, mean±SD) was assessed. Ultrasound snapshots were acquired at 50% of femur length using a 5 cm linear transducer. EFOV scans were acquired from the distal to proximal insertions. Trigonometric equation A (2) and B (3) were used to estimate Lf. The visible portion of Lf was manually digitised and LE method was performed. Lf from EFOV scans was determined for the same ROI. One-way repeated measures ANOVA was used to determine whether differences existed between the methods. Correlations were performed between values evaluated using distinct techniques and measure of agreement were assessed by Bland-Altman analyses.
RESULTS: Greater Lf was estimated when using equation A (9.98±2.17 cm) compared to Lf assessed by EFOV (8.07±1.39 cm, P=0.002), LE (8.4±1.71 cm, P=0.003) and equation B (8.57±1.62 cm, P=0.02). EFOV Lf correlated to LE and equation B values (r2= 0.65, P<0.001 and r2= 0.58, P<0.001, respectively) but not to equation A values (r2= 0.16, n.s.). Bland-Altman analyses showed an average absolute error of

1.91±2 cm when EFOV Lf values were compared to equation A and of 0.33±1 cm and 0.5±1 cm when compared to LE and equation B, respectively.
CONCLUSION: The present data show that, when assessing Bflh Lf, the most commonly used extrapolation method (equation A) could result in a Lf overestimation up to almost ~2 cm compared to EFOV and LE methods. Equation A has been shown acceptable for other muscles (VL, GM) but could be not suitable for BFlh. This raises a call for caution for physiologists, as well as biomechanics and sports medicine experts investigating adaptations to training, muscle models, and injury prevention strategies. Alternative techniques (DTI, EFOV) should be implemented in the search for a gold-standard for the assessment of BFlh Lf.

OP-PM15 Physiology

NON-INVASIVE ESTIMATION OF MUSCLE FIBER TYPOLOGY IN VARIOUS DISCIPLINES OF PROFESSIONAL CYCLING

VAN VOSSEL, K., LIEVENS, E., BEX, T., DERAVE, W.
GHENT UNIVERSITY

INTRODUCTION: Classic muscle biopsy studies demonstrated that elite endurance athletes exhibit a high proportion of slow-twitch (ST) fibers, while elite sprinting athletes benefit from a predominant fast-twitch (FT) fiber profile (1). Muscle carnosine quantification by proton magnetic resonance spectroscopy (1H-MRS) was developed as a non-invasive method to estimate muscle fiber type composition (2). The validity was initially demonstrated in track-and-field, where muscle carnosine levels in elite athletes gradually decrease with increasing running distance discipline (2). Also in cycling, it is anticipated that the various disciplines span a range of muscle typology requirements, but solid data are scarce. Therefore, the aim of this study was to compare muscle carnosine levels between professional cyclists excelling in different cycling disciplines.
METHODS: The muscle carnosine content of 29 male and 9 female elite Belgian cyclists (5 road climbers, 8 classic road cyclists, 3 road sprinters, 8 mountain bikers, 10 track-fond cyclists, 3 BMX riders and 1 track-sprint cyclist) was measured in the gastrocnemius medialis muscle by 1H-MRS on a 3-T whole body MRI scanner (Siemens Trio). Z-scores of muscle carnosine were calculated for each cyclist relative to a reference population with same age and sex (163 men, 112 women). Independent sample T-tests were used to compare the carnosine concentrations between the reference population and the different cycling disciplines.
RESULTS: BMX riders (z=+1.61; range:+1,17 to +2.28; p=0.007) and the track-sprint athlete (z=+3.86) show higher carnosine levels compared to reference population, characteristic for a higher proportion of FT fibers. Road sprinters (z=-0.21; range:-0.41 to +0.11) and track-fond riders (z=-0.51; range:-1.64 to +0.89) have an intermediate profile, slightly below population average. Mountain bikers (z=-1.17; range:-2.05 to -0.14; p(men)=0.034; p(women)=0.048), classic road cyclists (z=-1.30; range:-2.24 to -0.55; p=0.001) and road climbers (z=-2.21; range:-2.57 to -1.78; p<0.001) exhibit significantly lower carnosine levels suggesting a higher proportion of ST fibers than population average. No sex differences were found in muscle profile within the same discipline.
CONCLUSION: Prominent differences in muscle carnosine levels exist between elite cyclists of various disciplines, in line with the expectations and their respective functional demands. Road cyclists and mountain bikers display typical slow-twitch profile, whereas riders from BMX and track sprint have a dominant fast-twitch profile. The non-invasive character and the high intra-individual stability of the method open opportunities for application in cycling talent orientation.

METABOLIC POWER AND ENERGY EXPENDITURE IN THE GERMAN BUNDESLIGA

VENZKE, J.1, WEBER, H.2, SCHLIPSING, M.3, SALMEN, J.3, PLATEN, P.1
RUHR-UNIVERSITY BOCHUM1, DEUTSCHE FUßBALL LIGA2, ATHLENS GMBH3

INTRODUCTION: Soccer can be characterized as a physically demanding, high-intense intermittent team sport. Player tracking technology is used to determine displacement variables and the distribution of movement across speed and acceleration zones. Additionally, a mathematical approach allows calculating energetic load and metabolic power. Recent research shows that there are differences in positional groups in field hockey and Australian football and claims that the approach to classify intensity out of speed zones is not suitable anymore. The aims of this study were: (1) to describe the metabolic power demands for different position groups; and (2) to compare the traditional speed-zone with the metabolic power approach.
METHODS: 1344 video match analysis (25Hz) datasets from 416 players (182.3±6.7cm, 77.1±7.0kg, 25.8±3.9y) out of 96 matches of the German Bundesliga were gathered by an automatic player detection and tracking system. Displacement (speed, acceleration, distance) and energetic (Metabolic Power, energy expenditure) variables were determined and intensity was classified utilizing conventional thresholds. Metabolic and running profile were analyzed and compared between 6 positional groups. Time spent, Distance covered and energy expended at high speed (>15.5 km/h) was compared to those at high metabolic power (>20W/kg) by using one-way analysis of variances.
RESULTS: Main findings are that Central-Attacking (CAM) and central midfielders (CM) expended more energy (CAM: 47.8±3.3 kJ/kg; CM: 47.6±2.8 kJ/kg) and covered more distance (CAM: 11494±765 m; CM: 11445±638) than all other position groups (Wingbacks (WB): 43.7±2.5 kJ/kg; 10387 564 m; Centre-backs (CB): 40.5±2.8 kJ/kg; 9755±615 m; Wide Midfielder (WM): 45.6±3.3 kJ/kg; 10807±772 m; Striker (ST): 43.3±4.2 kJ/kg; 10319±1018 m) (p<0.001). Less time (t) was spent and less energy (EE) was expended at high speed (t: 302±84 s; EE: 7.18±1.98 kJ/kg) when compared to high metabolic power (t: 377±78 s; EE: 11.59±2.37 kJ/kg) (p<0.001) but players covered more distance at high speed (1638±148 m) than at high Metabolic Power (1593±360 m) (p<0.001).

CONCLUSION: Data show that soccer can be defined as intense and highly intermittent sport and that positional differences for metabolic power and running parameters exist. Generally, central attacking midfielders and central midfielders had greater activity profiles compared to the other position groups. Although displacement variables can provide an activity profile for each positional group and can help to understand the different movement patterns, these parameters underestimate the amount of high-intensity activities. Therefore, metabolic power rather than displacement variables should be used for the determination of the metabolic demands of soccer.

NEUROMUSCULAR EVALUATION OF ARM-CYCLING REPEATED SPRINTS UNDER HYPOXIA AND/OR BLOOD FLOW RESTRICTION

PEYRARD, A., WILLIS, S.J., PLACE, N., MILLET, G.P., BORRANI, F., RUPP, T.

UNIV. SAVOIE MONT BLANC, INTER-UNIVERSITY LABORATORY OF HUMAN MOVEMENT SCIENCES EA7424, F-73000 CHAMBÉRY, FRANCE

INTRODUCTION: Sprint repetition induces fatigue due to a complex interaction between muscular (peripheral) and neural (central) responses leading to an impairment of neuromuscular function. The purpose of this study was to determine the effects of systemic hypoxia and/or blood flow restriction (BFR) on an arm-cycling repeated sprint ability test (aRSA) and the impact on elbow flexor neuromuscular function when exercise is performed to exhaustion.
METHODS: Fourteen volunteers performed an aRSA (10s sprint / 20s recovery) to exhaustion in four randomized conditions: normoxia (NOR), normoxia with BFR (45% of resting full ischemia, NBFR), hypoxia (FiO2=0.13, HYP), and hypoxia with BFR (HBFR). Pre and post-exercise, maximal voluntary contraction (MVC), resting twitch force (Db10), and electromyographic responses from the elbow flexors (biceps brachii) were obtained from electrical and transcranial magnetic stimulation to assess elbow flexor neuromuscular and corticospinal function. Throughout the protocol, peripheral oxygen saturation (SpO2 by pulse oxymetry) and pre-frontal cortex oxygenation (TSI by near-infrared spectroscopy) were recorded.
RESULTS: BFR and hypoxia decreased the number of sprints during aRSA with no significant cumulative effect (NOR: 16 ± 8; NBFR: 12 ± 4; HYP: 10 ± 3 and HBFR: 8 ± 3; P<0.01). MVC decrease from pre- to post-exercise was comparable whatever the condition (mean MVC change of -12 ± 10.7% over conditions). SpO2 and TSI were decreased before aRSA with hypoxia (mean SpO2 NOR + NBFR: 98 ± 1%, HYP + HBFR: 91 ± 2%, P<0.01; mean TSI NOR + BFR: 72 ± 6%, HYP + HBFR: 67 ± 6%, P=0.01) but not by BFR. SpO2 and TSI diminution from the end of the warm-up to the end of aRSA were similar in all conditions (e.g. NOR: SpO2 pre aRSA: 98 ± 1%, post aRSA: 96 ± 3%, P<0.01; TSI pre aRSA: 71 ± 6%, post aRSA: 67 ± 6%, P<0.01). M-wave amplitude (-9.4 ± 1.9% vs. +0.8 ± 2.0%, P<0.01) and Db10 force (-41.8 ± 4.7% vs. -27.9 ± 4.5%, P<0.01) were more altered after aRSA with BFR compared to without BFR. The exercise-induced increase in corticospinal excitability was significantly lower in hypoxic vs. normoxic conditions (e.g. biceps brachii motor evoked potential at 75% of MVC: -2.4 ± 4.2% vs. +16.0 ± 5.9%, respectively, P=0.03).
CONCLUSION: The number of sprints performed during an aRSA test and the decline in the ability to produce force after exercise decreased to a similar extent when exercise was performed under hypoxia and/or moderate BFR. However, fatigue etiology differs depending on the currently studied hypoxic modalities. Specifically, BFR led to an impairment of the muscle excitation-contraction coupling likely due to impairment in metabolite removal efficiency during exercise. Whereas systemic hypoxia predominantly impacted corticospinal excitability in line with lower levels of cerebral oxygenation, potentially indicating incapacity of the corticospinal pathway to adapt to fatigue as in normoxia.

FIVE WEEKS OF HIGH INTENSITY CIRCUIT TRAINING LED TO A DECREASE OF SERUM FIBROBLAST GROWTH FACTOR-21 IN OVERWEIGHT ADULT WOMEN

MICIELSKA, K., GMIAT, A., JAWORSKA, J., KOZLOWSKA, M., RODZIEWICZ, E., KORTAS, J.A., DUDA-BIERNACKA, B., LYSAK-RADOMSKA, A., ZYCHOWSKA, M., ZIEMANN, E.

GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Fibroblast growth factor 21 (FGF21) is a factor regulating the metabolism and energy homeostasis. Circulating FGF21 concentration is apparently increased in cases of metabolic disease, especially with impaired glycemia, such as diabetes type 2 (1). Obesity and the accompanying pro-inflammation state may, thus, give rise to an FGF21-resistance. Paradoxically, a single bout of exercise also increases serum FGF21 concentration. Limited data, however, describe the impact of different forms of regular training on this growth factor. The presented study aimed to assess the effects of a single bout of as well as five weeks of high intensity circuit training (HICT) on growth factor (FGF21) and other myokines (irisin, interleukin-6) in overweight women.
METHODS: Eighteen untrained women (average age= 48± 5; BMI=27.3± 3.6, API= 0.52± 0.11) were randomly assigned into either training (HICT, n=9) or control group (CON, n=9). The HICT group completed a 5-week training program (including 15 HICT sessions) following American College of Sport Medicine recommendations (2). The CON group completed the training twice, at the beginning and at the end of the study period. Each training consisted of 3 series of 9 exercises with body weight as a resistance. Each exercise lasted 30s with 10s rest. Blood samples were taken before and 1h after the first and last training session. Additionally, oral glucose tolerance test (OGTT) was performed. Concentration of irisin (Phoenix Inc), insulin (Immuniq), interleukin-6 (IL-6) and fibroblast growth factor (FGF21) (R&D System) were determined.
RESULTS: The single bout of exercise led to an increase of FGF21 concentration 1h post-exercise among all subjects, however alternations were not significant. The whole training program triggered a decrease in FGF21 (p=0.02) in HICT group and the opposite trend of change in CON was observed (p=0.008). This drop was accompanied by the improvement of insulin sensitivity, expressed in Matsuda Index in training women (p=0.02). Neither the single session nor the training program affected IL-6 and irisin circulating concentration.
CONCLUSION: Fifteen units of HICT resulted in diminished concentrations of circulating FGF21 and improvement of glucose metabolism in overweight adult women. These data suggest that HICT as a time-saving form of home-based exercise is associated with beneficial metabolic effects. This investigation was supported by grant from the National Science Centre (Poland) 2016/23/N/NZ7/02479.

LOAD AND LIMB LOCATION DO NOT MEDIATE RESISTANCE TRAINING-INDUCED CHANGES IN LIMB STRENGTH AND LEAN MASS

MORTON, R.W., FLISS, M.D., MCKELLAR, S.R., SIDHU, R.S., MCGLORY, C., BURNISTON, J.G., PHILLIPS, S.M.

MCMASTER UNIVERSITY

INTRODUCTION: Performing resistance exercise training (RET) to volitional failure, independent of external load, results in muscle hypertrophy; however, there is substantial inter-individual variability in the hypertrophic response. We aimed to investigate the effect of load, limb location (upper vs. lower body), and endogenous factors on RET-induced changes in muscle mass and strength.
METHODS: Twenty healthy young men (22±3 y, 181±7 cm, 85±24 kg, means±SD) completed three resistance exercise sessions weekly for 10 wk. Each resistance exercise session consisted of three sets to volitional failure where each limb was randomly assigned to perform unilateral biceps curls or knee extensions with either higher-loads (8-12 repetitions at ~80% one repetition maximum [1RM]) or lower-loads (20-25 repetitions at ~40% 1RM). Lean mass and muscle strength were measured before and after 10 weeks of RET. Muscle mass was measured in each limb via dual x-ray absorptiometry (DXA), ultrasonography, and muscle biopsies (from the vastus lateralis [VL] only) and muscle strength was measured by unilateral 1RM and isometric peak torque. Hypertrophic response to RET was classified by summing each participant's rank (1-20) in each outcome used to assess muscle mass. The highest- and lowest-five ranked subjects were selected as the highest quartile (HIQR) and lowest quartile (LOQR) of response, respectively.
RESULTS: Following 10 weeks of RET there was an increase in each outcome: whole-body lean mass, leg lean mass, arm lean mass, VL cross sectional area (CSA), biceps brachii (BB) CSA, VL thickness, BB thickness, VL type I fibre CSA, VL type II fibre CSA, knee extension 1RM, biceps curl 1RM, knee extension peak torque, and biceps curl peak torque (all $P<0.05$). However, there were no significant interactions between time and load or time and limb for any outcome. As hypothesized, there was substantial inter-individual variability for each outcome, which manifested in significant differences between HIQR and LOQR in each outcome: leg lean mass (9±6 vs. 3±2 %), arm lean mass (5±2 vs. 2±3 %), VL CSA (10±10 vs. 2±11 %), BB CSA (16±10 vs. 7±6 %), VL thickness (11±10 vs. 3±6 %), BB thickness (8±6 vs. 3±5 %), VL type I fibre CSA (23±26 vs. 1±12 %), and VL type II fibre CSA (26±23 vs. 2±16 %; all $P<0.05$).
CONCLUSION: Performing RET to volitional failure resulted in similar RET-induced muscle hypertrophy that was independent of the external load lifted (i.e., higher- vs. lower-loads) or limb location (i.e., arms vs. legs). However, we identified substantial variability in each outcome of measurement and classified individuals in an upper (HIQR) and lower (LOQR) quartile in terms of hypertrophic responses, which will allow for ongoing omic-level analyses. We conclude that an individual's propensity to increase muscle mass and strength with RET is influenced primarily by endogenous variables and not by load or limb location.

MUSCLE DISUSE RESULTS IN A RAPID DECLINE IN DAILY MYOFIBRILLAR PROTEIN SYNTHESIS RATES

KILROE, S.P.1, JACKMAN, S.R.1, FULFORD, J.1, HOLWERDA, A.M.2, VAN LOON, L.J.C.2, WALL, B.T.1

1: EXETER UNIVERSITY; 2: MAASTRICHT UNIVERSITY

INTRODUCTION: Muscle disuse has been reported to lower both post-absorptive and acute post-prandial myofibrillar protein synthesis (MPS) rates. This study assessed the impact of muscle disuse on daily MPS rates following acute (2 days) and more prolonged (7 days) muscle disuse under free living conditions.
METHODS: Thirteen healthy young men (age, 20±1 y; BMI, 23±1 kg·m-2) underwent 7 days of unilateral leg immobilisation via a knee brace with the non-immobilised leg acting as a control. Three days prior to immobilisation participants ingested 400 ml deuterated water, with 50 ml daily doses consumed thereafter. Saliva and blood samples were collected at regular intervals throughout immobilisation for the determination of body water and amino acid precursor deuterium enrichments, respectively. Upper leg serial section MRI scans and muscle biopsies were collected from both legs before and after 2 and 7 days of immobilisation to determine quadriceps volume, and daily MPS rates, and the expression of genes involved in the regulation of muscle mass, respectively. A paired samples t-test was used to compare the MPS rates of the control (CON) and immobilised (IMM) legs between 0-7 days. A two-way repeated measures ANOVA (leg x time) was used to assess the effects of immobilisation on quadriceps volume, gene expression and MPS rates. Pearsons correlation coefficient was used to assess the relationship between tracer precursor pools.
RESULTS: Immobilisation reduced quadriceps volume in the IMM leg by 1.7±0.3 and 6.7±0.6 % after 2 and 7 days, respectively, with no changes in the CON leg. The deuterated water dosing regimen resulted in elevated and steady state body water (saliva) enrichments of ~0.76±0.02% and plasma (2H) alanine enrichments of ~3.12±0.20%, with a strong correlation between the two precursor pools ($r=0.96$; $P<0.001$). Over the immobilisation period MPS rates were 35±4 % lower in the IMM (0.82±0.04%·d-1) compared with the CON (1.27±0.04%·d-1) leg ($P<0.001$). MPS rates in the CON leg did not change over time; 1.34±0.08%·d-1 from 0-2 days and 1.24±0.07%·d-1 between days 2 and 7 ($P>0.05$). MPS rates in the IMM leg tended to be lower during the 0-2 day period (16±6%, 1.12±0.09%·d-1, $P=0.063$) and, to a greater extent ($P<0.01$), were lower during the 2-7 day period (43±6%, 0.70±0.06%·d-1, $P<0.001$) when compared with the CON leg. Muscle mRNA expression of genes involved in muscle protein breakdown were generally elevated in the IMM vs CON leg after 7 (but not 2) days of immobilisation (e.g. MAFbx 122±26%; MuRF1 175±51% and PSMB1 83±15%, all $P<0.001$).
CONCLUSION: Muscle disuse induces a rapid (within 2 days) and sustained (up to 7 days) decline in daily myofibrillar protein synthesis rates in healthy young men.

OP-PM12 Training and testing

COMPARISON OF THE ENERGETICS OF THE BOSCO AND WINGATE TEST

KAUFMANN, S., BECK, A., FUELLER, F., BENEKE, R., HOOS, O.

JULIUS-MAXIMILIANS-UNIVERSITY WUERZBURG

INTRODUCTION: The Wingate Anaerobic Test (WAnT) (1) and the Continuous-Jumping Test (CJ30) (3) both aim at determining anaerobic power and capacity. However, previous research shows considerable differences in peak and mean power as well as in fatigue measures (4). Additionally, the differences in locomotion may affect total and relative energy contribution. Consequently, the tests might tax different energetic pathways. Therefore, this study compares the energetic profiles of these two anaerobic standard tests.

METHODS: n=11 well trained, competitive, male team sport athletes (age: 23.7±2.2yrs, height: 184±3cm, weight: 82.3±6.4kg, 6-8h team-sport training per week) completed one WAnT (1) and one CJ30 (3). During the tests, peak and mean power (PP, MP), oxygen consumption (VO2) and blood lactate (blc), values were collected. Besides, number of jumps (NJ), ground-contact time (CT) and flight time (FT) in CJ30, and revolutions per 30s (RP30s) in WAnT were measured. The metabolic profiles (Wtot kJ, Ptot W/kg, Waer %, Wpcr %, Wblc %) were calculated using the PCr-LA-O2 method (2). Additionally, mechanical efficiency (ME) and fatigue index (FI) were estimated. Kolmogorov–Smirnov testing and the Levene statistics for homoscedasticity were used to verify the normality of distribution. Differences between variables were tested by paired t-tests. Effect sizes are denoted as Cohen´s d.
RESULTS: In CJ30 athletes showed NJ of 26±3.3, CT of 0.67±0.15s and FT of 0.48±0.04s, respectively. In WAnT, 62±2 RP30s were pushed. In CJ30 Wtot was lower (109.3± 18 vs. 143.0±13.1kJ, p<.001, d= -2,302) while PP (24.8±4.4 vs. 11.8±0.5 W/kg, p<.001, d=3.59) and MP (20.8±3.6 vs. 9.1±0.5W/kg, p<.001, d=4.14) were substantially higher in CJ30 than in WAnT. In contrast Ptot was lower in CJ30 than in WAnT (44.4±7.6 vs. 58.1±5.4 W/kg, p<.001, d=-2.07). Waer (20.0±4.7 vs. 16.2±3.1%, p=.089, d=0.95) and WPCr (45.6±4.5 vs. 34.8±5.0%, p=.001, d=2.25) were higher in CJ30, whereas WBLC and ΔBLC were lower in CJ30 (34.5±5.2 vs. 49.0±3.3%, d=-3.3, 7.3±1.5 vs. 13.8±1.0mmol/l, p<.001, d=-5.21). ME was substantially higher in CJ30 compared to WAnT (37.9±4.5 vs. 15.6±1.0%, p<.001, d=6.86), while FI was lower than in WAnT (18.5±3.8 vs. 23.2±3.1%, p<.001 d=-1.38).
CONCLUSION: ME, Wtot and energy shares of CJ30 and WAnT are considerably different. Although both anaerobic pathways are taxed largely, the energy share of the two anaerobic pathways is reversed. Therefore, CJ30 and WAnT should not be used interchangeably for anaerobic performance testing. We recommend choosing the test that suits best to the respective form of locomotion.

COMPARISON OF TRAINING MONITORING AND PRESCRIPTION METHODS IN FLAT-WATER SPRINT KAYAKING

HOGAN, C.1,2, BINNIE, M.J.1,2, DOYLE, M.2, LESTER, L.1, PEELING, P.1,2

1: THE UNIVERSITY OF WESTERN AUSTRALIA, 2: THE WESTERN AUSTRALIAN INSTITUTE OF SPORT.

INTRODUCTION: Current practice for the classification of exercise intensity in flat-water sprint kayaking involves the use of heart rate (HR) and stroke rate (SR) measures (1). However, HR measures are limited by cardiovascular drift during aerobic intensity efforts, and a lag time during high intensity, short-duration bursts (2). Moreover, measures of SR are typically delineated into generic SR-bands which ignore individual variation (1). In other sports, measures of power output (PO) are used for load quantification, since this measure provides a direct intensity indicator (2). In kayaking, recent advances in wireless instrumented paddle technology have enabled coaches to utilise real-time PO measures for training monitoring and prescription; however, a comparison of individualised HR, SR and PO-zones for quantifying sprint kayak training remains to be investigated.
METHODS: Twelve (n=12) well-trained, sprint kayak athletes completed a preliminary on-water 7x4-min graded exercise test and a 200, 500 and 1000m time-trial for the delineation of individualised training zones for HR (5-zone model, T1-T5), SR and PO (8-zone model, T1-T8). Subsequently, athletes completed two repeated trials of an aerobic (AER), a high-intensity interval (HIIT) and a sprint interval (SIT) training session (6 sessions total), where intensity was prescribed by individual PO-zones. Time spent in T1-T8 during each training session were then compared between PO, HR and SR.
RESULTS: Compared to PO, time-in-zone using HR was higher in T1 ($p \leq 0.008$) across all training sessions, was lower for T2 and higher for T4 ($p<0.001$) in AER, and lower for T5 ($p<0.001$) in HIIT. Average and peak HR were not different between HIIT and SIT ($p=0.823$; $p=1.00$). Time-in-zone using SR was higher for T4 ($p<0.001$) and T5 ($p=0.028$) in AER, higher for T4 ($p<0.001$) and lower for T5 ($p=0.005$) and T6 ($p<0.001$) in HIIT, and lower for T7 ($p=0.001$) and higher for T8 ($p=0.004$) in SIT compared to PO. In all training sessions, differences were found between the prescribed and actual time spent in T1-T8 when using PO ($p<0.001$).
CONCLUSION: Heart rate and SR misrepresented the time spent in T1-T8 as prescribed by PO. Heart rate measures were unable to differentiate the training demands across different high-intensity interval sessions and could therefore misrepresent the training load of such sessions. Measures of SR appear limited for quantifying decrements in intensity due to fatigue, whereas PO may be more suitable. The stochastic nature of PO and the influence of capricious on-water conditions likely explain the discrepancies between the prescribed and actual time-in-zone for this measure. For optimised training prescription and monitoring, coaches should consider the discrepancies between different measures of intensity, and how they may influence intensity distribution.

NURTURE, NATURE AND NON-RESPONSE: A NOVEL RANDOMISED CROSS-OVER STUDY OF CHANGES IN BODY COMPOSITION AND METABOLIC PROFILE IN RESPONSE TO ENDURANCE VERSUS RESISTANCE TRAINING IN TWIN PAIRS

THOMAS, H.J., MARSH, C.E., SMITH, K.J., NAYLOR, L.H., GREEN, D.J.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Body composition, metabolic profile and blood pressure (BP) are all important predictors of cardiovascular mortality and morbidity. We compared the impacts of closely supervised and centre-based endurance (ET) versus resistance training (RT) in mono-(MZ) and same-sex di-zygotic (DZ) twin pairs to determine responsiveness, concordance of response and heritability to these distinct exercise modalities. We hypothesized that ET would improve fat mass, metabolic profile and BP more than RT, but that the opposite might be true for lean mass. We also hypothesised that responses to all variables would be more highly correlated in MZ than DZ pairs.
METHODS: Healthy, untrained pairs of MZ (22 pairs, n=44) and DZ (5 pairs, n=10) twins (all 16-40 yrs), underwent three months of progressive overload RT and ET (closely monitored sessions 3x per week, matched intensities between twins, 60-90% one rep max and 60-90% VO2max respectively), separated by a three-month washout. Outcome measures included DEXA, resting BP, resting heart rate (RHR) and fasting glucose, insulin and C-reactive protein (hs-CRP). RHR and BP are reported as an average of five readings taken over 10 minutes.
RESULTS: Following RT there was a significant increase in total lean mass (827±18g, $p<0.01$), driven by increases in arm (190±43g, $p<0.01$), leg (281±115g, $p<0.05$) and trunk (383±124g, $p<0.01$) lean mass, as well as a reduction in total fat mass (-443±203g, $p<0.05$). Following

ET there was a significant increase in total lean mass (426±155g, p<0.01) driven by changes in leg lean mass (363±115g, p<0.01), but no significant changes in total fat mass. There was a significant decrease in RHR (-3.7±1.3bpm, p<0.01) following ET, but not RT. For the metabolic variables, the magnitude of change between the two modalities differed, showing decreases in both insulin (-9.38±3.36pmol/L, p<0.01) and HOMA-IR (-10.61±5.09%, p<0.05), favouring ET. There were significant correlations as a result of ET between MZ twins in insulin (r=0.58, p<0.01), hs-CRP (r=0.43, p<0.05) and HOMA-IR (r=0.63, p<0.01), whereas no correlations for any of these variables existed in DZ twins.
CONCLUSION: In contrast with our expectations, RT elicited more effective improvement in body composition (including fat mass) compared to ET. However, ET had a larger impact on insulin, HOMA-IR, hs-CRP and HR. Our within-subjects cross-over design has therefore revealed an interesting dissociation between changes in body composition and those in metabolic profile that occur in response to distinct training modalities. We also observed that metabolic responses to ET were highly correlated in MZ twins, but not same-sex DZ pairs, suggesting a contribution of heritability for these variables. However, there were no correlations between twin pairs in the changes observed in body composition, suggesting that environment plays a more significant role in training-induced adaptation.

INCLUSION OF REPEATED 30-S MAXIMAL SPRINTS IN PROLONGED LOW-INTENSITY ENDURANCE CYCLING IMPROVES SPRINT-ABILITY AND 5-MIN ALL-OUT PERFORMANCE IN ELITE CYCLISTS.

INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES AND NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: To enhance performance, elite cyclists increase low-intense training (LIT) volume for short periods, often organised as training camps [1]. Adding repeated sprint sessions to LIT has been shown to increase both sprint-ability and 40-km time trial (TT) performance in well-trained cyclists [4]. However, the effect of including repeated sprints within LIT-sessions has not previously been investigated during training camps with high volumes of LIT. To achieve super-compensation and avoid overreaching after periods of high training load, a subsequent reduction in training volume (tapering) by 41-60% is recommended [2]. As little as 1 wk of tapering has led to hypervolemia [2], improvements in maximal oxygen uptake (VO2max) and TT performance [3] in well-trained cyclists.
The aim of this study was to compare the effects of a 14-d high-volume training camp with either a) inclusion of 30-s maximal sprints within LIT-sessions or b) work-matched LIT-sessions on 5-min all-out performance, sprint-ability, physiological measurements and haematological values in elite cyclists.
METHODS: 18 elite cyclists (VO2max: 75±5mL·min-1·kg-1) were equally split into a Sprint group (S) performing 10±2 x 30-s maximal sprints on 5 of the LIT bouts and a Control group (C) performing work-matched LIT during a 14-d training camp. Compared to baseline, training volume was increased by approximately 50% in both groups during the 14-days, and thereafter decreased by approximately 60% compared to baseline training in the 10-d taper. Testing was performed on a Lode Excalibur cycle ergometer and oxygen uptake was measured using a Jaeger Oxycon Pro. Haematological values were determined using the CO-rebreathing method [5].
RESULTS: S increased the 5-min all-out power by 3±4% and mean sprint power output by 4±4 % (P<0.05), whereas no corresponding changes were observed in C (-1±5% and 0±4%, respectively) from pre to after the taper (post). Red blood cell mass increased equally in both groups by 4±4% (P<0.05), while haemoglobin mass, plasma volume, blood volume, last minute power output of an incremental test to exhaustion (Wmax), VO2max, power output- and fractional utilization of VO2max at 4 mmol [La-] were unchanged in both groups from pre to post.
CONCLUSION: Inclusion of repeated 30-s maximal sprints in 5 LIT sessions improved both sprint-ability and 5-min all-out performance compared to work-matched LIT-sessions during a 14-d high-volume training camp.

EFFECTS OF AN ECCENTRIC HAMSTRING TRAINING ON COMPONENTS OF PHYSICAL FITNESS IN FEMALE YOUNG HANDBALL PLAYERS

CHAABENE, H., NEGRA, H., MORAN, J., PRIESKE, O., SAMMOUD, S., RAMIREZ-CAMPILLO, R., GRANACHER, U.

UNIVERSITY OF POTSDAM

INTRODUCTION: Developing the eccentric strength of the knee-flexor (i.e., hamstring) plays an important role from performance and injury prevention perspectives (Jones et al, 2017). In this regard, the Nordic-hamstring exercise (NHE) is widely used to improve eccentric hamstring strength. The NHE is a partner-assisted eccentric hamstring exercise that can be easily performed on the pitch or in the gym without any additional equipment (Ishoi et al, 2018). To the authors' knowledge, no study has examined the impact of NHE training on measures of physical fitness in females. Therefore, this study aimed to investigate the effects of a short-term (8 weeks) in-season progressive NHE training program on components of physical fitness (i.e., linear sprint-time, jumping, CoD, and RSA) in female young handball players.
METHODS: Nineteen female elite handball players were assigned to an experimental group (EG, n=10) or an active control (CG, n=9). Pre- and post-training, tests were carried-out for the assessment of speed (i.e., 5-m, 10-m, and 20-m sprint-time), CoD (i.e., T-test), jump performance (i.e., CMJ height), and RSA (RSA total-time [RSAtotal], RSA best-time [RSAbest], RSA fatigue-index [RSAFI]). The training intervention consisted of one-to-three sessions per week with 2-to-3 sets per session and 5-to-12 repetitions per set (Ishoi et al, 2018). The CG followed its regular handball training.
RESULTS: Within-group analyses derived from magnitude-based inferences for the EG revealed moderate performance improvements for 5-m, 10-m, 20-m, T-test, and CMJ. Small effect sizes were found for RSAtotal and RSAbest and a trivial effect size was observed for the RSAFI. In the CG, within-group analyses revealed small performance decrements for the 5 m sprint and RSAbest and trivial decreases for the 10-m and 20-m sprint, and the RSAtotal. Moderate performance decrements were observed for the T-test. Small performance improvements for the RSAFI and trivial increases for the CMJ were noted. The between-group analyses favored EG over CG for 5-m, 10-m, 20-m, T-test, RSAtotal, RSAbest, and RSAFI with small-to-large sized effects. A trivial between-group difference was found for the CMJ.
CONCLUSION: The results of this study indicated that eccentric knee-flexor strength training using the NHE is a time-efficient and a highly beneficial method for the improvement of physical fitness measures in female young handball players.

A COMPARISON OF LINEAR AND REVERSE LINEAR PERIODISED PROGRAMS WITH EQUATED VOLUME AND INTENSITY FOR ENDURANCE RUNNING PERFORMANCE

BRADBURY, D.G., LANDERS, G.J., BENJANUVATRA, N., GOODS, P.S.R.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: It is well established that training program design is important in attaining optimal athletic performance. Fitness variables that govern performance are often ordered or periodized within a training program to achieve peak performance for a specific competition. This is done whilst considering the interrelationship between the key performance variables. Due to the number and complexity of fitness variables, there is a plethora of commonly utilized periodization methods. Few studies have directly examined the effectiveness of these methods on performance. The primary aim of this investigation was to determine the effectiveness of 2 different periodization methods on endurance running performance. A secondary aim was to examine any changes to key physiological changes which may underpin endurance performance.
METHODS: Thirty recreational runners (25.2 ± 7.4 years; 175.4 ± 8.1 cm; 69.0 ± 9.8 kg) were assigned to 3 groups based on preintervention test results: linear periodization group (LPG, n = 10), reverse linear periodization group (RPG, n = 10), and control group (CG, n = 10). The LPG and RPG completed 3 training sessions (2 supervised and 1 unsupervised) per week in two 6-week blocks. The LPG went through a high-volume training program while the RPG performed higher intensity, lower volume training in the initial block. Training volume and intensity was reversed in the second 6-week training block. All subjects completed pre-training (week 0), midpoint (week 7), and post-training (week 14) testing, which included anthropometric measurements (body mass and sum of 8 skinfolds), treadmill tests for running economy (RE) and V[Combining Dot Above]O2max, and a 5,000-m time trial (TT) on a 400-m grass track.
RESULTS: Greater improvements in the 5,000-m TT were observed in the LPG (76.8 ± 55.8 seconds, p = 0.009, d = 1.27) and the RPG (112.8 ± 83.4 seconds, p = 0.002, d = 1.51) than the CG (3.6 ± 59 seconds). No significant differences were found between the LPG and RPG (p = 0.321, d = 0.51). No group differences were found for V[Combining Dot Above]O2peak (p = 0.955) or RE at 9 km·h (p = 0.329) or 11 km·h (p = 0.558), respectively. However, significant improvements were seen in these variables after training: V[Combining Dot Above]O2peak (p = 0.010), RE 9 km·h (p < 0.001), and RE 11 km·h (p = 0.004).
CONCLUSION: These results do not support linear periodization or reverse linear periodization as a superior method; however, periodized training elicited greater improvements in endurance performance than nonperiodized training, highlighting the importance of planned training structure.

ADAPTATIONS TO HIGH-LOAD AND LOW-LOAD RESISTANCE TRAINING IN COPD PATIENTS AND HEALTHY OLDER SUBJECTS

MØLMEN, K.S.1, LIE, A.C.L.2, HAMMARSTRÖM D.1, RØNNESTAD, B.R.1, ERIKSEN, A.L.3, MALERBAKKEN, B.4, RAASTAD, T.2, ELLEFSEN, S.1

1: INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES; 2: NORWEGIAN SCHOOL OF SPORT SCIENCES; 3: INNLANDET HOSPITAL TRUST; 4: HOSPITAL FOR RHEUMATIC DISEASES

INTRODUCTION: For individuals suffering from chronic obstructive lung disorder (COPD), resistance training is considered as an important part of treatment and rehabilitation, counteracting the muscle pathophysiology inherent to the disease. There is, however, little evidence on how resistance training should be conducted in this patient group [1]. Here, we compare the effect of 13 weeks of supervised unilateral high- and low-load resistance training of the legs on muscle strength and muscle mass in COPD patients and healthy controls.
METHODS: Nineteen COPD patients (COPD; predicted FEV1, 52 ± 10%; GOLD stage 2 and 3, age 69 ± 5) and 58 healthy controls (HEALTHY, age 67 ± 4) conducted 13 weeks of supervised high- and low-load resistance training of the legs (leg press, knee extension and leg curl; 3 x 10 RM and 3 x 30 RM), with two weekly sessions. Each participant performed both training modalities in a contralateral fashion, randomly assigned to the two legs. The efficacy of the intervention was measured as one repetition maximum (1RM) and muscular endurance (maximal number of repetitions at 50% of pretraining 1RM) in knee extension and leg lean mass (Dual-energy X-ray absorptiometry).
RESULTS: Resistance training led to increased 1RM and muscular endurance in knee extension and leg lean mass in both COPD and HEALTHY, regardless of training modality. In COPD, 10RM and 30RM led to similar increases in 1RM (31 ± 20% and 27 ± 17%, ES = 0.04), muscular endurance (66 ± 34% and 61 ± 41%, ES = 0.01) and leg lean mass (2.0 ± 6.1% and 3.6 ± 5.2%, ES = -0.08). In HEALTHY, 10RM led to superior increase in 1RM (22 ± 16% and 17 ± 18%, p<0.05, ES = 0.16), with no difference between training modalities for muscular endurance (73 ± 43% and 77 ± 58%, ES = -0.32) and leg lean mass (1.4 ± 3.8% and 1.6 ± 3.6%, ES = -0.00).
CONCLUSION: Overall, 10RM and 30RM training led to improved muscle strength and endurance, in addition to increased muscle mass in COPD and HEALTHY. In COPD, the two training modalities resulted in similar adaptations, suggesting that load is of little importance for resistance training adaptations when exercising to volitional failure in this patient group. On the other hand, HEALTHY displayed superior strength improvement after 10RM training, though the improvement and increase in muscular endurance and muscle mass were similar between 10RM and 30RM training.

SOCIAL INEQUALITY AND READINESS FOR HEALTH TECHNOLOGY – RISKS OF TECHNOLOGY-ASSISTED PHYSICAL ACTIVITY REHABILITATION OF INDIVIDUALS WITH TYPE 2 DIABETES

THORSEN, I.K., ROSSEN, S., KAYSER, L., MIDTGAARD, J., GLÜMER, C., PEDERSEN, B.K., RIED-LARSEN, M.
RIGSHOSPITALET

INTRODUCTION: Technology-assisted physical activity (PA) rehabilitation of individuals with type 2 diabetes (T2D) is increasingly advised (1). The introduction of technology-assisted solutions may however introduce a barrier to those who are not familiar with technology. Existence of such barriers may be related to socio-demographic status. Failing to consider this may introduce inequity in PA rehabilitation and may thus widen the gap in healthcare related to socio-demographic status.
We here present socio-demographic characteristics and receptiveness to technology-assisted PA rehabilitation of individuals with T2D with distinct levels of readiness for health technology.
METHODS: Individuals with T2D (n=156) initiating or undergoing lifestyle rehabilitation completed a questionnaire survey covering: (A) socio-demographic characteristics, (B) receptiveness to technology-assisted PA rehabilitation; and (C) the Readiness and Enablement index for Health technology (READHY) (2), which measures eHealth literacy, self-management, and social support. READHY scores were analyzed using cluster analysis. Socio-demographic characteristics are presented as mean (SD) or proportion for each cluster.
RESULTS: Four clusters were identified (eHealth literacy/self-management/social support): 1. low/low/low (n=41); 2. low/high/high (n=32); 3. medium/medium/medium (n=56); and 4. high/high/high (n=27). The mean (SD) age were 1. 59.5 (10.5); 2. 64.6 (9.9); 3. 57.6 (10.7); and 4. 61.3 (10.5) years and the proportion of males were 1. 49%; 2. 66%; 3. 54%; and 4. 59%. The proportion of participants with a short education were 1. 63%; 2. 78%; 3. 71%; and 4. 56%, who lived alone were 1. 56%; 2. 47%; 3. 52%; and 4. 44%, and who were receptive to technology-assisted PA rehabilitation were 1. 61%; 2. 47%; 3. 80%; and 4. 81%.
CONCLUSION: Overall, data suggest that among participants with low readiness for health technology (cluster 1) fewer were males, and more had short educations and lived alone. Of the participants with high readiness for health technology (cluster 4) it appears that a larger proportion were males, fewer had short educations, and fewer lived alone. Fewer participants with low vs. high readiness for health technology appeared to be receptive to technology-assisted PA rehabilitation.
Altogether, this indicate that a gap may exist among individuals with T2D with low vs. high readiness for health technology. Failing to consider readiness for health technology when introducing technology-assisted PA rehabilitation may risk widening this gap.

COMPARISON OF THE EFFECTS OF ECCENTRIC AND CONCENTRIC CYCLING TRAINING ON MUSCLE FUNCTION, BODY COMPOSITION AND QUALITY OF LIFE IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE PATIENTS

PEÑAILILLO, L., GONZALEZ, R., VALDES, O., INOSTROZA, M., ZBINDEN-FONCEA, H., NOSAKA, K.
UNIVERSIDAD FINIS TERRAE

INTRODUCTION: Chronic obstructive pulmonary disease (COPD) is a lung disorder with progressive airflow obstruction resulting from inflammation and remodelling of the airways, which often includes development of emphysema. Hence, COPD patients present low exercise tolerance, muscle wasting (loss of muscle strength and mass) and low quality of life (QOL) (1). Eccentric cycling requires less cardio-metabolic demand but can induce greater increases in muscle strength and mass when compared with concentric cycling (2). Thus, the present study compared the effects of 12-week eccentric and concentric cycling training on muscle function, body composition and QOL in patients with moderate COPD.
METHODS: Twenty moderate COPD patients (70.7 ± 9.7 y, forced expiratory volume in 1 second; FEV1=70.6 ± 12.9% of predicted) were randomly allocated to one of the two groups: eccentric (ECC) and concentric (CONC) cycling training groups (n=10 per group). They performed each training 3 times a week for 12 weeks on a recumbent cycle ergometer. The training intensity was set at the rate perceived exertion to be between 10 and 13. Power output, oxygen saturation, dyspnoea and heart rate were monitored during cycling. Shuttle walking test (SWT), timed up and go test (TUG), ascending and descending stairs time (AST and DST), peak oxygen consumption (VO2peak), maximal voluntary isometric contraction strength of the knee extensors (MVC), QOL by the St. Georges Respiratory Questionnaire (SGRQ), lower limb fat mass (LL-FM) and fat-free mass (LL-FFM) by dual-energy x-rays were measured before and after training. Changes in these variables were compared between groups using a two-way ANOVA, and the magnitude of the changes from baseline was compared between groups by independent Student t-tests.
RESULTS: On average ECC produced 300% greater workload than CONC during training sessions, with 30% lower cardio-metabolic demand. ECC improved SWT (38%) and TUG (24%), but CONC did not. ECC and CONC improved DST and AST (9-16%) similarly. No significant differences were found for the magnitude of increases in VO2peak (2-3%) and MVC (22-31%) after ECC and CONC. LL-FFM increased (4.5%) after ECC only, and LL-FM decreased (3.5%) after CONC only. The SGRQ showed that QOL improved only for CONC (22-45% overall).
CONCLUSION: These results show that ECC can produce 3-fold greater workload at lower cardio-metabolic demand than CONC, which appears to be related to the greater increases in functional tests and LL-FFM after ECC than CONC. CONC improved AST and DST, decreased LL-FM and improved QOL more than ECC. This may be due to the greater cardio-metabolic demand in CONC. It is concluded that ECC is more effective for improving muscle function and muscle mass, and CONC is more efficient for decreasing fat mass and improving QOL of patients with moderate COPD.

THE PHYS-CAN STUDY: ADJUVANT CHEMOTHERAPY IS ASSOCIATED WITH A REDUCTION WHEREAS PHYSICAL ACTIVITY LEVEL BEFORE TREATMENT IS POSITIVELY ASSOCIATED WITH MAINTENANCE OF VO2MAX IN PATIENTS WITH CANCER

WIESTAD, T.H.1, RAASTAD, T.3, NORDIN, K.2,4, IGELSTRÔM, H.4, HENRIKSSON, A.4, DEMMELMAIER, I.4, BERNTSEN, S.2,4

1: HAUKELAND UNIVERSITY HOSPITAL, 2: UNIVERSITY OF AGDER, 3: NORWEGIAN SCHOOL OF SPORT SCIENCES, 4: UPPSALA UNIVERSITY

INTRODUCTION: There is emerging evidence that adjuvant therapy may cause multiple sideeffects on long term health, including reduced cardiorespiratory fitness (CRF) in patients with breast cancer (1). CRF, measured as maximal oxygen uptake (VO2max), is a strong predictor of cardiovascular risk. However, there is currently limited knowledge regarding the effect of different types of adjuvant cancer treatment on CRF in mixed cancer populations. The primary objective of the present study was to examine what type of adjuvant cancer treatment that was associated with reductions in VO2max. Secondarily, whether age, diagnosis, initial CRF, physical activity level or fatigue was associated with changes in VO2max during treatment.
METHODS: 85 patients with breast, prostate or colorectal cancer scheduled for adjuvant chemotherapy, radiotherapy or endocrine therapy treatment, were included and stratified by primary adjuvant treatment. Cardiorespiratory fitness was assessed by VO2max during a maximal incremental cardiopulmonary exercise test before start of adjuvant therapy and at follow-up six months later. Physical activity level was recorded with a physical activity monitor (Sense Wear™ Mini) at baseline as average minutes of moderate-to-vigorous intensity physical activity (MVPA) (≥ 3Metabolic equivalent tasks) per day. Physical fatigue at baseline was reported using the Multidimensional Fatigue Inventory-20 questionaire.
RESULTS: 55 patients (64%) had measures of VO2max at baseline and follow-up. Fatigue, age and diagnosis were not associated with changes in VO2max. A 30 min higher MVPA at baseline was associated with a 5% higher VO2max at six months follow up when adjusted for adjuvant treatment (P=0.010). Patients receiving adjuvant chemotherapy had a mean decline in VO2max of 10% (-19, -1; 95% confidence intervals) compared to patients receiving adjuvant endocrine treatment (P=0.028). Adjuvant radiotherapy was not associated with significantly changes in VO2max.
CONCLUSION: Adjuvant chemotherapy was associated with a reduction in VO2max in cancer patients whereas MVPA before start of adjuvant treatment were positively associated with a higher VO2max after end of adjuvant treatment. These results highlight the importance of physical activity on cardiorespiratory fitness in patients with cancer and add more knowledge that adjuvant cancer treatment may influence physical fitness.

EFFECTS OF A MULTICOMPONENT EXERCISE PROGRAM COMBINED WITH A MULTI-NUTRIENT SUPPLEMENT ON MUSCULOSKELETAL HEALTH IN MEN WITH PROSTATE CANCER RECEIVING ANDROGEN DEPRIVATION THERAPY: A 12-MONTH RCT

DALLA VIA, J.1, DALY, R.M.1, OWEN, P.J.1, MUNDELL, N.L.1, LIVINGSTON, P.L.1, RANTALAINEN, T.1,2, MILLAR, J.L.3, MURPHY, D.G.4, FRASER, S.F.1

1: DEAKIN UNIVERSITY, AUSTRALIA, 2: UNIVERSITY OF JYVÄSKYLÄ, FINLAND, 3: ALFRED HEALTH, AUSTRALIA, 4: PETER MACCALLUM CANCER CENTRE, AUSTRALIA

INTRODUCTION: Androgen deprivation therapy (ADT) improves survival in men with advanced prostate cancer (PCa), but is associated with multiple adverse effects including accelerated bone and muscle loss. While exercise is recommended to ameliorate some of the adverse effects of ADT, no studies have examined the combined effects of exercise with a nutritional supplement on musculoskeletal health outcomes in this group. Therefore, the aim of this 12-month randomised controlled trial (RCT) was to investigate whether a community-based, multimodal exercise program combined with a protein, calcium and vitamin D enriched drink could optimize musculoskeletal health outcomes in ADT-treated men.
METHODS: In this 12-month RCT, 70 ADT-treated men (mean age: 71.3 ± 6.2 years, median [IQR] ADT duration: 12 [5-23] months) were randomly allocated to either exercise+supplementation (ExSuppl, n=34) or a usual care control group (CON n=36). The multimodal exercise program (3 d/week) included moderate-high intensity aerobic and progressive resistance training (2 sets, 8-12 reps) with weight-bearing impact exercises (3 sets, 10-20 reps). The daily nutritional supplement (25g whey protein with 2.4g leucine, 1200mg calcium carbonate, 1000IU vitamin D) was consumed every morning before breakfast and within 1-2 hours of completing each exercise session. Key outcomes (assessed at baseline, 6- and 12-months) included: DXA areal hip and spine bone mineral density (aBMD), and total body lean mass and fat mass; pQCT cortical and/or trabecular volumetric BMD, bone structure and strength at the distal (4%) and proximal (66%) tibia and radius, and muscle strength (leg press, chest press and seated).
RESULTS: Sixty men (86%) completed the study. Ex+Suppl resulted in an 11% greater increase in leg press muscle strength ($p<0.05$), and a non-significant 2-9% greater gain in upper body/back strength. There was no effect of the intervention on DXA aBMD with both groups experiencing a similar and significant loss at the total hip (1.1-2.0%, both $p\leq0.001$) and femoral neck (1.3-1.8%, $p<0.05$-<0.001), but not lumbar spine, at 12-months. Similarly, there was no effect of Ex+Suppl on any pQCT bone outcomes with both groups exhibiting a significant loss ($p<0.05$-<0.001) in distal radius trabecular vBMD (2.7-2.9%) and proximal tibia and radius cortical bone area (1.4-2.3%) and strength (2.1-3.5%). There was no effect of the intervention on lean mass or fat mass. There were no serious adverse events related to the intervention and no effect on prostate-specific antigen (PSA) levels.
CONCLUSION: In men with prostate cancer treated with ADT, a 12-month, community-based multifaceted intervention incorporating a targeted multicomponent exercise program with daily consumption of a protein, calcium and vitamin D enriched drink was effective for improving muscle strength, but did not ameliorate bone and muscle loss.

THE EFFECT OF AN EXPANDED LONG-TERM PERIODIZATION EXERCISE TRAINING ON HEALTH-RELATED PHYSICAL FITNESS IN PATIENTS WITH CORONARY ARTERY DISEASE

PINTO, R.1, ANGARTEN, V.1, MELO, X.1,2, LEMOS PIRES, M.1, BORGES, M.1, SANTOS, V.1, ABREU, A.3, SANTA-CLARA, H.1

1: EXERCISE AND HEALTH LABORATORY, CIPER, FACULDADE DE MOTRICIDADE HUMANA, UNIVERSIDADE DE LISBOA 2: GINÁSIO CLUBE PORTUGUÊS, GCP LAB; 3: CCUL, FACULDADE DE MEDICINA, UNIVERSIDADE DE LISBOA

INTRODUCTION: The existing models of exercise prescription in Cardiac Rehabilitation focus predominantly on walking and cycling continuously at moderate intensity, but the repetitive nature of this type of exercise can become monotonous for the patient, affecting compliance and health-related physical fitness (HRPF) outcomes. In this regard, much insight could be gained from periodized approaches

used in sport conditioning, designed and planned to be physiologically and psychologically challenging. It has never been tested previously if periodized exercise training in patients with coronary artery disease (CAD) to improve HRPF outcomes may be feasible and beneficial. Thus, the aim of this study was to conduct a 6-month randomized controlled trial to evaluate the effects of a periodized versus non-periodized exercise training regime on HRFP outcomes in patients with CAD.
METHODS: Thirty patients with CAD (age: 62.1±10.1 years) were randomized to a concurrent (aerobic and resistance training) supervised periodized training group (PG) (n=15) and non-periodized training group (NPG) (n=15), three times a week for 24 weeks. Exercise training consisted in individualized loads prescribed according to the Training Impulses (TRIMP) method (i.e., volume x intensity). Patients performed 1) an incremental symptom-limited cycling cardiopulmonary exercise test; 2) had their body composition measured with dual-energy X-ray absorptiometry; and 3) had their muscle strength assessed with one repetition maximum (1RM) in 6 major muscle groups; at the beginning and at the end of the exercise intervention. Differences between groups, changes over time within each group and any interactions were assessed by two-way repeated measures analysis of variance (ANOVA).
RESULTS: Since this study was designed as an efficacy study, we focused on a per-protocol analyses, which included 27 patients with CAD (PG: n=13, 10 males and NPG: n= 14, 11 males) that successfully completed the exercise protocols with attendance rates superior to 75%. A model-by-time interaction effect was detected for work capacity at peak exercise (pgroup*time interaction<0.001, η2=0.346) as increments were superior in the periodized training model compared to those of the non-periodized model (15.3±5.5%, p<0.001 vs 4.7±9.8%, p=0.094; respectively). Both exercise models significantly increased peak VO2 (p=0.023, η2=0.191), total body skeletal muscle mass index (p<0.001, η2=0.345), upper (p<0.001, η2=0.724) and lower (p<0.001, η2=0.540) body muscle strength ratios.
CONCLUSION: A periodized training model is more effective in inducing benefits in working capacity in patients with CAD. Nevertheless, both training models were equally effective in improving peak VO2, skeletal muscle mass and upper and lower body muscle strength. These findings may have important implications for exercise training prescription in supervised long-term Cardiac Rehabilitation programs.

THE RELEVANCE OF SCHOOL COMMUNITY WORKING RELATIONSHIPS IN PHYSICAL EDUCATION PRE-SERVICE-TEACHERS IDENTITY DEVELOPMENT: THE CASE OF THE INSTITUTE UNIVERSITY OF MAIA PETE PROGRAMME

AMARAL-DA-CUNHA, M., PINTO, J., PINTO, T., ARAÚJO, R., MARCELINO, R.

UNIVERSITY INSTITUTE OF MAIA

INTRODUCTION
Identity under the perspective of situated learning (Lave & Wenger, 1991; Wenger, 1998) has been used as an analytical tool to capture how teachers work, learn and develop professionally (e.g., Luehmann, 2007). However, few studies have looked into how pre-service teachers learn to become Physical Education teachers through the working relationships established within their communities of practice in the course of the school placement (Amaral-da-Cunha et al, 2018).
METHODS
This study examines the relevance of interpersonal interactions in the identity development of physical education pre-service teachers. The participants were post-graduate students from the PE Teacher Education Programme of the Institute University of Maia, Portugal. Data were collected throughout focus groups (Macnaghten & Myers, 2010) in the final-term of the PST' school placement.
RESULTS AND DISCUSSION
An inductive thematic analysis revealed that: i) the first steps to integrating the profession and the school community happened through formal and informal conversations with the more experienced colleagues; ii) the mutual support and commitment between the members of the school placement group, especially with respect to the role of the cooperating teacher, were underlined as fundamental to learning the schools' sociocultural repertoires (rules, discourses and practices); iii) the reflective practices undergone during the academic year were also considered as key elements to the participants' identity development as physical education teachers; iv) the school placement experience modifies not only the way the pre-service teachers act, but also the type of person (and teacher) they become, both from the individual and collective points of view (Gee, 2000-2001).

OPPORTUNITIES FOR ENGAGING IN PRACTICAL ACTIVITIES AT CONTINUING PROFESSIONAL DEVELOPMENT (CPD) WORKSHOPS ASSOCIATED WITH SELF-EFFICACY CHANGE IN SECONDARY SCHOOL PHYSICAL EDUCATION (PE) TEACHERS

NEVILLE, R.D.1, MAKOPOULOU, K.M.2

UNIVERSITY COLLEGE DUBLIN [1], UNIVERSITY OF BIRMINGHAM [2]

BACKGROUND:
Whilst there is consensus that continuing professional development (CPD) is beneficial for physical education (PE) teachers, questions remain about the features of CPD that enhance their self-efficacy (SE) and thereby positively affect pupil outcomes. Research suggests that CPD is maximised when teachers are actively engaged in the professional learning process, rather than passive recipients of cookie-

cutter lesson plans and overly formulaic routines. However, there are no published studies of PE-CPD to date that have tested this claim empirically.
AIMS:
The purpose of this study was to explore whether increased opportunities for engaging in practical activities during formal CPD workshops was associated with enhanced PE teacher SE over time.
METHODS: The context for this study was an independent evaluation of a national CPD programme on inclusive PE in England. The CPD was delivered in the form of a day-long workshop, wherein teachers were tutored on the principles and practices of inclusive PE. A total of 27 CPD workshops across England were observed and recorded in their entirety. The primary independent variable of interest at workshops was the proportion of time-on-task devoted to theory-based and practical learning activities. To measure the impact of the workshop on PE teachers' SE, a repeated measures design was adopted and data were collected at three points in time: prior to (T1 n=427), immediately following (T2 n=379), and 6 months after attending the CPD workshop (T3 n=58). SE change (T3-T1) served as our dependent variable and data were analysed using hierarchical linear mixed modelling.
RESULTS: The intraclass correlation coefficient revealed that a substantial proportion (10%) of the variation in SE change over time was associated with workshop-level factors. This justified the evaluation of practical activities within CPD workshops as a meaningful predictor of SE change. Primary analyses revealed a substantial interaction effect based on whether the teacher worked in a primary or secondary school. That is to say, there was a substantial difference between primary and secondary school teachers in terms of the effect of practical activities on SE change (1.12, ±0.99; difference between groups; ±95% confidence limits) (p = .03). There were also differences between these groups in terms of the effect of course size (0.88, ±0.92) (p = .06) and course quality perceptions (0.99, ±1.09) (p = .07) on SE change. However, these effects were not statistically significant and were therefore only possibly substantial.
CONCLUSION: Opportunities for engaging in practical activities at formal CPD workshops appear to be more important predictors of SE change for secondary school teachers. This is most likely due to the fact that secondary school PE teachers are subject specialists and will therefore have had greater exposure in their initial teacher training to the theoretical underpinnings of inclusion in PE.

PRIVACY AND CONFIDENTIALITY IN EXERCISE AND SPORTS SCIENCES WORK PLACEMENTS: LEGAL AND ETHICAL CONSIDERATIONS

SEKENDIZ, B.

CENTRAL QUEENSLAND UNIVERSITY

Introduction
Work placements are an integral part of exercise and sports sciences curriculum. Due to the type and location of these work placements students can often be required to access sensitive client information. There is currently a gap of knowledge about the implications of the privacy laws for exercise and sports sciences work placements and related course work requirements at private sector health service providers such as allied health clinics, fitness facilities or gyms. The aim of this study is to describe the rules for accessing and sharing sensitive client information from the perspectives of the higher education and health service providers within the relevant legal and ethical frameworks that regulate the handling of such personal information by organisations.
Methods
The first stage of the study consists of a review of primary sources of law such as the relevant legislation in each jurisdiction, legal principles, and case law. The second stage of the study consists of a review of secondary sources of law such as case digests, text books, and legal peer-reviewed journal articles in order to explain the findings from the first stage of the study.
Results
The findings show that regardless of the type and location of exercise and sport science work placements, a person`s right for personal autonomy to know and decide how their personal information will be maintained, used and shared is a protected legal right under the privacy laws. Government health organisations have developed very strict policy and procedures to ensure patient confidentiality during work placements or in medical research including online data security and informed consent. However, the industry standards or practices for handling private and confidential client information at exercise and sport sciences work placements at private health sites is not clear.
Conclusion
The higher education providers, industry bodies, and private sector health service providers are urged to work in collaboration to develop and implement risk management strategies to ensure high standards of ethical practice and confidentiality of sensitive client health information are maintained that can support high quality learning outcomes for the work placement students. Future studies that investigate the relationship between the implementation of risk management practices and the perceptions about client privacy at exercise and sport sciences work placements are warranted.

INSPIRING STORIES: THE CASE OF AN EXERCISE PRESCRIPTION CLINIC AND PRACTICUM PROGRAM

HODGES, L.D., MARTIN, A.J., REES, M.

MASSEY UNIVERSITY

INTRODUCTION: The benefits of Work-Integrated Learning (WIL) programmes are well documented in terms of the tripartite outcomes for students, workplace organisations and the university. Enhanced self-efficacy, career development, and employability outcomes have been highlighted for exercise science students through participation in WIL programs. However, the benefits for the clients of such programs have not been documented. This presentation examines how a WIL programme within a Bachelor of Sport and Exercise major in Exercise Prescription and Training has benefitted students and clients alike. Students exercise test and train clients impacted by non-communicable diseases, including cardiovascular, neurological and/or muscular skeletal problems which substantially limit their physical activity, for example chronic fatigue syndrome, multiple sclerosis and spinal cord injury, in a supervised exercise clinic.
METHODS: Case study narratives will be presented of individuals (students and clients) stories of their learning journey of being part of the clinic. In this study feedback was analysed from 20 students and 60 clients after their participation in an exercise prescription WIL program.
RESULTS: The WIL opportunity required students to use principles of specificity and individuality due to the various health needs of clients. These challenges added to the student's knowledge and application of different exercise prescription testing and training methods. Findings indicated that from the student's perspective there has been learning from the clients in terms of their health challenges and life experiences, which has been humbling, motivating and rewarding. The WIL experience has also provided benefits for the clients too. The exercise clinic provided an affordable, supervised and safe environment to exercise. The clinics enabled social connections and a shared

experience with others whom also had compromised health conditions. Clients, who were often initially nervous about exercising, received an individualised specific program, and met with the same student trainer over a period of 10 weeks. Clients were monitored and provided with motivation. As this formed course work for the students, the clients were accountable for completing the programme and had accountability. Clients enjoyed that they could build a relationship with their trainer and could exercise and achieve their specific exercise goals within a safe and social environment.
CONCLUSION: The findings reinforce the importance of developing WIL experiences that enhance the learning outcomes for both the student and the client. Designing authentic industry WIL clinical experiences for future health professionals should enable students the opportunity to engage with a range of clients. Such clinics should provide affordable, supervised and safe environments for clients to exercise, enabling social connections and a shared experience with others having compromised health conditions.

OP-MI02 Training and testing: Rugby

GAME PERFORMANCES AND WEEKLY WORKLOAD IN RUGBY UNION: USING OF DATA MINING PROCESS AND MACHINE LEARNING TO ENTER IN THE COMPLEXITY.

DUBOIS, R.1, PAILLARD, T.1, BRU, N.2, PRIOUX, J.3

1: LAPPS , 2: LAMP , 3: M2S ,

INTRODUCTION: Since 1995, Rugby union became a professional team sport whose the sport and financial issues have continued to grow over the years. The continued increase in game intensity and competitive aspect in competition (ascent-descent championship), among others, contributed to the injury risk and non-functional adaptation (Cross et al., 2016; Williams et al., 2017). Therefore, the optimization of the physical performance is the prior objective for the team sport's staffs. In this way, the workload (WL) monitoring, management and adaptation are important parameters to consider in elite team sport (Bourdon et al., 2017). Thus, this study aimed to i) identify the performance factors during professional rugby games, ii) construct some synthetic indicators of the performance, iii) and finally to analyze how weekly workload (W-WL) at different terms (up to 8 previous weeks) influences the game performance throughout an entire season.
METHODS: This study consists in using abundant sports data and data mining techniques to assess player performance and the influence of W-WL on the performance. The W-WL, locomotor activity and the specific actions were collected on 14 professional players (26.9 ± 1.9 years) during training and games throughout a TOP14 season. To highlight the factors of the performance, mixed-linear model was used to compare players' activity depending on game results, players position and status. A principal component analysis was used to analyze the variability in locomotor and specific activities and two different statistical models (linear correlation and threshold-based models) were used to identify relationships between W-WL and physical performance.
RESULTS: The forwards performed a greater defensive performance during the games won with more tackle completed ($p<0.05$, $d=0.8$) and more offensive tackle performed ($p<0.05$, $d=0.6$) compared to the games lost. Moreover, the forwards have a greater activity index (number of coded actions relatively to ball-in-play time when the player played) during the games won ($p<0.05$, $d=0.5$). This showed that the defensive skills represent a discriminate factor of collective performance. A principal component analysis demonstrated that the 88% of locomotor activity would be resume by 2 dimensions including the total distance, high-speed/metabolic efforts and the number of sprints and accelerations. On the contrary, no synthetic index was found concerning the specific activity parameters. Finally, Threshold-based model, from machine learning process, allows to highlight, among others, the positive influence ($p<0.05$) of the chronic number of severe impacts on the ability to win offensive duals in game.
CONCLUSION: This study gives some practical application in the way to better understand the performance during elite rugby games and testify of the future contribution of machine learning process to optimize training process.

INTERNAL LOAD MONITORING, NOTATIONAL AND TIME MOTION ANALYSES, PSYCHOMETRIC STATUS, AND NEUROMUSCULAR RESPONSES OF ELITE RUGBY UNION PLAYERS' TRAINING.

LUPO, C., BRUSTIO, P.R., UNGUREANU, A.N., LICCIARDI, A., BOCCIA, G., RAINOLDI, A.

UNIVERSITY OF TURIN

INTRODUCTION: The present study aimed to verify if practicing tackles during rugby union training sessions would affect the players' internal training load (ITL) and acute strength loss.
METHODS: Nine male Italian Serie A rugby union players (age: 21±2 yrs; height: 184±7 cm; body mass: 91±9 kg) were monitored by means of an integrated approach of measurement during 17 training sessions (93±19 min) including (WT, 6 sessions) or not (NT, 11 sessions) the practice of tackles. In particular, heart rate monitors (Team Pod; Firstbeat, Finland) and global system positioning devices (Spin_GNSS_50Hz, Spinitalia S.r.l., Italy; LagalaColli 10.03 software, Spinitalia SRL, Italy) were used to quantify the internal (Edwards, 1993) and external (total distance, time spent > 16 km/h) training load. In addition, the sessions were video-recorded to analyze the work-to-rest ratio (W/R) and verify the presence of tackles. Before each session (PRE), the Well-being Questionnaire (Blake et al., 2010) was filled in by players. After each session (POST), rating of perceived scale (RPE; Foster et al., 1995) was used to quantify ITL according to Session-RPE method. Finally, at PRE and POST, countermovement jump (CMJ) and push up jump (PU) tests were performed on a force plate (9286AA Kistler; Switzerland) to record players' concentric peak force.
A linear mixed model was used to verify if players' ITL (according to Edwards' or Session-RPE methods) was influenced by practicing tackles when controlling for training load parameters regarding volume (total distance, session duration), intensity (total distance/session duration, time spent >16 km/h), and density (W/R) of session, as well as player' conditions at PRE (well-being score, CMJ and PU peak force). A second linear mixed model has been applied to evaluate if the PRE-POST difference in CMJ or PU peak force was affected by practicing tackles when controlling for Edwards' ITL, W/R, well-being score, and session duration. In both models the players were included as a random effect.
RESULTS: Edwards' ITLs resulted higher in WT than NT sessions (estimated mean, EM; standard error, SE; WT: EM = 214, SE = 11.8; NT: EM = 194, SE = 11.1; $p=0.01$). In addition, Edwards' ITL resulted positively influenced by CMJ at PRE ($p=0.01$). Session-RPE ITLs resulted higher in WT than NT (WT: EM = 379, SE = 21.9; NT: EM = 277, SE = 16.4; $p<0.001$). However, no effect between the two types of session emerged for the PRE-POST difference in CMJ and PU peak force.

CONCLUSION: Although the ITL of elite rugby union players can be influenced by practicing tackles during the sessions, these differences seem to have no impact on the acute strength production of upper- and lower-limbs.

BODY COMPOSITION AND SYMMETRY CHARACTERISTICS OF PROFESSIONAL RUGBY UNION PLAYERS

POSTHUMUS, L.R.1,3,4, MACGREGOR, C.B.1,2, GILL, N.D.3,4

TOI OHOMAI INSTITUTE OF TECHNOLOGY

INTRODUCTION: Rugby union is a collision-based sport in which varied body compositions exist depending on the position played in order to perform effectively. For example, forwards generally have a larger body mass and a large strength emphasis in order to gain and retain possession of the ball, scrummage with more force and tolerate more collisions (1). Backs on the other hand, require more speed and agility in order control possession of the ball and create scoring opportunities which generally favours a slightly smaller body mass and more efficient muscle to fat mass ratio (2). The purpose of this study was to examine the body composition and symmetry characteristics of professional rugby union players during the pre-season.
METHODS: Thirty-eight Super Rugby Championship players (age=26.6±3.3yrs, height=187.6±6.6cm, mass=108.0±14.1 kg) were measured for height and weight followed by lean, fat, and bone mass whole body scans using Discovery A Hologic Dual-Energy X-ray Absorptiometry (DEXA). Participants were categorised into their forward and back positions for comparison.
RESULTS: Forwards had significantly greater stature (190.9±5.6 cm vs. 183.0±7.5 cm), body mass (117.7±9.7 kg vs. 97.2±9.3 kg) lean mass (92.3±5.7 kg vs. 77.8±7.6 kg) fat mass (21.4±4.4 kg vs. 15.8±1.9 kg) and bone mass (4.1±0.4 kg vs. 3.6±0.3 kg) than backs. Backs however, displayed less body fat percentage compared to forwards (16.3±1.1% vs. 18.0±2.3%, respectively). Both forwards and backs demonstrated non-significant differences in left versus right leg lean mass (Forwards=0.45±0.32 kg, P= > .05 vs. Backs=0.34±0.30 kg, P= >.05). However, they both displayed significant differences in left versus right arm lean mass (Forwards=0.43±0.25 kg, P= < .01, Backs=0.27±16 kg, P= .010). Forwards exhibited no significant differences in left versus right arm fat mass (0.12±0.12 kg, P= > .05) however, there was a significant difference between left and right leg fat mass (0.34±0.48 kg, P= < .01). Backs on the other hand, presented significant differences in both left versus right arm and leg fat mass (0.24±0.10 kg, P= < .01 and 1.24±0.44 kg, P= < .01, respectively).
CONCLUSION: Body composition characteristics between forwards and backs continue to highlight the different positional demands of these athletes and what is needed in order to physically perform at a high level. With asymmetries identified within these professional rugby union players, future research may want to explore whether these types of asymmetries are an area for concern and if addressing them has any benefit to performance and/or injury prevention.

TECHNICAL FEEDBACK AND INSTRUCTION USING VIDEO IMPROVES TACKLING TECHNIQUE OF RUGBY UNION PLAYERS

DAVIDOW, D.1, WATSON, M.1, LAMBERT, M.1, BURGER, N.1, JONES, B.2,1, KRAAK, W.3, HENDRICKS, S.1,2

1: UNIVERSITY OF CAPE TOWN, SOUTH AFRICA 2: LEEDS BECKETT UNIVERSITY, UNITED KINGDOM 3: STELLENBOSCH UNIVERSITY, SOUTH AFRICA

INTRODUCTION: In rugby union, the tackle is a physical and technical contest where the opposing players compete for territory and ball possession. The tackle is the most frequently occurring contact event, and the ability to repeatedly contest and win the tackle has been associated with team success. The nature and frequency of the tackle exposes players to high risk of injury, with more than 50% of all injuries occurring during the tackle. Proficient tackling technique in rugby union matches has been associated with a reduced risk of injury and higher likelihood of tackle success. However, strategies to improve players' tackle technique training are limited. In other sport, instructional feedback has shown to improve players' technical abilities. Therefore, the purpose of this study was to determine the effect of an instructional feedback intervention on tackling technique in rugby union.
METHODS: Twenty-four rugby union players participated in a non-randomised control-intervention study design. Participants were divided according to positional groupings for training reasons (forwards and backs). These positional groupings were subsequently used as the grouping factor for the study i.e. instructional feedback group (forwards) and no instructional feedback group (backs). During 3 sessions (baseline, intervention, retention) separated by one week, participants in each group performed six tackles (3 tackles on each shoulder) on a tackle contact simulator. Each tackle was video recorded and analysed using a standardised list of tackling technical criteria. The technical criteria outlines a list of observable actions, and a player is awarded either one point or zero depending on whether a particular action is performed or not. The sum of these points is subsequently used to represent the technical proficiency score of the player. During week 2, before executing the six tackles, the intervention group received technical feedback and instruction using the video and their technical proficiency score.
RESULTS: The instructional feedback group scored significantly higher during the intervention (mean 7.92, 95%CI 7.63-8.21 AU, p<0.0001) and retention (mean 8.32, 95%CI 8.02-8.62 AU, p<0.0001) sessions compared to baseline (mean 7.08, 95%CI 6.74-7.42 AU). Differences were also found between intervention and retention sessions (mean 7.92, 95%CI 7.63-8.21 vs. mean 8.32, 95%CI 8.02-8.62 AU, p<0.05). The group that did not receive instructional feedback scored higher during the retention session compared baseline (baseline 6.64, 95%CI 6.40-6.88 AU vs. retention 7.12, 95%CI 6.87-7.46 AU, p<0.05).
CONCLUSION: This study showed that technical feedback and instruction using video improved tackling technique of rugby union players. The findings of this study can be used to design and develop tackle training programmes to better prepare players for match tackle demands, with the ultimate goal of reducing the risk of injury while improving tackling performance.

PEAK RUNNING INTENSITIES OF ELITE YOUTH RUGBY LEAGUE MATCH PLAY

SMITH, M.R.1, ARMSTRONG, P.1, THORNTON, H.R.2,3, BORGES, N.R.1

1: UNIVERSITY OF NEWCASTLE, AUSTRALIA, 2: LA TROBE UNIVERSITY, AUSTRALIA, 3: GOLD COAST SUNS

INTRODUCTION: Understanding the peak running intensities experienced during team sport competition allows coaches to accurately replicate demands during training. Peak running intensities of elite rugby league have previously been reported (Delaney et al. 2015),

however no data exists for youth rugby league athletes. Therefore, the aim of this study was to investigate the peak running intensities of elite youth rugby league athletes during match play, comparing between age and positional groups.
METHODS: Global positioning system units were used to obtain match activity data from elite youth rugby league athletes, recording at a sampling rate of 5 Hz (interpolated to 15 Hz). Speed (m/min) data were collected across two age groups (U16 and U18) during one competitive season. Data were cropped to ensure only time on field was obtained, and one- to ten-minute moving averages (window) were applied to each data file. All data were averaged across six positional groups (fullbacks, outside backs, halves, edge forwards, middle forwards, hookers) within each age group. Linear mixed models were used to determine differences between positional and age groups. Differences within age, between positional groups, and within positional groups, between age were further described using standardised effect sizes (ES) and 90% confidence limits. These magnitudes were further interpreted using a non-clinical magnitude-based inference approach.
RESULTS: As the window length increased, peak running intensity decreased. Indeed, peak intensity using a one-minute window length was substantially higher than all other window lengths in both age groups ($p<0.05$; ES range = 1.81 – 5.09). There were no significant or substantial differences in peak running intensity between positional groups or age groups. Peak running intensities using a one-minute window (U16 = 168 m/min, U18 = 165m/min) were similar to those previously reported in elite senior rugby league (170 m/min; Delaney et al. 2015).
CONCLUSION: This study identified the peak running demands of competition in elite youth rugby league athletes. The limited differences in peak running intensity between positional groups and age groups suggest a broad range of elite youth rugby league athletes can receive similar training stimuli. Further research is required to assess whether similar trends exist in other teams. Although peak running intensities of youth match play appear to be similar to senior competition, assessment of additional variables (e.g. accelerations) would allow for a more accurate comparison of match demands.

OP-SH01 Sociology

SOCIAL NETWORKS AND ITS INFLUENCE ON NUTRIENT INTAKE, NUTRITIONAL STATUS AND PHYSICAL FUNCTION OF COMMUNITY-DWELLING ETHNICALLY DIVERSE OLDER ADULTS: A MIXED METHOD LONGITUDINAL STUDY

ASAMANE, E.A., GREIG, C.A., THOMPSON, J.L.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Social networks (SN) have consistently been shown to influence health outcomes in later life. However, little is known about the SN of older ethnic minorities, and how they impact on nutrient intake and physical function over time.
METHODS: A longitudinal mixed-methods design was employed. 100 community-dwelling ethnically diverse older adults 60 years and above, living in Birmingham, UK were recruited. SN were assessed using the Wenger Practitioner Assessment of Network Type (PANT). Energy and nutrient intake were measured using multiple-pass 24-hour recalls. Physical function was measured using the Short Physical Performance Battery (SPPB), Katz Activities of Daily Living (ADL) and hand grip strength tests. A bespoke questionnaire was used to collect socio-demographic and health-related data. Measures were taken at baseline and after 8-months follow-up. MANOVA and linear regression examined associations between SN and changes in nutritional status, nutrient intake and physical function over time. The influences of SN were captured through semi-structured interviews at baseline and follow-up. Interviews were transcribed verbatim and analysed using directed content analysis.
RESULTS: 81% of participants recruited completed follow-up measures. Mean age at baseline was 70.8 ±8.1 years (59% male) comprising Africans/Caribbean (58%), South Asians (34%), and other ethnicities (7%). Five SN typologies were identified: locally integrated (44%), family dependent (25%), locally self-contained (16%), wider community (8%) and private restricted (6%). SN declined in 27% of older adults and were maintained or improved in 54% and 19% of older adults, respectively, at follow-up. There was a significant overall decrease in physical function ($F(1)=9.73$, $P=0.03$) and nutritional status ($F(1)=6.04$, $P=0.016$) over time. Older adults with integrated SN compared with non-integrated SN at baseline were less likely to experience a decline in physical function at follow-up (OR: 0.171; 95% CI: 0.047-0.627). Baseline and follow-up energy and nutrient intakes were not significantly different except for vitamin B6 (1.57 vs 1.42 mg, $P= 0.042$). Qualitative results indicated that for participants who experienced decreased physical function and nutrient intake, primary reasons included a decline in SN and/or increased current medical conditions, poor weather conditions and increasing age.
CONCLUSION: The findings from this longitudinal study indicate that changes in SN can occur in community-dwelling ethnically diverse older adults over a relative brief time period, with integrated SN associated with better physical function, nutrient intake and nutritional status. These findings can be used to inform interventions and community outreach programmes designed to enhance social networks and the health status of this population.

ADVENTURE SPORTS AND THE PERCEPTION OF BEING, OR NOT BEING, ELDERLY

MARINHO, A., VISCARDI, A.A.F., VIEIRA, I.M.

STATE UNIVERSITY OF SANTA CATARINA ; FEDERAL UNIVERSITY OF SANTA CATARINA

Introduction
The increasing proportion of older adults in Brazil, combined with increasing longevity, justifies the importance of seeking to improve this population's quality of life. Since two fundamental factors of quality of life are interpersonal relationships, which can be stimulated through sports activities, and reconnecting with nature, older adult interest in adventure sports is increasing. So, this study investigates the perception of the term "elderly" among adventure sports practitioners aged 60 and over.
Methods
Its a cross-sectional study, descriptive exploratory field survey with a qualitative data approach. The sample included 22 practitioners of adventure sports aged between 60 and 89 years. The participants were suggested by physical education professionals, adventure companies specializing in windsurfing, kitesurfing and Hawaiian canoeing, clubs, and research participants. The instruments included a

semi-structured interview and simple observation. Of the 23 individuals interviewed, 19 were observed during their activities, i.e., sailing, kayaking, cycling, running, climbing, caving, kitesurfing, mountaineering, stand-up paddle boarding, surfing, trekking, hang gliding and windsurfing. All interviews were conducted individually, digitally recorded and completely transcribed by the researchers. Observations were also recorded in a field diary. The data were organized using NVivo version 11.0 and were analyzed using content analysis.
Results and Discussion
Unease at being treated as "elderly" was reported or demonstrated by 50% of the interviewees, while the others did not feel constrained by such a designation. Although the participants expressed different opinions about how they like to be treated, many reported that the term "elderly" refers to a biased image of disability. Some point out that this image does not fit the current global scenario. All participants reported feeling well-disposed, active and full of life, which was verified in the field observations. For this reason, some participants felt conflicted, since they do not perceive themselves within expected social roles. Others reported feeing uninhibited by the thoughts and opinions of others, focusing on their own potential and physical abilities. Since it so happens that adventure sports is a means of intergenerational contact, this result is not surprising. Many participants even reported that they are well accepted, respected, and comfortable in this environment, in which youth prevails. In society's attempt to protect older adults, there is a tendency to consider adventure sports as inconceivable due to the involved risks and unpredictability. However, in the opinion of these participants, reality is otherwise. Group identification, a feeling of belonging and the perception of their potential, as well as improved physical fitness from engaging in adventure sports, interfere in this population's perception of being, or not being, elderly.

EFFECTS OF PARENTS SOCIOECONOMIC STATUS AND PHYSICAL ACTIVITY PARTICIPATION ON THE ADOLESCENTS PHYSICAL ACTIVITY LEVELS

TIAN, H., LI, J., WANG, M.

SCHOOL OF INTERNATIONAL SPORT ORGANIZATIONS, BEIJING SPORT UNIVERSITY

Effects of parents socioeconomic status and physical activity participation on the adolescents physical activity levels
TIAN, Hui, LI, Juan, WANG, Min
Beijing Sport University
INTRODUCTION: Parents physical activity behavior and family socioeconomic status (SES) may play a role in adolescents physical activity (PA) development. However, previous research has shown inconsistent results. Though much research proves that there is a positive association between SES and physical activity among adolescents, forty-two percent studies report no or an opposite relation (Stalsberg & Pedersen, 2010). Therefore, we aimed to investigate the impact of parents SES and PA participation on PA levels among adolescents in Beijing, China.
METHODS: The participants were 377 adolescents (180 boys, 197 girls) with the mean age of 16 years in a top-ranked high school in Beijing. Family SES was assessed using the adapted scale of social stratification in China (Li, 2010). Parents PA frequency was self-reported by students. The adolescents PA levels were calculated using the International Physical Activity Questionnaire (IPAQ) in the short format. One-way ANOVAs were employed to investigate the impact of SES and parents PA on students PA levels. Spearmans Rho bivariate correlation was used to test for association between parents PA and students interest in PA.
RESULTS: There was a significant difference in relation to family SES and the adolescents MVPA minutes per week ($F(2)=3.488$, $p=.032$). Students whose parents were of high SES group report more MVPA minutes than those whose parents were of low ($p=.022$) and moderate SES group ($p=.017$). Parents educational and occupational background play a significant role in influencing the adolescents MVPA minutes ($F(2)=7.823$, $p=.000$). There was a significant difference in relation to mothers physical activity participation and the adolescents total METs ($F(2)=6.932$, $p=.001$) and sitting time per week ($F(2)=3.681$, $p=.026$).The more physically active the mothers were, the less sedentary the adolescents were ($p=.011$). Significant correlations were observed between mothers PA and the adolescents interest in PA ($rs=.245$, $p=.000$), especially in girls ($rs=.282$, $p=.000$).
CONCLUSION: Parents SES and PA participation play a significantly positive role in influencing the adolescents PA levels. These findings support the recommendations to take parents background into consideration when enhancing the adolescents PA levels.

ACTIVE MOBILITY OF ADOLESCENT GIRLS IN PUBLIC URBAN SPACES

DIKETMÜLLER, R.

UNIVERSITY OF VIENNA

Introduction
Recent data of HBSC (BMFG, 2017) showed that less than 6% of the 15 to 17 years old girls in Austria meet the WHO recommendations for physical activity (PA). Especially adolescent girls in urban surroundings are at high risk of low levels of PA. How spaces and urban surroundings influence PA of adolescent girls and boys was assessed in the project "ActivE Youth". In addition, possibilities and opportunities of mobile devices to assess active mobility and to motivate young people for PA in the city were investigated. Especially the question was risen how girls use urban spaces for PA and how they evaluate geo-based gaming on mobile devices as a method (in PE) to stimulate active mobility.
Methods
Before and after an intervention with different geo-based methods, mobility patterns of pupils (n=35, 15-17yrs) out of two public schools were recorded by accelerometer (Actigraph GT3X+) and the smartphone-app Moves. Additional data was acquired by an analogue activity dairy, an online questionnaire and focus group discussions. The data were analysed statistically and by a multilayered triangulation.
Results
The findings show, that the intervention had positive impact on the PA levels and patterns of mobile activity of youngsters. More physically active girls show more complex active mobility patterns within the city and use more different types of urban spaces whereas inactive girls mostly use streets for their active mobility (e.g. way to school). Whereas normally higher socioeconomic status leads to higher levels of PA, especially girls in suburban Vienna benefit from a more mobility friendly environment (number of steps, moderate-to-vigorous physical activity). In addition, it was interesting, how girls and boys argued in the focus group discussion, how they use these methods to increase their PA patterns.

Discussion
The results indicate that geo-based games and mobile devices are seen as possibilities and support the activation of adolescents for PA. In addition, interdisciplinary and intersectional approaches offer new insights how different youth groups with regard to gender are physically active within urban spaces and what could support higher mobility patterns especially of girls.

FACEBOOK IS OUR PLAYGROUND NOW - A STUDY OF THE USE OF SOCIAL MEDIA IN EQUESTRIAN SPORTS

BROMS, L., RADMANN, A.
EDUCATION AND SOCIETY

The aim of this paper is to analyse how equestrians in different age groups use social media to attain information about equestrian sports. There has been a significant increase in daily use of social media and Facebook is the most widely used media. Yet, in the age group 9–16 Instagram has become more important (Eek-Karlsson, 2015, Davidsson 2016; Statens medieråd 2017). Internet is extra important for equestrians, as traditional media fail to cover equestrian sports (Dashper 2017). In order to understand how information and knowledge about sports are collected and given value through social media, it's crucial to understand how different agents use media and which rules and values form their usage. According to Bruce young women today understand and use the power of social media: they tell and create their own stories (Bruce, 2015). Two research questions will guide the study: How do riders explain their media habits and what information is given value and why; Are there differences, and in that case which differences can be found, in the usage of social media and the giving of value related to age, gender and riding experience? A qualitative research method is used. The source material consists of twelve focus group interviews in Sweden and Norway divided in to two age groups 16–25 and 26 and above. The analysis is inspired by Pierre Bourdieu's concepts field and doxa (Bourdieu 1984). In this project, it is argued that the horse world on Internet can be seen as (at least) one field, in which different agents interact in relation to specific rules, their habitus and capital. This study shows that different age groups use social media in different ways. Young and old riders stress that the other group can't behave or use social media platforms in a constructive way. In addition, the results also show (in line with earlier research) that Instagram and Snapchat are increasingly popular among adolescents. However, Facebook is still the most used social media platform among middle aged equestrians, "Facebook is their playground now!" This leads towards the conclusion that there are clear structures of how equestrians in different age groups position themselves on the field of social media. Knowledge about these patterns will be valuable in order to understand how different age group collect and share information about equestrian sport.

EQUALITY WORK IN THE SWEDISH VOLLEYBALL FEDERATION

KARLÉN, S., HELLBORG, A.M., HEDENBORG, S.
MALMÖ UNIVERSITY

Introduction
The aim of this presentation is to map out and analyse how the Swedish Volleyball Federation (SVF) has been working with gender equality. In Sweden, SVF is promoting themselves as one of the most gender equal sports. According to themselves, they have worked hard for equal representation, equal economic financing to the national teams and equal television time for many years (Larsson, Redelius, Kempe-Bergman, 2012). This raises the questions if volleyball in Sweden is gender equal and if so, how did they become gender equal?
Methods
The method consists of mixed research with document analysis and statistics. Documents from the Swedish volleyball federation such as annual reports in the period 1961–2018, their magazine, anniversary publications and their social media activity will be analysed. The material will be analysed through Connells (1987) theories of gender, power and structures.
Results & discussions
Preliminary results show that the SVF's ambition is to be and to become more gender equal. It has been important for the federation to keep working with this issue and historically women have always been part of the sport (Ottosson, 2011). Recruiting and representing women on all levels in the sports movement of volleyball from national to local level, as both leaders and trainers has played a significant role of becoming more gender equal. Yet, the gender equality work has to be interpreted as built on socially constructed gender differences in that girls are seen as playing volleyball because they are interested in social aspects, whereas boys are seen to be involved because of competitive aspects. This points to an understanding of gender equality built on complementary roles. The implications of this needs to be investigated further.
There seems to be a node were the quantitative and qualitative work with gender equality meets and splits. In one way, SVF might be quantitatively gender equal, but that does not necessarily include a qualitative measure of gender equality. Further result might show how gender equality are more complex than numbers of representation, even if it also is important. Maybe gender equality needs to be understood in cultural aspects. The question arises of when a sport is gender equal.

OP-SH05 Children

EFFECTS OF THE 10 MINUTES CLASSROOM-BASED PHYSICAL ACTIVITY INTERVENTION IN FOURTH GRADE CHILDREN'S MATHEMATICAL ABILITY IN TAIPEI

CHANG, W., WU, C., WANG, W.

UNIVERSITY OF TAIPEI, CHENG SHIU UNIVERSITY, UNIVERSITY OF TAIPEI

INTRODUCTION: Lack of proper physical activity among children and adolescents is a global issue (Kohl, Craig, Lambert, et al., 2012). The purpose of this study was to understand the effects of 10 minutes classroom-based physical activity intervention in fourth-grade Children's mathematical ability and their PA levels in Taipei.
METHODS: We focused on 8 elementary schools by 22 fourth-grade classes (11 were taken as the experimental group, 11 were the control group). In the experimental groups were Implementing 10 minutes physical activity program into 32 math lessons about 12weeks and control groups were maintain the traditional teaching. This program obtained valid data on mathematical abilities of a total of 422 students (220 in the experimental group, 202 in the control group), and at the same time, five students were selected from each class using ActiGraph wGT3X-BT to detect the difference Sedentary time and their MVPA during school time by pre and post-test. Valid data were obtained from 102 students (55 students in the experimental group and 47 students in the control group).
Result and discussion:
After intervention in 32 lessons over a period of 12 weeks, the obtained data were subjected to an independent sample t-test, which revealed that, although the students' mathematical abilities had improved, only one school showed a significant difference between the experimental group and the control group, despite the fact that the experimental group was indeed better than the control group in sedentary time and MVPA. Moreover, students and teachers generally had a positive attitude toward this program and believed that it could improve students' motivation to learn.

PHYSICAL FITNESS AND ACADEMIC ACHIEVEMENT IN CHINESE SENIOR HIGH SCHOOL STUDENTS

WANG, M., TIAN, H., LI, J.

SCHOOL OF INTERNATIONAL SPORT ORGANIZATIONS, BEIJING SPORT UNIVERSITY

Physical fitness and academic achievement in Chinese senior high school students
WANG, Min, TIAN, Hui, LI, Juan
Beijing Sport University
INTRODUCTION: The benefits of physical fitness are widely acknowledged and extend across many domains of wellness. The association between fitness and academic achievement, however, remains to be clarified, especially in China. Therefore, the purpose of this study was to examine the relationship between physical fitness and academic achievement in adolescents of Beijing, China.
METHODS: Data were collected from 299 first-, and second-grade adolescents (142 males, 157 females; 15.9 years) from a highly rated high school in Beijing. 50m run, standing long jump, sit and reach test, 800m run (for girls), 1000m run (for boys), bent-knee sit-ups for 1 minute (for girls), and pull-ups for 1 minute (for boys) data in the National Physical Fitness Test were collected from physical education instructors. Physical fitness scores were calculated based on the National Fitness Scoring Guideline. The full score of fitness is 120.
The academic achievement was measured by the schools final examinations at the end of the same semester of the fitness test. Academic areas include the three core subjects, i.e. Chinese, mathematics, and English. The raw scores of the three subjects were transformed into Z-scores reflecting the students actual performance relative to their peers. Pearson correlation coefficient was applied to assess the relationship between physical fitness test results and academic achievement scores. Statistical significance was set at $p<.05$.
Then the students were classified into two groups according to their physical fitness test scores. The high fitness group (Group I) consisted of students with fitness test scores equal to and more than 80, and the low fitness group (Group II) was made up of students with fitness test scores less than 80. The rationale is that fitness test scores of 80 is stipulated as the baseline criteria for any student award program in China. The academic Z-scores of Chinese, mathematics and English were compared between Group I and Group II by independent sample t-test.
RESULTS: A positive association ($P < .05$) was observed between fitness scores and Chinese and English scores ($r = .145$ and .116, respectively), but no significant association was evident between fitness scores and mathematics scores.
Chinese and English scores were the only areas that significantly differed between Group I and Group II. For Group I subjects, the Chinese and English Z-scores were 0.0983 and 0.1254, significantly higher than their Group II counterparts, which were -0.1581 and -0.1136, respectively ($P < .05$).
CONCLUSION: Associations were demonstrated in Chinese achievement, and English achievement, thus suggesting that physical fitness may be globally related to academic performance in adolescents. Therefore, promoting fitness by increasing opportunities for physical activity may support academic achievement.

SEDENTARY BEHAVIORS PROFILES TRANSITIONS AMONG SCHOOL-AGED YOUTH: ASSOCIATIONS WITH CHANGES IN ACADEMIC PERFORMANCE; THE UP&DOWN STUDY

SÁNCHEZ OLIVA, D.1, PEREZ-BEY, A.1, FERNÁNDEZ-SANTOS, J.R.1, CABANAS-SÁNCHEZ, V.2,3, ESTEBAN-CORNEJO, I.4, CASTRO-PIÑERO, J.1

1: DEPARTMENT OF PHYSICAL EDUCATION, FACULTY OF EDUCATION SCIENCES, UNIVERSITY OF CADIZ. 2: RESEARCH CENTRE IN PHYSICAL ACTIVITY, HEALTH AND LEISURE , FACULTY OF SPORT. UNIVERSITY OF PORTO, PO

INTRODUCTION: Emerging evidence shows that sedentary behaviours (SB) are associated with poor academic performance (Carson et al., 2016; Tremblay et al., 2011). However, most of these studies focused on TV viewing, and fewer researches have evaluated other SB modalities (i.e., playing video games, talking/chatting on the telephone, reading, doing homework, or motorized traveling). The purpose of this study was to analyze the associations between SB profiles transitions and changes in academic performance during 2-year follow-up.

METHODS: Participants were 1183 (50.8% boys) children (n = 466) and adolescents (n = 717) from 40 schools of Cadiz and Madrid regions (Spain). Self-reported domain-specific SB (i.e., screen, educational, social, and relaxing SB) were assessed using the Youth Leisure-time Sedentary Behavior Questionnaire (YLSBQ; Cabanas-Sánchez et al., 2018), whereas academic performance was assessed through grade point average calculated as a single average for the examinable subjects in each grade. Firstly, we estimated gender-specific Latent Profile and Transition Analysis to identify SB profiles at both baseline and 2-year follow-up, as well as profile membership transitions over time. Secondly, we performed general lineal models by including AP changes as dependent variable, profile transition as fixed factor, and age, and parent education as covariates.
RESULTS: Boys were grouped into four SB profiles (i.e., screen, educative, social, and relaxing profiles), whereas girls were captured into three SB profiles (i.e., screen/social, educative, and relaxing profiles) at both baseline and follow-up. Youth belonging to the educative profile tended to show higher academic performance when comparing to non-educative profiles at both time-points ($p<0.05$). Transition stability was higher among girls (range: 48%-67%) than boys (40%-52%). Given the higher scores observed in academic performance for the educative profile, profiles transitions were grouped as 1) keep educative, 2) change to educative, 3) change from educative, and 4) keep non-educative. Although all groups decreased academic performance over time, boys who "changed to an educative profile" displayed a significantly lower decrease on academic performance compared to boys who "changed from an educative profile" ($p<0.05$). No significant differences were found in girls.
CONCLUSION: Educative SB (i.e., doing homework/study and reading) were found as the more adaptive form of SB to be associated with academic performance, especially in boys. These findings suggest the need of developing interventions to decrease sedentary time by focusing on non-educative SB modalities.

NEW WAYS OF PREVENTIVE P.E. CURRICULUM

BODÓ, D., WILHELM, M.

UNIVERSITY OF PÉCS - FACULTY OF SCIENCES

Introduction
Our study focuses on possible changes in Hungarian physical education curriculum by adding progressive bodyweight exercises (calisthenics) to P.E. classes. Calisthenics exercises are great for physical education because they are easy to differentiate, can be used in long term progression plans and the movements can be used as preparation for sport specific practice. One of the aspects is to demonstrate our hypothesis in real physical education classes, and to create a better physical education curriculum with effective long term progressive calisthenics training plans.
Methods
We conducted our program in a regular high school P.E. curriculum for 30 classes, taking 10-12 minutes in each P.E. classes, and measured the changes in performance (strength, strength-endurance, movement quality) before and after the program. The other aspect is to confirm our program with laboratory tests and prove that a proper progression plan and exercises have positive effects on muscle strength and cardiovascular system. To identify differences between muscle activation during different calisthenics exercises we used EMG (Noraxon). 8 individual muscles - m. trapezius, m. front deltoideus, m. pectoralis major, m. triceps brachii, m. biceps brachii, m. latissimus dorsi, m. rectus abdominis, m. erector spinae, - were measured, during 4 different levels of push up variations - regular p.u., close (diamond) p.u., assisted one arm p.u., one arm p.u.. To measure the effect of the exercises on cardiovascular system laboratory tests (treadmill - Bruce protocol; calisthenics circuit training program) were preformed with ECG and spiroergometry.
Results
Our results shows that the program has great effect on students performance in strength and strength endurance levels ($P\leq0.05$) just like in movement quality ($P\leq0.05$). Our results also suggest that calisthenics exercises designed in circular training have similar effects on cardiovascular system by raising heart rate (average heart rate 162 bpm, 86% of max. heart rate, anaerob zone) to cyclic movements like running. The EMG part of the study suggest that our protocol based on proper progression (tendency shown in correlation between muscle activation and the difficulty of calisthenics exercises), but it also gave us unexpected results as well. We realized that certain movement patterns tell us more of the connection between muscle activation and movement quality and efficiency. The results suggest that the activation of trunk muscles are prior than activation of the limb muscles in term of movement quality. It shows us that movement practice and skill development should be designed by a proximodistal development model.
Conclusion
These data could be helpful in planning P.E. curriculum as a preventive physical activity program, such as professional strength training or rehabilitation by giving a selecting principal in skill development hierarchy.

Oral presentations

IS-SP03 Effective management of the return of training (RTT) - Sponsored by Catapult [Applied track]

OVERVIEW OF THE RETURN TO TRAINING PHASE OF REHABILITATION

DRUST, B.

LIVERPOOL JOHN MOORES UNIVERSITY

This talk will provide an overview of the rehabilitation process post sports injury, discussing the sequential transition through the 3 subcomponent phases. Entry and exit criteria for RTT will be introduced, using real case histories. The talk will emphasise the value of a true interdisciplinary approach to the RTT phase, with shared planning and ownership contributing to reduced risk of breakdown or recurrence. Attention will be given to the challenges associated with design of programmes which provide a relevant and progressive exposure to stress, and a safe reintroduction to team training regimes.

DESIGN, DELIVERY AND MONITORING OF RTT PROGRAMMES TO MEET INDIVIDUAL REQUIREMENTS

HARLEY, J.

NEWCASTLE UNITED FC

This talk will use practical case studies to illustrate how variables are manipulated to meet individual needs, within the context of a generic RTT framework. The design and implementation of progressive periodised plans will be discussed, as will appropriate methods of monitoring progress. The use of a combination of generic and more functional protocols will be introduced to illustrate how physiological, biomotor and sports specific targets can be addressed. Within the context of a multifaceted RTT plan, the delicate balance between rate of progression and risk of re-injury will be explored from the perspective of the S&C coach / Sports Scientist.

RTT POST INCIDENCE OF INFECTIOUS DISEASE

MEYER, T.

SAARLAND UNIVERSITY

This talk will summarize the current knowledge about potential dangers from early return to play after infectious diseases and formulate recommendations how to proceed safely. Different circumstances between professional players and amateurs will be recognized and taken into account. Criteria for a safe return to play include clinical indicators, results from technical measurements like ECG, Holter monitoring and echocardiography as well as laboratory parameters. Finally, directions for future research in the area will be presented

Oral presentations

OP-PM03 Nutrition: Vitamins, collagen and antioxidants

THE EFFECT OF VITAMIN D STATUS ON PHYSICAL PERFORMANCE, BONE QUALITY AND DENSITY IN UK UNIVERSITY ATHLETES AND SEDENTARY CONTROLS

WILSON-BARNES, S., HUNT, J.E., MENDIS, J., WILLIAMS, E.L., KING, D., ROBERTS, H., LANHAM-NEW, S.A., MANDERS, R.J.F.

UNIVERSITY OF SURREY

INTRODUCTION: Research into the potential ergogenic effects of vitamin D (vitD) and the relationship between vitD status and sport performance has become increasingly popular. However, there is little research in recreational or non-professional athletes residing at higher latitudes within Europe. This study aimed to investigate the effects of vitD status on physical performance, bone quality and density in UK university athletes and make comparisons with sedentary controls.
METHODS: A total of 34 athletes (Ath) and 16 sedentary controls (Con) from the University of Surrey (51ºN) were observed during spring (Feb-March) and summer (May-June) 2018. Serum vitD and sunlight exposure were assessed using LC-MS/MS and dosimetry, respectively. Muscular strength of the upper and lower body was assessed using handgrip and knee extensor isokinetic dynamometry (MVC). Muscular power was assessed through a countermovement jump (CMJ) and aerobic fitness (AF) was measured by a VO2MAX test. Bone quality (trabecular and cortical density; g/cm3) of the tibia was assessed using peripheral quantitative computed topography (pQCT) and whole-body bone density was measured using dual energy x-ray absorptiometry (DEXA; g/cm3). Statistical analysis was performed using t-tests statistical significance was set at P≤0.05.
RESULTS: VitD status increased significantly over the season, with Ath measuring higher concentrations both in spring (52 ±21 vs 37±19nmol/L, p=0.03) and summer (67±16 vs 56±19nmol/L, p=0.04) compared to Con , respectively. Ath had greater upper body strength (39±9 vs 31±10kg, p=0.01), CMJ (36±7 vs 27±8cm,P=0.01) and AF (47±9 vs 35±9 ml/kg/min-1,P<0.001) during the spring than Con. CMJ (33±9 vs 26±7cm,P=0.02) and AF (48±11 vs 36±5ml/kg/min-1,P<0.001) were also higher during the summer in the Ath group. When divided into 'insufficient' (≤50nmol/L) and 'sufficient' (≥50nmol/L) groups, 62% of participants were insufficient in the spring and had a lower CMJ (29±9 vs 36±8cm,P=0.05) and AF (41±11 vs 48±9ml/kg/min-1;P=0.05) when compared to sufficient participants. During summer, 25% of the cohort was classified as insufficient and measured lower values for CMJ (26±8 vs 32± 9cm,P=0.05) and AF (41±11 vs 48±9ml/kg/min-1,P=0.01) compared to sufficient participants. 15% of the Ath and 31% of Con were deficient (<25nmol/L) in spring, although none were deficient in the summer. Bone mineral content (BMC) of the distal tibia and trabecular density (BMD) were greater in the Ath group at both measurements. BMD (1.0 vs 0.9,p=0.03;1.0 vs 0.8g/cm3,P=0.004) and BMC (5.4 vs 4.4,P=0.02;5.2 vs 4.4g,P=0.01) were greater at the femoral neck when compared to Con.
CONCLUSION: These findings suggest that insufficient vitD status were associated with lower indices of muscular power and aerobic fitness in university-level Ath and sedentary Con. Therefore, an adequate vitD status may not only play an important role in musculoskeletal health but could also be a key determining factor in athletic performance.

THE EFFECTS OF A 12-WEEK HYPERTROPHY RESISTANCE TRAINING WITH A COLLAGEN HYDROLYSATE SUPPLEMENTATION ON THE SKELETAL MUSCLE PROTEOME OF RECREATIONAL MALE ATHLETES

OERTZEN-HAGEMANN, V.1, KIRMSE, M.1, DE MARÉES, M.1, EGGERS, B.2, MARCUS, K.2, PLATEN, P.1

RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: Resistance training and high quality protein (PRO) supplementation have been shown to enhance muscle strength and muscle mass, when compared to resistance training only. Due to its amino acid composition, collagen is considered as a low quality PRO and is therefore not supposed to support adaptations induced by hypertrophy. Nevertheless, there is some new evidence that collagen PRO has an influence on muscle growth and strength enhancement in sacropenic men, although the mechanisms are unknown [1]. The aim of the present study was to investigate whether a collagen hydrolysate supplementation, in combination with a resistance training, effects the PRO composition of the skeletal muscle.
METHODS: 20 young healthy moderately trained males (age: 24.6 ± 2.4 years; body mass: 79.2 ± 5.8 kg; height: 184.6 ± 4.6 cm, fat mass: 11.5 ± 3.7 %) completed two test trials in a double blinded randomized design, separated by a period of 12 training weeks. Subjects consumed either 15 g of a collagen hydrolysate (treatment group = TG) or a non-caloric placebo (control group = CG) every day immediately after their training session. The full-body hypertrophy workout was completed 3 times a week and included 4 exercises

using barbells. Muscle biopsies according to Bergström were taken before (T1) the first training session and before the 36th and thus the last training session (T2). Muscle proteome analysis was performed by LC-MS/MS analysis. The data analysis and interpretation were carried out using Progenesis QI for Proteomics. Cut-off values for PROs being significantly regulated between the two groups were determined with a fold change of at least 1.5 and a q-value <0.05 (corrected ANOVA p-value after Benjamini Hochberg).
RESULTS: 18 downregulated PRO were found in the TG group after the 12-week intervention compared to 20 downregulated PRO in the CG group, of which 9 PRO appeared in both groups.
367 PRO were higher regulated in the TG after the 12-week intervention, of which 144 were also upregulated in the PG, whichthus resulted from the hypertrophy training intervention. Hence 233 Proteins were upregulated in the TG compared to 45 PRO in the CG.
CONCLUSION: In conclusion, the change in the skeletal muscle PRO was more pronounced in the TG group compared to CG after the 12-week training intervention with collagen hydrolysate supplementation. This clearly indicates that the combination of strength training and supplementation induced more effects when compared to strength training alone. The physiological relevance of the changes in the skeletal muscle proteome has to be further analyzed.

EFFECTS OF ANTIOXIDANT-RICH FOODS ON ALTITUDE-INDUCED OXIDATIVE STRESS AND INFLAMMATION IN ELITE ENDURANCE ATHLETES: A RANDOMIZED CONTROLLED TRIAL

KOIVISTO, A.E., OLSEN, T., PAUR, I., PAULSEN, G., BASTANI, N.E., GARTHE, I., RAASTAD, T., MATTHEWS, J., BLOMHOFF, R., BØHN, S.K.

1NORWEGIAN OLYMPIC AND PARALYMPIC COMMITTEE AND CONFEDERATION OF SPORTS

INTRODUCTION: Altitude and intensified training regimes, which are systematically used to improve oxygen carrying capacity and sports performance, have been associated with increased susceptibility to oxidative stress and inflammation. We investigated whether increased intake of common antioxidant-rich foods attenuates these processes.
METHODS: In a randomized controlled trial, 31 elite endurance athletes (23 ± 5 years), ingested more than double their usual intake of antioxidant-rich foods (n=16), or eucaloric control foods (n=15) daily during a 3-week altitude training camp (2320 m). Fasting blood and urine samples were collected 7 days before altitude, following 5 and 18 days at altitude, and 7 days after altitude. Changes over time were compared between groups using mixed models for antioxidant capacity [uric acid free- (ferric reducing ability of plasma (FRAP)], an oxidative stress biomarker (8-epi-PGF2α) and inflammatory biomarkers [Interferon (IFN)γ, Interleukin (IL)1α, IL1RA, IL1β, IL2, IL5, IL6, IL7, IL10, IL12p70, IL13, IL17, tumor necrosis factor (TNF)α, monocyte chemoattractant protein (MCP)-1 and micro-CRP]. The cytokine response to a stress-test, either a VO2max ramp test or 100m swimming, was also assessed before and after altitude.
RESULTS: FRAP increased more in the antioxidant compared to the control group (p-interaction = 0.034). IL13 decreased in the antioxidant group, while increasing in the controls (pinteraction = 0.006). A similar trend was seen for IL6 (p-interaction = 0.062). A larger decrease in micro-CRP was detected in the antioxidant group compared to controls (β: -0.62, p-interaction = 0.02). We found no group differences for the remaining cytokines. 8-epi-PGF2α increased significantly in the whole population (p = 0.033), regardless group allocation. The stress response was significantly larger after altitude than before altitude for IL1β, IL6, IL7, IL13, IL12p70 and TNFα, but we found no group differences.
CONCLUSION: Increased intake of antioxidant-rich foods elevated the antioxidant capacity and attenuated some of the altitude-induced systemic inflammatory biomarkers in elite endurance athletes. The antioxidant intervention had no impact on the altitude-induced oxidative stress or changes in acute cytokine responses to exercise stress-tests.

VITAMIN D SUPPLEMENTATION DOES NOT INCREASE GAINS IN MUSCLE STRENGTH IN VITAMIN D INSUFFICIENT YOUNG MEN ENGAGED IN RESISTANCE TRAINING

SAVOLAINEN, L., TIMPMANN, S., MEDIJAINEN, L., MÄESTU, E., LELLSAAR, M., TÕNUTARE, L., ROSS, F., UNT, E., MOOSES, M., ÖÖPIK, V.

UNIVERSITY OF TARTU

INTRODUCTION: Recent meta-analysis revealed that vitamin D supplementation (D-S) may increase muscle strength in adults with low baseline vitamin D levels (1). Data on the potential impact of D-S combined with resistance training (RT) on increases in muscle strength in young healthy men is scarce. In one previous study no additive effect of D-S during 12 weeks of RT on quadriceps muscle strength was found, but both D-S and non-supplemented participants had relatively high blood vitamin D levels in that study (2). Considering these findings and high prevalence of vitamin D insufficiency in Estonia in winter months (3), the main purpose of the present study was to test the hypothesis that in vitamin D insufficient young males, D-S combined with RT induces greater improvements in muscle strength in comparison with RT alone.
METHODS: Young men (age 23.8 ± 2.6 years; BMI 23.5 ± 2.5 kg/m2) were included in the study. During the initial 4-week period participants trained without administering any supplements. For the next 12-week period participants were randomized into placebo (PLG; n=20) and V-S groups (VSG; n=22). The supplements were administered in a double-blind manner and the daily individual vitamin D dose in VSG was 8000 IU. The RT program (consisted of lateral pull-down, triceps push-down, leg press, pectoral, seated row, knee extension and biceps curl) was identical in both groups. After every 4 weeks, resting blood concentrations of 25(OH)D and testosterone were measured along with muscle strength assessment. Body composition (DXA method) was determined before and after 12-week period of RT with supplementation.
RESULTS: During 12-week period of RT with supplementation serum levels of 25(OH)D increased from 38.1 ± 12.2 to 143.1 ± 21.6 nmol/L ($p < 0.05$) in VSG, but remained persistently low between 37.9 ± 9.7 and 31.6 ± 9.2 nmol/L ($p > 0.05$) in PLG. Before and after the RT there were no differences in serum testosterone levels (22.72 ± 6.04 vs. 21.94 ± 7.38 nmol/L in VSG and 23.81 ± 7.58 vs. 23.19 ± 5.85 nmol/L in PLG, respectively ($p > 0.05$)). There was no difference in final strength test values in any exercise performed between VSG and PLG groups ($p > 0.05$). However, paradoxically, strength gain was greater in PLG than in VSG ($p < 0.05$) in chest press and in seated row (32,2 ± 6,4 vs. 26,0 ± 8,3 kg and 21,8 ± 6,0 vs. 16,5 ± 4,6 kg, respectively). In both groups there was a significant ($p < 0.05$) increase in total lean mass (1769 ± 1030 kg in VSG and 2060 ± 1316 kg in PLG) and decrease in total fat mass (-1258 ± 1579 kg in VSG and -896 ± 971 kg in PLG) without differences between groups ($p > 0.05$).
CONCLUSION: In young vitamin D insufficient men involved in 12-week RT program, daily D-S in amount of 8000 IU compared to placebo rapidly and significantly increases blood 25(OH)D levels, but does influence increments in muscular strength.

EFFECTS OF COLLAGEN SUPPLEMENTATION AND RESISTANCE TRAINING IN RECREATIONAL ATHLETES

KIRMSE, M.1, OERTZEN-HAGEMANN, V.1, DE MARÉES, M.1, BLOCH, W.2, PLATEN, P.1

1 RUHR UNIVERSITY BOCHUM DEPARTMENT OF SPORTS MEDICINE AND SPORTS NUTRITION; 2 GERMAN SPORT UNIVERSITY COLOGNE - DEPARTMENT OF MOLECULAR AND CELLULAR SPORTS MEDICINE

INTRODUCTION: The effect of protein supplementation in combination with resistance training (RT) is still under discussion for skeletal muscle cell hypertrophy and muscle strength, although meta–analysis suggest a positive impact. Previous studies on elderly men have demonstrated a positive impact of a collagen peptide supplementation on body composition and strength. Little is known about possible effects of collagen peptide supplementation in combination with RT in young recreational athletes. Therefore, the purpose of this study is to determine the effects of a specific collagen peptide intake in combination with RT on body composition, strength, and muscle cell size for that target group.
METHODS: 57 young men (24 ± 3 yr, 1.84 ± 0.06 m, 78.8 ± 7.4 kg) with slight experience in RT completed two testing procedures including 1RM and MVC strength testing, bio impedance body composition analysis, muscle biopsies for muscle cell size determination, and food record protocols prior to and after a RT intervention. Participants were randomly and double blinded divided in either a collagen peptide treatment group (TG, 15g/d of collagen peptides) or a placebo control group (CG, 15g/d silicon dioxide). TG and CG trained three times a week for 12 weeks with the identical protocol including barbell exercises in a controlled manner.
RESULTS: Prior to the intervention no differences were found in any parameter. Also no differences were found in training loads and dietary food intake during the intervention between the groups. At the end of the investigation a significant increase in FFM was found in TG compared to CG (TG: Δ2.0 ± 1.9 kg, CG: Δ0.6 ± 1.3 kg; ANOVA $p<0.05$) as well as an increase in FM was found in CG in contrast to TG (TG: Δ-0.1 ± 1.5 kg, CG: Δ0.8 ± 1.9 kg; ANOVA; $p<0.05$). CSA of type I and type II muscle fibers increased significantly but without group differences. A significant improvement was found in all 1RM tests (squat, deadlift, bench, bent over row) as well as improved MVC values in both groups without group differences. However, a trend was found for a higher increase in TG compared to CG in squat 1RM (TG: Δ20.6 ± 11.7 kg, CG: Δ14.8 ± 9.4 kg; $p= 0.054$).
CONCLUSION: This was the first study to show an effect of long-term collagen supplementation on human body in young men. Data demonstrated an increase on FFM after specific collagen peptide treatment and RT compared to placebo and RT and confirms previous studies. Interestingly, this did not result in higher strength in recreational athletes compared to controls and requires further research.

HIGH-INTENSITY INTERVAL TRAINING IS MORE EFFECTIVE IN YOUNG THAN IN ELDERLY HUMAN SUBJECTS

SCHLITTLER, M.1,2, WYCKELSMA, V.1, KAMANDULIS, S.2, SKURVYDAS, A.2, EIMANTAS, N.2, SNIECKUS, A.2, PAASUKE, M.3, WESTERBLAD, H.1,2

1. KAROLINSKA INSTITUTET ; 2. LITHUANIAN SPORTS UNIVERSITY ; 3. UNIVERSITY OF TARTU

INTRODUCTION: High-intensity interval training (HIIT), consisting of short bouts of high-intensity exercise (e.g. cycling or running) alternated with short recovery periods, is a time-efficient alternative to traditional continuous endurance training. The production of reactive oxygen/nitrogen species (ROS) increases in skeletal muscle fibers during energetically demanding high-intensity bouts of exercise and ROS may act as important signaling molecules, which trigger adaptations towards increased muscular endurance. Accordingly, beneficial effects of endurance training have been shown to be blunted by antioxidant treatment (vitamin C and E supplementation). Here, we studied whether HIIT is as effective in improving endurance exercise capacity in elderly as in young subjects. Furthermore, we studied whether antioxidant treatment affected positive endurance effects of HIIT.
METHODS: Recreationally active elderly (mean age 65 years, n = 18) and young (mean age 24 years, n = 19) men participated in the study. The study was approved by the local ethics committee and was in agreement with the Declaration of Helsinki. All participants gave written informed consent before participation. Both groups were divide into two sub-groups, one which received antioxidants in the form of vitamin C (1 g daily) and E (235 mg daily) and one which received placebo. Training consisted of nine sessions (3 sessions/week for 3 weeks) of 4-6 repetitions of 30-s all-out cycling bouts (Wingate tests) with 4 min of rest between bouts. Maximal power output and oxygen uptake (VO2 max) were assessed before and after the training period using a standard incremental cycling test to failure.
RESULTS: We observed no obvious differences in the physiological adaptations to the three weeks of HIIT between subjects receiving vitamins and placebo, hence results from the two sub-groups were pooled both for young and elderly subjects. Before the training period, the incremental cycling test revealed a markedly higher maximal power output at exhaustion (4.06 +/- 0.14 vs. 2.79 +/- 0.15 W/kg; mean +/- SEM) and VO2 max (46.3 +/- 1.4 vs. 33.7 +/- 1.6 ml/min/kg) in the young than in the old subjects ($P < 0.001$). At the end of the training period, the improvement in power output at exhaustion (7.3 +/- 1.1% vs. 5.4 +/- 1.3%) was similar in the two groups, whereas the increase in VO2 max (7.7 +/- 1.7% vs. 1.9 +/- 1.7%) was markedly larger in the young group ($P < 0.001$).
CONCLUSION: In contrast to previous endurance training studies, we could not detect any negative effects of vitamin C and E supplementation on the response to training. Moreover, three weeks of HIIT appeared slightly more effective in young than in elderly subjects, despite young subjects having a markedly higher aerobic capacity before the training period.

ENDURANCE-TYPE EXERCISE TRAINING PERFORMED BEFORE VERSUS AFTER BREAKFAST INCREASES ORAL GLUCOSE INSULIN SENSITIVITY AND CUMULATIVE FAT OXIDATION IN OVERWEIGHT MEN

EDINBURGH, R.M., CHRZANOWSKI-SMITH, O.J., KOUMANOV, F.K., BETTS, J.A., THOMPSON, D., HENGIST, A., GONZALEZ, J.T.

UNIVERSITY OF BATH

INTRODUCTION: The timing of breakfast in relation to a single bout of exercise acutely alters substrate metabolism during- and post-exercise and intramuscular signalling responses post-exercise. However, the chronic adaptations to exercise training performed before

versus after breakfast are less clear. The aim of this study was to assess the metabolic effects of 6-weeks exercise training performed before versus after breakfast in overweight or obese men.
METHODS: Thirty overweight or obese, sedentary men ([mean ± SD] body mass index: 30.9 ± 4.5 kg·m-2; Physical Activity Level: 1.69 ± 0.14), were randomly allocated to a non-exercising control group (CON; n = 9), a breakfast before exercise group (BR-EX; n = 12), or an exercise before breakfast group (EX-BR; n = 9) for the 6-week intervention. The exercise was laboratory-supervised cycling, progressing from 30- to 50-min and 50 to 55 % peak power output, three times weekly. An identical breakfast was prescribed (1.3 g carbohydrate·kg-1 in a 20 % maltodextrin solution) for all participants and this was consumed either 2-h before exercise in BR-EX, 2-h after exercise in EX-BR, or as breakfast during rest in CON. Pre- and post-intervention an oral glucose tolerance test (OGTT) was completed and vastus lateralis muscle was sampled in the resting fasting state. Substrate utilisation was assessed during all exercise sessions via indirect calorimetry.
RESULTS: Exercising before breakfast (EX-BR) decreased the insulin AUC and increased the oral glucose insulin sensitivity (OGIS) index in response to the post-intervention OGTT compared to both CON (mean [95% CI] for OGIS: 54 [1 to 107] mL per min per m squared; p=0.04) and BR-EX (46 [3 to 96] mL per min per m squared; p=0.01) but no clear difference was apparent in BR-EX compared to CON (7 [57 to -42] mL per min per m squared; p=0.72). The change in OGIS positively correlated with cumulative whole-body lipid utilisation during exercise training (r=0.50 [0.08 to 0.77]; p=0.02) but not with cumulative energy expenditure (r=0.07 [-0.37 to 0.49]; p=0.77). The vastus lateralis GLUT4 protein content increased to a greater extent with EX-BR versus CON (p=0.04) and tended to increase compared to BR-EX (p=0.08) but did not differ with BR-EX compared to CON (p=0.58). The change in OGIS was correlated with the change in the vastus lateralis GLUT4 protein content (r=0.60 [0.20 to 0.83]; p=0.01). No differences were detected for the change in body mass or the waist to hip ratio between BR-EX and EX-BR (both p>0.05).
CONCLUSION: In overweight and obese men, exercise training performed before versus after breakfast increases oral glucose insulin sensitivity which may be related to the increased lipid utilisation and augmented skeletal muscle adaptations with regular exercise before versus after breakfast. Therefore, to increase the metabolic benefits of exercise training in overweight men, it may be preferable to perform the exercise sessions before, rather than after, breakfast.

WHICH WHEY FORWARD? NUANCING THE EFFECTS OF POST-EXERCISE WHEY INGESTION IN TYPE 2 DIABETES MELLITUS

PEETERS, W.M., GRAM, M., SHEARD, P., DIAS, G., ROWLANDS, D.S.

MASSEY UNIVERSITY

INTRODUCTION: There is evidence that post-exercise whey protein ingestion increases skeletal muscle mass, contractile and metabolic function. Moreover, acute whey ingestion has insulinotropic effects, which when applied chronically, could benefit Type 2 diabetes mellitus (T2DM). However, the evidence to justify chronic post-exercise whey protein ingestion in T2DM is mixed. Accordingly, we determined the effect of whey protein supplementation, during 14 weeks of supervised exercise, on glucose homeostasis and skeletal muscle insulin sensitivity in T2DM.
METHODS: Twenty-four men and women with T2DM (56.1 ± 8.3 y, [HbA1c]: 64.3 ± 14.1 mmol/mol) participated in a 14-week exercise intervention (mixed-mode high intensity endurance and resistance training 45 min/d, 5 d/wk) as part of a wider exploration into protein-type effects, while randomly assigned to ingest either two daily doses (immediately post-exercise and evening) of 20 g whey protein (WHEY, n=12) or placebo (CON) isocaloric maltodextrin (n=12). Glucose homeostasis (fasting blood glucose concentration, [GLU]; serum insulin; HOMA-IR; HbA1c) and glucose clearance rate (GCR) during a hyperinsulinaemic isoglycaemic clamp were assessed pre and post intervention. Muscle from the m. vastus lateralis was harvested prior to and at 1-h into the clamp to determine changes in insulin-stimulated GLUT4 translocation and IRS-1-serine 312 phosphorylation using immunofluorescence. Results were inferred as likelihoods relative to smallest clinical or mechanistic (Cohen d) change thresholds.
RESULTS: Relative to the smallest clinical change threshold (-5.5 mmol/mol), 14-wk of exercise training with WHEY supplementation likely suppressed (WHEY-CON: 10.6 mmol/mol; 90%CI 4.8, 16.5) the substantial decrease in [HbA1c] produced in CON (within-group post-pre score, CON: -12.3 mmol/mol, -8.9, -15.7; WHEY: -1.7, -6.8, 3.5). WHEY possibly increased mean overall [GLU] (WHEY-CON: 7.8%; -3.0%, 19.7%), but effects on serum insulin (WHEY-CON: 4.3%; -14.2%, 26.8%) and HOMA-IR (WHEY-CON: 0.4 units; -0.3, 1.1) were inconclusive. In contrast, WHEY had no impact on GCR (WHEY-CON: 1.4%; -18.7%, 26.5%), despite clinically substantial (threshold 5.4%) within-group post-pre improvements after 14-wks' exercise (CON: 21.8%; 3.3%, 43.5%; WHEY: 19.5%, 5.1%, 35.9%). Similarly, the WHEY-CON effect on insulin-stimulated GLUT4 translocation was unclear (2.5%; -12.4%, 20.1%), despite within-group post-pre improvements (CON 9.7%, -3.0%, 24.1%; WHEY 12.5%; 2.0%, 24.1%). Insulin-stimulated IRS-1 serine 312 phosphorylation possibly decreased in WHEY-CON (-17.0%; -35.8%, 7.3%).
CONCLUSION: Whey protein ingestion combined with exercise training failed to accentuate improvements in glucose homeostasis or skeletal-muscle insulin sensitivity compared to an exercise-only control in T2DM. Data even indicates that whey protein supplementation may harm exercise-mediated improvements in measures of chronic glycaemic control (HbA1c, [GLU]).

THE DIURNAL IMPACT OF EXERCISE TIMING ON DIETARY BEHAVIOUR: A RANDOMIZED CONTROLLED TRIAL

TEO, S.Y., KANALEY, J.A., GUELFI, K.J., FAIRCHILD, T.J.

MURDOCH UNIVERSITY, PERTH WA

INTRODUCTION: Exercise and diet are considered integral components in the management of tight glycaemic control in Type 2 Diabetes Mellitus (T2DM) individuals [1]. Despite the acknowledgement of exercise having a profound effect on dietary behaviour traits [2], the importance of diurnal exercise timing has not been considered. Therefore, this study aimed to determine the diurnal effect of exercise timing on dietary responses in individuals enrolled into a 12-week supervised multi-modal exercise training program.
METHODS: Forty sedentary overweight males (n = 17) and females (age: 51 ± 13 years; BMI: 30.9 ± 4.2 kg/m2) were randomly allocated to either a morning (amEX) or evening (pmEX) exercise training group. All participants completed a 12-week supervised multi-modal exercise training program (3 days per week), which consisted of 30 minutes of aerobic exercise (walking protocol) and 4 resistance-based exercises (3 sets of 12-18 repetitions). The amEX and pmEX training sessions occurred between 0700-0900h and 1700-1900h, respectively. Body anthropometrics (height; weight), body composition (dual energy x-ray absorptiometry; body fat, BF; lean muscle mass, LMM), daily energy intake (EI, 24 h recall), dietary behavioural traits (cognitive restraint and disinhibition) and hunger in response to standardized meals were assessed at baseline and post-intervention at 12 weeks. All data is displayed as mean differences ± SD.
RESULTS: Exercise training significantly reduced (main effect of time: both $p < 0.01$) body weight (amEX: -2.29 ± 1.39 kg; pmEX: -2.28 ± 1.77 kg) and BF mass (amEX: -2.37 ± 1.59 kg; pmEX: -2.57 ± 1.51 kg). A significant change was observed in EI (main effect of time: $p < 0.01$) for both groups (amEX: -280.11 ± 521.62 calories; pmEX: -438.84 ± 349.38 calories) after the 12-week intervention. With regards to dietary

behavioural traits, significant changes (main effect of time: both $p \leq 0.02$) for disinhibition and hunger scores after 12-weeks. However, no significant differences ($p = 0.54$) were observed for cognitive restraint scores at post-intervention. No time by group interactions were observed for all measures of body anthropometrics (all $p \geq 0.70$), EI ($p = 0.53$) and dietary behavioural traits (all $p \geq 0.10$).
CONCLUSION: The 12-week multi-modal exercise training program improved body anthropometrics, EI and dietary behavioural traits for both overweight T2DM and non-T2DM individuals. However, the diurnal (morning versus evening) timing of exercise training did not alter the changes in body anthropometrics or dietary behavioural patterns. However, large individual variability in dietary responses were observed within this study which could have potentially masked differences.

THE EFFECT OF POWER TRAINING ON HABITUAL PHYSICAL ACTIVITY IN OLDER ADULTS WITH TYPE 2 DIABETES: SECONDARY OUTCOMES OF THE GREAT2DO RANDOMIZED CONTROLLED TRIAL

MOSALMAN HAGHIGHI, M., MAVROS, Y., FIATARONE SINGH, M.A.

THE UNIVERSITY OF SYDNEY

INTRODUCTION: Physical activity (PA) has been endorsed as a key component in the management of type 2 diabetes (T2D), and is effective in improving glycaemic control [1]. However, individuals with T2D are less likely to engage in recommended levels of PA compared to healthy peers [2]. There is some evidence that structured aerobic exercise may simply substitute for habitual PA participation, precluding increases in overall PA. We hypothesised that power training, by contrast, would be associated with a maintenance or increase in habitual PA level, as shown in previous trials of progressive resistance training (PRT). We also hypothesized that increases in habitual as well as habitual total PA (structured + habitual) would be associated with improvements in metabolic profile and body composition.
METHODS: One-hundred and three older adults with T2D were randomized to receive 12 months of power training (high intensity, high velocity, PRT) or sham-exercise (low intensity, non-progressive exercise). Habitual PA was assessed using the Physical Activity Scale for the Elderly (PASE). Insulin resistance (HOMA2-IR) and glycosylated haemoglobin (HbA1c) were used as indices of metabolic control. Skeletal muscle and total fat mass were estimated using bioelectrical impedance and abdominal and thigh composition were quantified via computed tomography. Depression symptoms were assessed by Geriatric Depression Scale (GDS).
RESULTS: At baseline, PASE scores were 107.7 ± 61.4 in the PRT group and 125.1 ± 63.0 in the sham group ($p= 0.30$). Habitual PA increased in the PRT group at 6 and 12 months (115.1 ± 54.3 and 116.0 ± 69.2) and decreased in sham group at 6 months (109.8 ± 55.9) but returned to baseline at 12 months (126.4 ± 70.0), with no significant group x time interaction across the 12 months. Changes in total PA were not associated with changes in HbA1c ($p= 0.92$), HOMA2-IR ($p= 0.59$), waist circumference ($p=0.09$), total abdominal fat ($p= 0.87$), visceral fat ($p=0.68$), intermuscular thigh fat ($p=0.68$), fat mass ($p=0.37$), total muscle mass ($p= 0.72$), thigh muscle cross-sectional area ($p= 0.92$) or depressive symptoms ($p=0.26$) in the overall cohort.
CONCLUSION: As hypothesized, older adults with T2D undertaking power training maintain or increase their habitual levels of PA. Thus, overall PA level is enhanced with the addition of power training. Clinical benefits may require larger improvements in overall PA levels than observed in this cohort however.

ADHERENCE AND ENJOYMENT OF A WALKING-FOOTBALL PROGRAM FOR PATIENTS WITH TYPE 2 DIABETES: SWEET-FOOTBALL PROJECT

BARBOSA, A.1, BRITO, J.2, SÁ, M.J.3, PUGA, F.3, FIRMINO-MACHADO, J.1,3, SEABRA, A.2, FIGUEIREDO, P.2, RAMOS, E.1, LUNET, N.1, MENDES, R.1,3

1: EPIUNIT – INSTITUTO DE SAÚDE PÚBLICA, UNIVERSIDADE DO PORTO, PORTUGAL; 2: PORTUGAL FOOTBALL SCHOOL, PORTUGUESE FOOTBALL FEDERATION, PORTUGAL; 3: NORTHERN REGION HEALTH ADMINISTRATION, PORTUGAL

INTRODUCTION: Traditional exercise programs for type 2 diabetes (T2D) patients are associated with a high number of dropouts and a low level of adherence over time. Therefore, it is essential the development of attractive and feasible strategies to overcome this problem. Community programs based on popular sports, such as football, have been used with success in the past few years for the prevention and control of noncommunicable diseases. We aimed to analyze the levels of adherence and enjoyment during an exercise program based on walking football for middle-aged and older male patients with T2D.
METHODS: This 12-week quasi-experimental study enrolled 31 participants recruited from primary health care units of Porto Oriental (Porto, Portugal) by family doctors, according to the following criteria: diagnosis of T2D at least for 12 months; male; aged 50-70 years old; major complications of diabetes screened and controlled; no cardiovascular, respiratory and musculoskeletal contraindications to exercise practice; non-smokers; without limitations in gait or balance; independent living in the community. All participants underwent a cardiac stress test on a treadmill to exclude cardiac or hemodynamic problems. Participants were organized in two teams and each of them played 60-min walking football sessions three times per week (non-consecutive days), for 12 weeks (36 sessions). Sessions were conducted in a sports hall (artificial turf) by a football coach and supervised by an exercise physiologist and a nurse. Sessions included strength and conditioning exercises, technical skills drills, and small-sided games.
Participant's adherence was assessed by calculating the proportion of sessions that each individual participated. The enjoyment of each walking football session was determined by the participants using a 5-point Likert scale (1: nothing fun; 2: little fun; 3: indifferent; 4: fun; 5: very fun).
RESULTS: Twenty-nine participants completed the walking football program, with a mean age of 64.5 years (standard deviation (SD) = 4.5). Two dropouts were registered: one because of job problems and other due to worsening of clinical status, not related with physical activity. The median (P25-P75) adherence to the program was 86.1 % (77.8 – 97.2). The median (P25-P75) enjoyment reported by participants during the walking football sessions was 5 points (5 – 5).

CONCLUSION: This walking football program showed high levels of adherence and enjoyment in middle-aged and older men with T2D. These exercise strategies can be implemented by local communities with the involvement of football clubs and primary health care centres, and may have potential to be used for T2D control.

EFFECT OF HIGH INTENSITY COMBINED (RESISTANCE AND AEROBIC) TRAINING ON BG VARIABILITY, COGNITIVE FUNCTION AND PHYSICAL CAPACITY IN TYPE-1 DIABETIC AND NON-DIABETIC INDIVIDUALS

MINNOCK, D., ANNIBALINI, G., KRAUSE, M., LE ROUX, C.W., BARBIERI, E., DE VITO, G.
UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Increased exercise is associated with decreased occurrence and severity of diabetic complications in individuals living with type 1-diabetes (T1DM). How chronic exercise training affects blood glucose (BG) control, physical capacity adaptions and cognitive function processes is not fully understood. Individuals with T1D, undertake less exercise than non-diabetic (Non-D) individuals due to fear of hypoglycemia. In this study, we compared the effects of high intensity, Combined (Resistance and Aerobic) exercise on BG variability, cognitive function and physical capacity in individuals living with T1DM.
METHODS: 10 sedentary T1DM (HbA1c 8.8 ± 2.8 %) and 10 sedentary Non-D individuals performed, three days weekly, for 12 weeks: 40 min exercise (COMB; 20 min AER; cycling at 80% heart rate reserve and 20 min RES; 2 sets of six exercises [Lat Pull-Down, Biceps Curl, Knee extension, Squat Press, Triceps Extension, Goblet Squat] of 25 repetitions at 80% of 1 repetition maximum). To measure the effect of exercise on cognitive function, a battery of tests (AVLT, STROOP, Digit Span, Verbal Fluency, etc.) were taken baseline, pre and post intervention. BG variability was measured continuously over week long periods at baseline, pre and post intervention. Cardiopulmonary exercise (CPX) tests were carried out at baseline and again post intervention to assess changes in VO2max.
RESULTS: Exercise intervention induced a significant BG stabilizing effect over a weeklong period ($p < 0.001$) compared to baseline. No cognitive function differences were observed between T1D and Non-D groups at baseline or post intervention. T1D group reported significant 1RM improvements ($p<0.05$) for 2 exercises (Squat Press & Goblet Squat). Non-D group reported significant 1RM improvements ($p<0.05$) for (Lat Pull-Down, Biceps Curl, Knee extension, Triceps Extension and Goblet Squat) and ($p<0.001$) for Squat press. CPX reported no change to VO2max in the T1D group, but significantly increased in the Non-D group ($p<0.05$).
CONCLUSION: Our results indicates that COMB exercise is effective in minimizing BG fluctuations and reducing the risk of severe hypo/hyperglycemia in individuals with T1D. No cognitive function differences were observed between groups, or following exercise interventions. T1D group showed limited 1RM improvements, whereas, Non-D group reported 1RM improvements for all exercises assessed. Moreover, only Non-D group displayed significant improvements in aerobic power. This response to training, between T1D and Non-D participants, may indicate that T1D individuals present an impaired ability to adapt/respond to exercise compared to healthy individuals.

TOTAL VOLUMES AND ACCUMULATION PATTERNS ACROSS THE ACTIVITY SPECTRUM AND ASSOCIATIONS WITH CARDIOMETABOLIC HEALTH IN YOUTH: A LATENT PROFILE & COMPOSITIONAL DATA ANALYSIS APPROACH

VERSWIJVEREN, S.1, LAMB, K.2,3, LEECH, R.1, SALMON, J.1, TIMPERIO, A.1, MACKINTOSH, K.4, MCNARRY, M.4, TELFORD, R.5, RIDGERS, N.1
1: INSTITUTE FOR PHYSICAL ACTIVITY AND NUTRITION, 2: MURDOCH CHILDREN'S RESEARCH INSTITUTE, 3: DEPARTMENT OF PAEDIATRICS, 4: SWANSEA UNIVERSITY; 5: CENTRE FOR RESEARCH AND ACTION IN PUBLIC HEALTH

INTRODUCTION: Regular participation in physical activity (PA) and limiting sedentary time (SED) is essential for youth cardiometabolic health (1). However, it is currently unknown if the manner of accumulating SED and PA (i.e. in bouts and breaks) impacts on cardiometabolic risk (2). Recent studies investigating associations between accumulation patterns and cardiometabolic health in youth have rarely considered the accumulation of different PA and SED patterns simultaneously (2). Furthermore, PA and SED are usually studied without taking into account that time is finite during the day and that time spent in one behaviour is linked to time spent in another (3). Therefore, the aim of this cross-sectional study was to identify distinct groups of youth based on combinations of accumulation patterns and their associations with cardiometabolic health. A secondary aim was to compare time use compositions between the distinct groups.
METHODS: ActiGraph accelerometer data from 7-15 year olds from three studies were pooled (n=1288). Time accumulated in >5-min and >10-min SED bouts, in >1-min and >5-min light (LPA), and >1-min moderate (MPA) and vigorous (VPA) PA bouts were calculated. Frequency of breaks in SED were also obtained. Latent profile analysis was used to identify distinct groups of participants based on these patterns (4). Linear regression models were used to test associations of groups with adiposity, lipids, blood pressure and a summary score. Compositional data analysis of total time spent in SED, LPA, MPA and VPA were performed using isometric log-ratio methodology to adequately adjust for time spent in other behaviours (3). Time use compositions were then compared across the derived group
RESULTS: Three distinct groups were identified: 'Prolonged sitters' (36%) had the most time in prolonged SED bouts and least in VPA bouts; 'Breakers' (49%) had the highest number of SED breaks and lowest engagement in sustained bouts across SB and PA intensities; 'Prolonged movers' (15%), had the least time accumulated in SED bouts and most in PA bouts across intensities. Whilst 'Breakers' accumulated the lowest amount of time in sustained PA, their total volume of PA was higher when compared to 'Prolonged sitters' and they had the healthiest adiposity profiles (BMI ß [95% CI]: -0.38 [-0.58, -0.19]; waist circumference: -2.51 [-4.07, -0.95]).
No differences in time use compositions were observed across groups.
CONCLUSION: The results highlight different accumulation patterns in youth, however, these patterns were not related to time use compositions. Breaking up sitting time and increasing time in sporadic PA may be useful obesity prevention strategies; however, longitudinal and experimental research in this area is needed. This information may help elucidate what determines total PA and SED and how accumulation patterns may contribute to better health.

THREE-YEAR SURVEILLANCE OF CARDIORESPIRATORY FITNESS IN UK PRIMARY SCHOOL CHILDREN.

TUVEY, S., STEELE, J., HORTON, E., MANN, S., JIMENEZ, A.

COVENTRY UNIVERSITY

INTRODUCTION: Recently, there has been a growing recommendation for cardiorespiratory fitness (CRF) surveillance among children and youth (Lang et al. 2018), and national standardised testing of CRF has become a common practice in several countries (Hungary, Slovenia, Japan, China, South Korea, and certain states in the United States). However, in the UK the national measurement to monitor health status of children is only body mass index (BMI). The aim of this study was to track the changes in CRF in children across the final three years of primary school in the UK.
METHODS: This study recruited 432 children (at baseline 49.3% male; age 9±1years) from 8 primary schools in London. Testing was performed by trained in-place delivery staff from an external organisation. Data collection took place in the Autumn and Summer Terms over three academic years for children in Years 4-6 (age 8-11 years). CRF was measured using the 20m Multistage Shuttle Run (20mMSR). Height and mass were measured to calculate BMI, and socio-economic status (SES) was also measured. Age and sex-specific z-scores were calculated for 20mMSR and BMI. Linear Mixed Models were used for 20mMSR raw scores and 20mMSR z-scores, where time-point (TP) and SES were fixed factors and BMI z-score was a covariate.
RESULTS: The 20mMSR raw scores showed a significant increase ($p<0.01$) across all TPs apart from TP6 which decreased from TP5 ($p<0.001$). "Time" and "SES" had a significant effect on both 20mMSR raw scores and z-scores ($p<0.01$), whilst "sex" only had a significant effect on 20mMSR raw scores ($p<0.001$). In the 20mMSR z-scores, there was a significant effect by "time" ($F5,844.245=7.902$, $p<0.001$), although post hoc pairwise comparisons showed that there was only a significant increase ($p<0.001$) between TP4 ($z=0.172$ (95% CI 0.038, 0.307)) and TP5 ($z=0.622$ (95% CI 0.485, 0.760)), and a significant decrease ($p=0.001$) between TP5 ($z=0.622$ (95% CI 0.485, 0.760)) and TP6 ($z=0.311$ (95% CI 0.216, 0.407)). There was a significant effect of "SES" on CRF ($F1,769.521=20.759$, $p<0.001$), post hoc pairwise comparisons showed low SES children ($z=0.161$ (95% CI 0.044, 0.279)) had significantly lower ($p<0.001$) CRF compared to high SES children ($z=0.533$ (95% CI 0.448, 0.618)). There was also a significant "time" x "SES" effect for CRF ($F5,844.245=3.442$, $p=0.004$) where low SES children had significantly lower ($p<0.05$) CRF at four of the six TPs.
CONCLUSION: Our data found that children's absolute CRF measured through raw scores in the 20mMSR improved with age. However, the normative data demonstrated that children's CRF in the UK is at a plateau, but with a decrease found at the end of primary school education. This highlights the need for interventions to increase physical activity in this period so that it may continue into adolescence, especially for children with lower SES.

IS THERE AN ASSOCIATION OF TRAINING VOLUME AND ARTERIAL STRUCTURE AND FUNCTION IN CHILDREN AND ADOLESCENTS?

THOMANDL, L., WEBERRUß, H., HOFMANN, H., OBERHOFFER, R., SCHULZ, T.

TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: Physical activity positively affects vascular health in humans. Applying metabolic equivalents (METs) to classify different intensity levels (low, moderate, high), exercise capacity can be assessed and energy consumption of physical activities compared. In adults, frequency and duration of endurance activities positively influenced arterial function in humans, whereas resistance training induced negative effects. The aim of this study was to investigate the association of training volume, quantified by MET-hours/week of club sports activities, with arterial structure and function in children and adolescents.
METHODS: 207 children and adolescents (13.9 ± 2.0yrs) answered the MoMo Physical Activity Questionnaire regarding type of sports, duration, frequency, months/year and intensity level of club sports activities. An individual MET-value was allocated to each type of sport depending on intensity levels (1, 2). MET-minutes/week were calculated by multiplying duration, frequency, months per year and MET-value for all sports. The transformed index MET-hours/week was classified in 3 groups: A (≤60), B (61 to 90) and C (>90). Weight, height and blood pressure were obtained and body-surface-area (BSA) was calculated. Using B- and M-mode ultrasound measurement, carotid intima-media thickness (cIMT), arterial lumen and cIMT-Lumen-Ratio were assessed as parameters of arterial structure. Arterial compliance (AC), elastic modulus (Ep), pulse wave velocity ß (PWVß), and stiffness index (ß) were estimated as parameters of arterial function. Age and sex independent z-scores of cIMT, AC, Ep, PWVß and ß were generated (3).
RESULTS: Participants performed 68.3 ± 25.9 MET-hours/week (group A: 34.3%, group B: 49.8%, group C: 15.9%) in club sports activities. Significant lower arterial stiffness and higher elasticity ($p < 0.01$ for all parameters), but no difference in arterial structure compared to normative values was observed. 18.8% of children and adolescents had cIMT values > 90th percentile. After correction for sex, age, BSA and blood pressure, cIMT (beta = 0.000219, $p = 0.045$) and cIMT-Lumen-Ratio (beta = 0.007, $p = 0.016$) increased with higher MET hours/week. Group C had significant higher cIMT (A: 0.467mm, B: 0.468mm, C: 0.497mm, $p = 0.038$) compared to A and higher cIMT-Lumen-Ratio compared to group A and B (A: 8.7%, B: 8.7%, C: 9.5%, $p = 0.029$).
CONCLUSION: Increased training volume is associated with impaired arterial structure in active children and adolescents, especially in subjects with high exercise capacity per week. In contrast, vascular function is positively influenced by physical activity but seems to be independent of training performance. These results indicate a vascular adaptation of exercise already in early adolescence.

HUMAN SKELETAL MUSCLE METABOLITES BEFORE AND AFTER PUBERTY: A 6-YEAR LONGITUDINAL NON-INVASIVE STUDY

LIEVENS, E., VAN VOSSEL, K., BAGUET, A., DERAVE, W.

GHENT UNIVERSITY

INTRODUCTION: Cross-sectional data show marked differences in muscle metabolism between children and adults. Despite an adequate aerobic exercise capacity, the anaerobic muscle energy delivery system is less well developed in children when compared to adults. Accordingly, children show a 20% lower abundance of muscle carnosine, a metabolite with a role in anaerobic metabolism (pH buffering). Moreover, the adult muscle carnosine concentrations are 28 to 36% higher in men compared to women (1). This sexual dimorphism most likely originates during puberty, but no longitudinal data are available, probably due to the invasive character of muscle biopsies. We aim, by non-invasive measurement of muscle metabolites by proton magnetic resonance spectroscopy (1H-MRS), to close this gap in the literature. As non-invasive muscle carnosine measurements are performed as estimates of muscle fiber type composition in sport science settings (2), a better understanding of its longitudinal stability in general, and during puberty in particular, is needed.
METHODS: 1H-MRS was used for absolute quantification of carnosine on a 3-T whole body MRI scanner (Siemens Trio) in the soleus and gastrocnemius medialis of 57 children before puberty (average age: 10.17 ± 1.23y). Six years later, 50 of these children (24 women and 26 men) were rescanned (average age: 16.61 ± 1.32y) to measure puberty-induced changes. In the same spectra, creatine and carnitine were quantified, though this abstract only relates to carnosine data. Maturity status was assessed by anthropometric measurement using the Mirwald equation (3), 2 boys were excluded as they were not yet beyond peak height velocity at the post measurement. A repeated measures ANOVA was used to interpret changes over time and between sexes.
RESULTS: Over puberty, muscle carnosine in the soleus increased in men and in women (respectively, +27% and +13%, main effect of time; $p<0.001$). Moreover, puberty induced a sexual dimorphism in the gastrocnemius as the carnosine content increased in men (+9%) but decreased in women (-12%) (interaction effect; $p=0.007$). Although absolute muscle carnosine changed during puberty, within-subject pre and post puberty measurements of the mean carnosine concentrations in both muscles were significantly and strongly correlated in both male and female (respectively, $r=0.80$; $p<0.001$ and $r=0.87$; $p<0.001$).
CONCLUSION: Despite a thorough and sex-specific disturbance of muscle carnosine levels during puberty, we still found a high degree of tracking. Future studies should directly assess whether muscle typology at adulthood can indeed be predicted from childhood muscle profile. Furthermore, this study illustrates the value of magnetic resonance spectroscopy in pediatric muscle physiology.

VALIDITY AND RELIABILITY OF A PHOTOPLETHYSMOGRAPHY DEVICE FOR MEASURING HEART RATE VARIABILITY IN PAEDIATRICS

SPEER, K., SEMPLE, S., NAUMOVSKI, N., MCKUNE, A.

UNIVERSITY OF CANBERRA

INTRODUCTION: Heart rate variability (HRV) is an accepted method for determining autonomic nervous system activity, health and cardiovascular risk in sport, health and exercise (1). Electrocardiograms (ECG) are accurate for measurement of HRV in adults and children (1). However, HRV derived ECG measurement is costly and often inaccessible to caregivers or research participants. Over the last decade, commercially available HRV measurement devices have been developed. Many of these devices use photoplethysmography (PPG), a technique that predicts interbeat (R-R) intervals from readings taken at the forearm, wrist or finger to calculate HRV. PPG systems have been validated for use in adults and they could be a viable option for use in paediatric research (2). However, it is unknown whether PPG HRV measurement is valid and reliable in young children (1). The aim of this study was to determine the validity and reliability of a PPG system to measure paediatric HRV.
METHODS: A validity and test-retest reliability design were used to compare two commercially available HRV devices: 1) finger PPG monitor; 2) chest belt (used as gold standard). Sixteen pre-schoolers (4 girls, 12 boys) between 3 – 5 years old (4.06 ± 0.58 years) were recruited for this study. Short-term (3.5 min), seated, resting R-R intervals were recorded for the calculation of time, frequency and nonlinear HRV domains. Participants were measured on 3 days, each separated by 2-3 days, between 8 – 10am. R-R intervals were transmitted from the chest belt and PPG system via Bluetooth to the EliteHRV app©. Data were then exported to Kubios HRV software for analysis of Day 2 vs Day 1 and Day 3 vs Day 2 datasets. Paired t-tests ($p<0.05$), effect sizes and Bland-Altman analyses were performed to determine the validity of the PPG system for all HRV parameters. For reliability of the two HRV methods, relative [intra-class correlation (ICC)] and absolute reliability [typical error of measurement (TEM) and typical error of measurement as a percentage (TEM%)] were calculated.
RESULTS: Only heart rate (HR) and R-R intervals demonstrated some, although poor, validity and reliability for the PPG system. No HRV parameters were valid for the PPG system. The chest belt yielded moderate (0.50 – 0.75) to good (0.75 – 0.90) relative reliability with R-R intervals and the ratio of the standard deviation of short and long-term R-R variability (SD1/SD2) showing the best results (ICCs = 0.84). The belt also displayed better absolute reliability for all parameters with RMSSD, R-R intervals and HR showing the lowest values (TEM% < 12%).
CONCLUSION: Use of the chest belt and not PPG in young children is encouraged for valid and reliable HRV, specifically those parameters indicative of parasympathetic activity. These parameters can be used to track the effects of exercise and lifestyle interventions in young children aged 3 – 5 years old.

CHILDREN'S HEAVY SCREEN USE ON WEEKENDS PREDICTS HIGHER BODY MASS INDEX IN ADOLESCENCE

ENGBERG, E., FIGUEIREDO, R.A.O., ROUNGE, T.B., WEIDERPASS, E., VILJAKAINEN, H.

FOLKHÄLSAN RESEARCH CENTER

INTRODUCTION: The high prevalence of childhood obesity is one of the most serious global health challenges of the 21st century (NCD-RisC, 2017). Sedentary behaviour is associated with excess weight in children and adolescents, but the causal relationship remains

unclear (Barnett et al., 2018). We aimed to examine whether children's leisure-time sedentary screen use, on school days and on weekends separately, predicts their body mass index (BMI) three years later.
METHODS: This prospective 3-year follow-up study included 5 084 children from the Finnish Health in Teens (Fin-HIT) study. The mean age of the children was 11 (SD 1) years at baseline and 14 (1) years at follow-up, and the proportion of overweight/obese children was 13.8% at baseline and 14.4% at follow-up. The children reported leisure-time screen use, more specifically TV viewing (broadcast, online etc.) and computer use, performed while sitting. We categorized the children into Light (≤0.5 hours/day), Medium (1-2 hours/day) and Heavy (≥3 hours/day) TV viewers separately for school days, and for weekends (≤1, 2-3 and ≥4 hours/day, respectively). Similarly, we categorized the children into Light (0 hours/day), Medium (0.5-1 hours/day) and Heavy (≥2 hours/day) computer users separately for school days, and for weekends (≤0.5, 1-2 and ≥3 hours/day, respectively). BMI was calculated based on measured weight and height, and transformed into an age- and sex-specific BMI z-score (BMIz).
RESULTS: Heavy TV viewers and computer users both on school days and on weekends at baseline had a higher BMIz at follow-up when compared with Medium and Light viewers and users. Particularly, Heavy TV viewers and computer users during weekends had the highest BMIz at follow-up: the follow-up BMIz was 0.21, 0.30 and 0.46 in Light, Medium and Heavy TV viewers on weekends, and 0.22, 0.27 and 0.44, respectively, in computer users on weekends (all p<0.001). After adjusting for age, sex, language, and baseline BMIz, sleep duration, eating habits, leisure-time exercise duration and the other screen time variables, Heavy TV viewing on weekends predicted higher BMIz at follow-up (B 0.078, p=0.013) when compared with Light TV viewing. We detected no interactions between sex and the screen time variables, or between exercise and the screen time variables in relation to the follow-up BMIz.
CONCLUSION: Heavy TV viewing on weekends in 11-year-old children predicts higher BMI three years later. Directing attention to children's sedentary screen use on weekends could be effective in preventing overweight and obesity among youth.

OP-PM13 Muscle damage and repair I

URINARY N-TERMINAL FRAGMENT OF TITIN IS A NOVEL NONINVASIVE BIOMARKER FOR THE EXERCISE-INDUCED MUSCLE DAMAGE IN HEALTHY YOUNG ADULTS

TANABE, Y., SHIMIZU, K., SAGAYAMA, H., FUJII, N., TAKAHASHI, H.
UNIVERSITY OF TSUKUBA

INTRODUCTION: Titin, a scaffolding protein in striated skeletal, plays a major role in muscle extensibility and elasticity. Recent studies demonstrated that noninvasively-assessed urinary N-terminal fragment of titin (U-titin) could reflect the magnitude of muscle damage under pathophysiological conditions including patients with muscular dystrophy. However, it remains unclear whether U-titin can be used as a biomarker for exercise-induced muscle damage in healthy individuals. If so, the magnitude of elevations in U-titin following eccentric exercise would be related to typical indices of exercise-induced muscle damage such as reductions in maximal voluntary contraction (MVC) torque and range of motion (ROM), prolonged transverse relaxation time (T2) assessed by MRI (an index of edema), and/or muscle soreness. Furthermore, U-titin would closely track changes in serum creatine kinase (CK), an invasive muscle damage marker. Thus, the aim of the present study was to test our hypothesis that changes in U-titin are positively and highly associate with those of typical muscle damage markers following eccentric exercise.
METHODS: Twenty-eight healthy men (age, 28.5 ± 3.1 yrs; height, 172.0 ± 4.9 cm; body mass, 67.9 ± 8.9 kg; %fat, 19.0 ± 5.9%) performed 30 maximal isokinetic (120°/s) eccentric contractions of the elbow flexors using an isokinetic dynamometer. U-titin, MVC torque of the elbow flexors, ROM of the elbow joint, muscle soreness, and serum CK were measured before and 1 to 4 days after the eccentric exercise. T2 was measured before, 2 days, and 4 days after the eccentric exercise. U-titin was evaluated by a highly-sensitive sandwich ELISA. The values of U-titin were corrected by urine creatinine concentration to minimize the influence of changes in urine concentration on U-titin.
RESULTS: U-titin, serum CK, T2, and muscle soreness all increased, whereas MVC torque and ROM decreased following the eccentric exercise (all $p < 0.05$). The peak values of U-titin following the eccentric exercise were positively correlated with those of serum CK ($r = 0.89$, $p < 0.05$), MVC torque decline rate ($r = 0.69$, and $p < 0.05$), and T2 ($r = 0.81$, $p < 0.05$). U-titin increased earlier than serum CK such that % of peak response was greater in U-titin vs. serum CK on the second and third day into recovery period ($p < 0.05$).
CONCLUSION: As per our hypothesis, in healthy young adults, changes in U-titin measured following a series of eccentric exercise are positively and highly associated with those of typical indices of exercise-induced muscle damage. Noteworthy, since U-titin increases earlier than serum CK following eccentric exercise, the magnitude of exercise-induced muscle damage may be evaluated earlier when U-titin is employed in comparison to serum CK. Therefore, U-titin may be a novel noninvasive biomarker of exercise-induced muscle damage in healthy young adults.

REPEATED MRI AND CLINICAL EXAMINATIONS OF HAMSTRING INJURIES IN AMATEUR FOOTBALL PLAYERS.

STEENDAHL, I.1,2, MEYER, T.1, KALTENBACH, B.3, YEL, I.3, MAEDER, R.3, AUS DER FÜNTEN, K.1, HAUSER, T.2, VOGL, T.3, EICHLER, K.3
1. SAARLAND UNIVERSITY, 2. DFB-ACADEMY , 3. UNIVERSITY HOSPITAL FRANKFURT

INTRODUCTION: Hamstring strain injuries (HSIs) are the most common acute non-contact muscle injuries in football (1). Magnetic Resonance Imaging (MRI) can be used to diagnose HSIs, however low availability and high costs complicate repeated MRI under normal circumstances, leaving practitioners to determine return-to-play based on non-validated tests and examinations (2). This study aims to investigate the rehabilitation of injured muscle tissue, by assessing HSIs using MRI and clinical examinations immediately after injury onset as well as 3- and 6-weeks post injury.
METHODS: 18 male amateur football players (24±4 years; 182±6 cm; 80±8.9 kg) with acute non-contact HSIs and no previous injuries within the last year were prospectively included in this ongoing study and examined both clinically and with MRI 3 times: within 72 hours,

3- and 6-weeks post injury. The MRI (3.0 T) protocol included anatomical proton density fat saturated scans, which were graded (Munich Injury Classification, 3) and assessed for oedema and muscle fibre disruption (MFD). Flexibility was assessed with the passive straight leg raise (PSLR) and active knee extension (AKE) using an electronic inclinometer. Participants completed a logbook of physical activities and pain levels from injury onset and until full return to football. The preliminary data was descriptively analysed.
RESULTS: All 18 HSIs were sustained during football play, with 78% affecting the Biceps Femoris and 67% involving the myotendinous junction. All injuries were positive for oedema and MFD at the first MRI (8 classified 3B; 10 classified 3A). After 3 weeks oedema and MFD were present at all 3B injuries and some 3A injuries (70% oedema; 30% MFD), as well as after 6 weeks (Oedema: 10% of 3A; 100% of 3B; MFD: 10% of 3A; 50% of 3B). At the first assessment the 3B injuries had a greater mean inter-limb difference in flexibility than 3A injuries (PSLR: 8.98°; AKE: 14.79°), but at follow up tests the mean differences were all <3°. The players reported no pain during daily life after 10 ± 7 days and returned to match play 52 ± 19 days post injury.
CONCLUSION: Despite the low sample size, the results clearly indicate that even though clinical tests do not detect inter-limb differences and players are not reporting pain, MRI still confirms structural damage and oedema up to 6 weeks post injury. This is in accordance with previous research of elite athletes (4,5) and highlights the lengthy healing time of MFD for amateur players not undergoing specific rehabilitation training.

TIME COURSE OF MUSCLE INJURY RECOVERY AFTER COLD AND INTERMITTENT HYPOBARIC HYPOXIA TREATMENTS

SANTOCILDES, G., VISCOR, G., RIZO-ROCA, D., PAGÈS, T., TORRELLA, J.R.
UNIVERSITAT DE BARCELONA

INTRODUCTION: Muscle undergo adaptive response to different environmental stimuli, such as high altitude exposure, where hypoxic and cold stress coexist. We aim to test if cold and hypoxia exposure, separately and together, can modulate the muscle repair process from a functional point of view (in situ force test) and if these stimuli produce changes in the muscle fibre profile.
METHODS: After inducing injury in the right gastrocnemius of rats, animals were submitted for 4 h/day during 9 or 21 days to 3 different treatments: 1) Intermittent hypobaric hypoxia (HYPO) at 4,500m; 2) Intermittent cold (COLD) at 4ºC; and 3) Simultaneous intermittent hypobaric hypoxia and cold (COHY). A control group (CTRL) was maintained normoxic at 27ºC. Force properties of both injured and healthy gastrocnemius were registered stimulating sciatic nerve and obtaining peak (PF, mN/g) and tetanic force (TF, mN/g), and fatigue properties at low frequency (30 Hz). After the 21-day treatment muscle histological slides were stained for demonstrating fibre types, total capillary density (CD), individual fibre capillarization (CCA) and fibre cross-sectional area (FCSA) in the red, white and intermediate parts of the gastrocnemius.
RESULTS: 9 days after injury, PF and TF showed significant lower values in injured versus healthy leg in CTRL (50±4 vs 57±5, p=.012 and 193±17 vs 222±17, p=.034), COHY (54±6 vs 60±9, p=.023 and 225±33 vs 241±30, p=.005) and COLD (51±7 vs 54±3, p=.010 and 201±22 vs 215±20, p=.0008). However, injured legs from HYPO animals recovered force parameters (60±8 vs 59±8, p=.824 and 222±23 vs 211±22, p=0.227). CTRL and COLD groups presented a significant lower resistance to low frequency fatigue in injured leg (p=.053 and p=.022), while COHY and HYPO groups did not show any difference between the two legs. After 21 days, only the CTRL group registered significant lower force values in injured legs (PF: 43±12 vs 51±6, p=.049; TF: 142±44 vs 179±27, p=0.024) and lower resistance to fatigue (p=.038), whilst the experimental groups recovered all force parameters. The three treatments induced a decrease in FCSA, ranging from 13 to 41%, in all the fibre types. Animals evidenced significant higher CD (capillaries/mm2) in COLD (885), HYPO (901) and COHY (962) in comparison with CTRL (702) in the red zone, and significant higher CD in COLD (542) and HYPO (506) in the white zone (CTRL: 382). No changes in CD were found in the intermediate zone. No fibre type changes were found after any of the treatments.
CONCLUSION: Injured muscles underwent a total functional recovery after 21 days of exposure to cold, hypoxia or a combination of both stimuli. The improvement of muscle irrigation would have provided the injured tissue extra nutrients and growth factors responsible for accelerating muscle injury recovery. An additive effect of cold and hypoxia was evident. After 9 days, only HYPO treatment was efficient in complete restore of muscle functionality.

COMPARISON BETWEEN HIGH AND LOW INTENSITY ECCENTRIC CYCLING OF EQUAL TOTAL VOLUME FOR MUSCLE DAMAGE PROFILE

MAVROPALIAS, G., KOEDA, T., BARLEY, O., POON, W., FISHER, A., BLAZEVICH, A., NOSAKA, K.
EDITH COWAN UNIVERSITY

INTRODUCTION: High-intensity eccentric contractions induce greater muscle damage than low-intensity eccentric contractions, when performed for the same number of contractions [1]. This is also the case, when the total volume is matched between low- and high-intensity eccentric contractions [2]. During eccentric cycling, large numbers of submaximal eccentric contractions are performed, resulting in muscle damage [3], but no previous study has compared different intensities of eccentric cycling. The present study compared low- and high-intensity eccentric cycling of the same volume for changes in indirect markers of muscle damage to test the hypothesis that the magnitude of muscle damage would be greater after high-intensity than low-intensity eccentric cycling.
METHODS: Twenty men (25.0 ± 4.7 y) were placed to a high-intensity (HI; n=11) or a low-intensity (LI; n=9) eccentric cycling group. HI performed eccentric cycling at 40% of their peak power output obtained during a 10-s isokinetic maximal concentric cycling effort at 60 rpm (Maxpower), for 5 sets of 1 minute, while the LI at 10% of Maxpower for 5 sets of 4 minutes, with 1-min rest between sets. Maximal voluntary isometric (MVIC) and isokinetic concentric contraction torque (MVCC) of the knee extensors, rate of force development (RFD), squat (SJ) and countermovement jump (CMJ) height, delayed onset muscle soreness (DOMS) with palpation of the knee extensors using a CR-10 scale, plasma creatine kinase (CK) activity, vastus lateralis and medialis ultrasound echo intensity and muscle thickness were measured before, immediately after, and 24, 48 and 72 h after exercise. The changes in the variables over time were compared between groups by a two-way repeated measures ANOVA.
RESULTS: No significant differences between the groups for the changes in MVIC (-10.3 ± 4.8%), MVCC (-10.5 ± 6.5%), RFD (-21.5 ± 10.7%), SJ (-7.3 ± 4.4%) and CMJ (-5.6 ± 4.1%) at 24 h, and these measures returned to the baseline by 48 or 72 h after cycling. Plasma CK activity

increased, but the magnitude of the increase was small (<301 U/L), without a significant difference between groups. No significant changes in echo intensity and muscle thickness were found after cycling for both groups. However, DOMS developed greater ($p<0.05$) for the HI (peak: 4.2 ± 1.0) than the LI group (1.4 ± 0.6).
CONCLUSION: These results indicate that the magnitude of muscle damage induced by eccentric cycling is not severe, and were similar to a previous study [3]. A significant difference between the HI and LI groups was found only for DOMS, with the extent of DOMS being more than double for the HI group. The significantly greater DOMS for the HI than LI group may indicate that connective tissue (e.g., muscle fascia) was affected more by higher intensity eccentric contractions.

EFFECT OF A HIGH SPEED RUNNING PROTOCOL ON DELAYED ONSET MUSCLE SORENESS AND MUSCLE PERFORMANCE AMONG HEALTHY AND ACTIVE ADULTS.

FARES, R., VICENTE-RODRIGUEZ, G., OLMEDILLAS, H.

UNIVERSIDAD ZARAGOZA

INTRODUCTION: Following intensive workout load muscle damage occurs and it is often characterized by delayed onset muscle soreness (DOMS). Muscle pain and discomfort start 24 hours after exercise and subside within 5 to 7 days post-exercise. Weakness, swelling of the muscle and increase in inflammatory markers are observed delaying normal recovery and decreasing performance (1). Active recovery methods play a key role in tissue remodeling (2). The choice of intensity remains a crucial factor, thus the aim of this study was to examine the effect of a high intensity running protocol on DOMS and the associated symptoms.
METHODS: DOMS was initiated with an exercise-induced muscle soreness (EIMD) consisting of 10 sets of 20 repetitions of squat jumps in 31 subjects (24 males and 7 females, average age: 22.29 ± 0.38 years). Following EIMD, subjects were divided into two groups: an intervention group (IG) and a control group (CG). Participants in IG performed, 24 hours after EIMD, five bouts of 30 sec of a running protocol with maximum self-selected speed on a 15 degrees inclined treadmill and 4 min of active rest between bouts, speed for each participant was determined one week prior to the experiment; participants in CG did not receive any intervention. Three weeks later participants repeated the EIMD and switched recovery groups. Data on six variables were collected: Visual analogue scale (VAS) for pain, muscle circumference, creatine-kinase (CK), counter-movement jump (CMJ), sprint performance, and maximal strength in leg extension. Variables were measured on four occasions: before EIMD, after the running protocol on day 2 and then on day 3 and 4. Pain was assessed every six hours after EIMD until day 4.
RESULTS: A Mixed Design ANOVA (repeated measurements) showed no significant differences between control and intervention groups ($p>0.05$) for CK, CMJ, muscle strength, sprint performance and muscle circumference. However, there was a significant group effect and a positive correlation between the intervention protocol and a decrease in pain ($p<0.05$). Additionally, a significant effect of time on CK and pain was also observed ($p<0.05$).
CONCLUSION: Pain was significantly reduced following the running protocol. This might be supported by the previously reported analgesic effect of exercise. On the other hand improvement was not observed on the level of muscle performance. An-in-depth study for several factors involved in the recovery process is needed in future research in order to optimize performance and improve recovery.

OP-BN03 Motor learning and motor control: Feedback - Talent - Balance

SHORT-TERM MOTIVATIONAL AND INFORMATIONAL EFFECTS OF AUGMENTED FEEDBACK DURING MAXIMAL MOTOR TASKS

BUGNON, M., WÄLCHLI, M., MORET, S., TAUBE, W.

UNIVERSITÉ DE FRIBOURG

INTRODUCTION: It was previously demonstrated that augmented feedback (AF) has a positive influence on motor performance and motor learning in the short and long-term (1). It is assumed that AF can affect motor performance in two ways: a) by enhancing the motivation and/or b) by providing useful information about the execution of the motor task (2). Therefore, we supposed that AF-induced performance increments that primarily relied on motivation should also occur when providing manipulated AF (MAF). In contrast, performance increments that rely on guidance towards the right execution should only occur when AF is correct. We further hypothesized that the informational content of AF is more important in motor learning tasks while motivational aspects dominate in non-learning tasks. Thus, we applied two different forms of feedback (proper AF and MAF) during maximal voluntary contractions (MVC; non-learning task) and during maximal explosive contractions (learning task) of thigh muscles.
METHODS: A total of 32 participants were allocated in either the AF or the MAF-group. Each participant performed a two sessions (one for each motor task) on two different days. Both sessions started with a neutral condition (NE; without any feedback), followed by a feedback condition (FB). The peak torque was measured for each MVC, while the peak rate of torque development (RTD) was calculated for each explosive contractions. During FB, the percentage difference with respect to the previous contraction was displayed on a screen, this percentage difference being either the correct (AF-group) or the opposite (MAF-group) difference.
RESULTS: MVC: there was a significant main effect of CONDITION(NE vs FB) ($F(1, 26) = 7.99$, $p = 0.009$, $n2 = 0.002$) indicating that the peak torque was different between NE and FB. However, no GROUP x CONDITION effect ($F(1, 30) = 0.53$, $p = 0.472$, $n2 < 0.001$) was found, suggesting that both groups similarly improved. RTD: a mixed design ANOVA revealed a significant interaction effect of GROUP x CONDITION ($F(1, 30) = 6.68$, $p = 0.015$, $n2 = 0.003$) demonstrating that AF had a positive influence on peak RTD while MAF had a negative influence on it.

CONCLUSION: As AF and MAF positively influenced motor output during MVCs to a similar extent, it might be assumed that mainly motivational aspects were responsible for the improvement in this non-learning task. In contrast, during explosive contractions, AF and MAF exerted opposing effects on motor performance proposing a strong dependency on the informational aspect. When generalizing, it might be speculated that motivational aspects of AF are prominent when performing non-learning (maximal strength) tasks whereas informational aspects are more important in learning tasks such as explosive contractions.

MOTOR PERFORMANCE AND ITS DEVELOPMENT IN ADOLESCENCE: RELEVANT PREDICTORS FOR ADULT SUCCESS IN ELITE FEMALE SOCCER?
LEYHR, D. 1, RAABE, J. 2, SCHULTZ, F. 1, KELAVA, A. 1, & HÖNER, O. 1
1 University of Tuebingen, Germany; 2 Penn State Altoona, USA
INTRODUCTION
Despite an increased interest in girls' soccer over the last decades, current research does not provide sufficient empirical evidence about valid indicators to identify the most promising young female players (Murr et al., 2018). To this end, this longitudinal, prospective cohort study focused on female athletes' motor performance development in early to middle adolescence in order to analyze (1) the prognostic validity of motor parameters for adult success over a long-term period, (2) the three-year development of highly talented girls' motor performances and the predictive value of this motor development for reaching a professional adult soccer level.
METHODS
A total of N = 737 young female players (birth cohorts 1993 – 1998) participated in nationwide motor diagnostics (sprinting, agility, dribbling, ball control, shooting, total motor score) within the German Soccer Association's talent identification and development program at least twice between the age groups Under-12 (U12) and U15. According to their adult performance level (APL) in the 2017/2018 season (i.e., a minimum prognostic period of four years depending on birth cohort) girls were assigned to the professional (first German division; N = 46, 6.2%) or non-professional group (lower divisions; N = 691, 93.8%). Using multilevel regression analyses, each motor parameter was predicted by players' development over Time, Time^2 (level-1 predictors), APL (level-2 covariate), and the interaction effects between the respective variables.
RESULTS
Time, Time^2, and APL contributed significantly to the explanation of participants' test performance across all motor parameters and the total score (each $p < .05$). Interaction effects distinctly failed to reach significance.
DISCUSSION
The current results indicate (1) a general prognostic relevance for the investigated motor parameters with respect to APL. Furthermore, the study found (2) a non-linear improvement in girls' performance for all considered motor performance factors from U12 to U15. However, non-significant interactions between APL and Time indicate that motor performance development within this three-year period itself could not assist in predicting future success in adulthood. Overall, the present findings provide valuable information for coaches and other stakeholders in the support of young female soccer players' development.

IMPROVED POSTURAL CONTROL IN THE ELDERLY AFTER LONG-TERM BALANCE TRAINING IS RELATED TO INTRACORTICAL INHIBITION MODULATION

KUHN, Y.A., BUGNON, M., EGGER, S., TAUBERT, M., TAUBE, W.

UNIVERSITY OF FRIBOURG

INTRODUCTION: Due to an impaired postural control, elderly subjects demonstrate higher fall incidence rates compared to young adults [1]. As a consequence, falls represent a major risk to health in older adults [2]. It seems that this impaired postural control is associated with age-related functional changes in the brain such as an over-activation and a reduction in motor intracortical inhibition [3]. However, modulation of cortical inhibition within the primary motor cortex (M1) seems crucial for an intact motor control [4]. So far, little is known whether targeted interventions can reverse the decline of intracortical inhibition. To answer this question, the present study aimed to investigate whether age-related cortical dis-inhibition could be reversed by balance training (BT) and whether an association between behavioral and brain adaptations exists.
METHODS: During 6 months, 18 healthy old adults followed 1h of BT twice a week (BT group) while 15 participants served as a control group (CON group). All subjects (66 – 81 years) were tested 4 times over a period of 1 year: at baseline, after 2, 6 and 12 months (follow-up). At each time point, the balance performance (center of pressure) on an instable device was tested. To compare the activity of inhibitory circuits within M1, transcranial magnetic stimulation was used to measure short-interval intracortical inhibition (SICI) in the tibialis anterior muscle while balancing.
RESULTS: The BT group improved balance performance significantly after 6 months of training showing a better level than the CON group at all time points except at baseline (all $p < .01$). For SICI, the BT group also showed significantly more inhibition after 6 months of training and more inhibition at all time points, except at baseline, when compared to the CON group (all $p < .01$). For both parameters, no significant modulation over time was found in the CON group. A significant correlation between the balance performance progression and the modulation of SICI ($r = -.42$, $p = .02$) was found.
CONCLUSION: The present study demonstrates that modulation of intracortical inhibition can be up-regulated in elderly subjects after long-term BT but is not changed after 2 months. This up-regulation may indicate a reversal of the age-related decline in inhibition. Furthermore, the correlation between changes in balance performance and changes in SICI found here and previously in young adults [5] strengthens the idea that increased levels of cortical inhibition are associated with improved postural control.

THE RELATION BETWEEN LIMB SEGMENT COORDINATION DURING WALKING AND FALL HISTORY IN COMMUNITY-DWELLING OLDER ADULTS

YAMAGATA, M., TATEUCHI, H., SHIMIZU, I., SAEKI, J., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: To prevent trip-related falls, control of the swing foot through limb segment coordination is crucial. Uncontrolled manifold (UCM) analysis is a method that can be used to evaluate how the segmental coordination stabilizes the swing foot. Within UCM analysis, two components of variance (V) are quantified: VUCM, does not affect the swing foot, and VORT, affects the swing foot. Previous studies have found an increase in VUCM for older adults and post-stroke patients, who are known to have a high risk of falls. We explored whether UCM indices, particularly VUCM, can be used as an index to evaluate fall risk.
METHODS: Thirty community-dwelling older adults participated in a baseline visit. The subjects walked on a 6-meter walkway 20 times at their self-determined comfortable speed, and lower limb kinematics were collected with VICON motion systems. Data were time normalized from right toe-off to right initial contact, and divided into three swing phases: early-, mid-, and late-swing. We calculated VUCM and VORT using UCM analysis. The swing foot variability (fSD) was also computed as the standard deviation across steps. One year after the baseline visit, we evaluated fall history in the participants using a questionnaire. Binary fall history was used as the dependent variable (yes/no). Univariate and multivariable logistic regression analyses were performed to assess the association between UCM index (VUCM or VORT) and fall history in each phase, with and without adjustment for gait speed and fSD. The significance level was set at 0.05.
RESULTS: Twenty-eight participants who responded to the fall history questionnaire were analyzed. There were 16 Non-fallers and 12 Fallers. VUCM (×10-3 rad2) in Fallers were 2.13 ± 0.70, 2.67 ± 0.81, and 4.91 ± 3.09, whereas those in Non-fallers were 1.30 ± 0.35, 1.51 ± 0.43, and 2.60 ± 1.04 in early-, mid-, late-swing, respectively. VUCM in all phases predicted incident falls, and adjusted VUCM values in early- and mid-swing were found to be significant predictors (early-swing OR = 1.54, 95% CI = 1.03–1.12; mid-swing OR = 1.38, 95% CI = 1.08–1.78). Fall history was positively correlated with VUCM.
CONCLUSION: Older adults who increased the component of limb configuration associated with swing foot stability tended to experience at least one fall within one year of measurement While post-fall increases in VUCM have previously been reported as a strategy for avoiding future, repeated falls, this is the first study of which we are aware to show that increased VUCM can both occur prior to falls, and predict future falls. This may imply that individuals are aware of their kinematic instability prior to falls and proactively increase VUCM to prevent as-yet unexperienced falls.

MOTOR LEARNING OF A NEW BALANCE TASK: THE INFLUENCE OF DIFFERENT KINDS OF PRIOR MOTOR PRACTICE ON TRAINING OUTCOMES.

KELLER, M., ROTH, R., FAUDE, O.

UNIVERSITY OF BASEL

INTRODUCTION: It has been shown that balance training results in highly task-specific improvements with no or only very limited transfer to untrained balance tasks (1). While this task-specificity with respect to balance training is well accepted, it is unknown if the acquisition rate when learning a new balance task is positively influenced by prior practice of other balance tasks. Based on the learning to learn hypothesis found in visuomotor tasks (2), we expected facilitated learning of a new balance task when prior motor practice contained related (balance) tasks.
METHODS: The study consisted of three measurements and two training periods: the effects of training period1 (6 sessions) was assessed as changes from PRE- to MID-test. Participants (n=42) were randomly allocated to one of three groups: (i) a COOR group that trained lower limb coordination using the agility ladder, (ii) a 1_BT group that trained on a half balance board with the right leg, and (iii) a 2_BT group that trained on the half balance board with bipedal stance. Training adaptations from PRE to MID were assessed for task-specific adaptations (trained tasks) and transfer effects (untrained tasks).
After training period1 that was different between groups, participants took part in training period2 (6 sessions). During period2, the participants of all groups trained the identical balance task that was new for all participants. The aim in this task was to bring a tiltboard into a horizontal position and maintain it while standing on it with the right leg. Training gains in the tiltboard task were compared between groups to test whether the training content of period1 (COOR vs 1_BT vs 2_BT) had an influence on the adaptations of period2.
RESULTS: Our preliminary data analysis shows that the 1_BT and 2_BT groups had higher training adaptations in the tiltboard task compared to the COOR group. The ANCOVA with the pre-test performance as covariate showed a large effect for balance improvements in period2 ($F2;38=4.13$; $\eta p2 = 0.179$; $p = 0.024$). The between-group comparisons of the learning rates in period2 showed better training gains for 1_BT vs. COOR (40.0 [95% CI 2.54; 73.7]) as well as when comparing 2_BT vs COOR (83.4 [95% CI: 24.3; 147.0]).
CONCLUSION: Our study shows that learning rates of balance training interventions can be influenced by prior motor practice. However, the type of prior motor practice seems to influence the steepness of the learning curve during the balance training. Our data show that related (balance) tasks in the prior motor training foster balance adaptations in period2. Thus, the positive effects of the learning to learn paradigm known from visuomotor tasks (2) seem to be transferable to balance training.

IS-BN01 Stability training throughout the lifespan

POWER PERFORMANCE DURING RESISTANCE EXERCISES UNDER STABLE AND UNSTABLE CONDITIONS

ZEMKOVA, E.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY IN BRATISLAVA

Most studies support the application of resistance exercises on unstable surfaces for the prevention and rehabilitation of injuries; however their utilization for improving an athletic performance remains a matter of debate. No significant changes in muscle power can be observed after instability resistance training in athletes practicing conventional resistance exercises as a part of their daily training routine. The main reason for this is that an unstable support base compromises the power in the concentric phase of resistance exercises. However, we have demonstrated that this effect depends on the type of exercise (chest presses, squats), instability device used (Swiss ball, BOSU ball), the weight lifted, number of repetitions and sets, as well as the athletes training background. These findings have to be taken into account when instability resistance exercises are implemented into the training program, namely for those practitiones whose performance requires production of maximal force in a short time. Experience indicates that feedback monitoring of velocity at lifting weights used may provide a better understanding of physiological mechanisms underlying power production during resistance exercises under unstable conditions. This is vital for designing efficient strength and conditioning training program for practitioners who want to incorporate unstable devices into their workouts.

Acknowledgment: This work was supported by the Scientific Grant Agency of the Ministry of Education, Science, Research and Sport of the Slovak Republic and the Slovak Academy of Sciences (No. 1/0824/17) and the Slovak Research and Development Agency under the contract No. APVV-15-0704.

EFFECTS OF INSTABILITY RESISTANCE TRAINING ACROSS THE EXERCISE CONTINUUM IN SENIORS

GRANACHER, U.

UNIVERSITY OF POTSDAM

Muscle weakness and deficits in postural control represent two major intrinsic fall-risk factors in seniors. In fact, approximately 24% of old adults aged ≥65 years suffer from muscle weakness and 20% from balance disorders. There is evidence that balance and resistance training are effective means to improve postural control and muscle strength in old adults. An alternative and time efficient approach constitutes the performance of resistance training using unstable devices and/or free weights. In the first part of my talk, I will focus on the importance of balance control and muscle strength for the successful performance of activities of daily living. The second part will introduce the exercise continuum with resistance training and balance training at the poles of the continuum and instability resistance training inbetween. The third part will highlight the effectiveness of balance vs. instability resistance vs. resistance training on measures of balance and muscle strength. Practitioners, therapists, rehab experts, and exercise scientists will benefit from the presentation by learning how to adequately implement balance and resistance training across the exercise continuum in seniors.

STABLE, UNSTABLE, AND METASTABLE STATES OF EQUILIBRIUM: DEFINITIONS AND APPLICATIONS TO TRAINING AND MOVEMENT WITH CHILDREN

BEHM, D.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Human postural demands and balance control during locomotive and rotational motion are of primary interest for athletic performance and daily life. The equivocal use of terms and expressions such as equilibrium, balance, stability/instability obstruct a clear communication of scientific knowledge. In particular, the terms stability and balance and their different forms are often used with various meanings and circular definitions not only in everyday language but in scientific communication as well. However, for dynamic human movement, stable and unstable equilibrium approaches are too simplistic. As an alternative, the 'metastability' concept predominantly used as part of the dynamic systems theory should be applied to human movement. In particular, an important application will involve discussing the importance of improving metastability capabilities for children.
METHODS: Of the 209 articles identified for review, only controlled trials were included
if they investigated unstable resistance training in healthy individuals and tested at least one measure of maximal strength, strength endurance, muscle power, or static/dynamic balance. In total, 22 studies met the inclusion criteria.
RESULTS: Our meta-analysis showed that unstable resistance training is effective in improving muscle strength, power and balance in adolescents. However, inconsistent results were particularly found in adolescents when the specific effects of unstable resistance training were compared with those of traditional stable resistance training.
CONCLUSION: It is concluded that the performance of unstable resistance training compared with traditional resistance training has limited extra effects on muscle strength, power and balance performance in healthy adolescents.

Oral presentations

OP-MI03 Training and testing

THE PHYSIOLOGICAL DEMANDS OF NATIONAL HUNT RACING ON PROFESSIONAL JOCKEYS

MICHAEL, K.

WATERFORD INSTITUTE OF TECHNOLOGY

INTRODUCTION: Horse racing has been identified as a physically demanding sport. Jockeys partake in either flat racing or national hunt racing, which take place over jumps. National hunt jockeys compete in multiple races per day, several days a week over course distances ranging from 3,200 up to 7000m. Previous research has indicated the high intensity nature of national hunt racing (Trowbridge, 1995),

however it is not known if the demands vary over course distance. The purpose of the study was to examine the physiological demands placed on jockeys over short and long race distances.
METHODS: Ten professional jockeys (height: 174 ± 5.0 cm; weight: 65 ± 3.3 kg; and age: 25 ± 4.2years) performed an incremental treadmill test to volitional exhaustion to identify maximal heart rate (HRmax) and maximal blood lactate [La]max concentrations which facilitated the reporting of in-race data as a representation of maximum values. All jockeys participated in two competitive races, over short (3200-4000m) and long (4400-5200m) national hunt race distances. Mean and peak heart rate (HR) were recorded during the race. Peak blood lactate concentration [La] and a perceived exertion score (RPE) were recorded between five and seven minutes post-race. A minimum rest period of two hours was required between races.
RESULTS: During the treadmill test HRmax was 194 ± 9 b·min−1 while [La] max was 11.1 ± 2.7 mmol·L-1. When riding over a short race distance (263 ± 33s), mean and peak HR were 181± 8 b·min−1 (93 ± 3% of HRmax) and 192 ± 6 b·min−1 (99 ± 3% of HRmax) respectively, while peak blood lactate concentration reached 7.4 ± 2.2 mmol·L-1 (50 ± 2% of [La]max). During the long distance race (355 ± 18s), jockeys mean and peak HR were 182 ± 9 b·min−1 (94 ± 3% of HRmax) and 195 ± 9 b·min−1 (101 ± 3% of HRmax) respectively, while peak blood lactate concentration reached 9.6 ± 3.2 mmol·L-1 (92 ± 40% of [La]max). The mean RPE score reported by jockeys was 11 ± 1.5 and 14 ± 2.8 arbitrary units for short and long races respectively. Peak lactate and RPE were statistically higher over the longer course distance ($p<0.05$).
CONCLUSION: The results of this study imply that national hunt racing is a physically demanding sport. Jockeys perform close to their physiological limit in both short and long race distances with higher peak blood lactate concentration and higher RPE reported over the longer race distance. Quantification of the outputs of professional jockeys over various race lengths can provide a framework to guide future training strategies to optimally prepare jockeys to meet the specific physiological demands of national hunt racing distances.

INVESTIGATING THE PHYSICAL DEMANDS OF AN ELITE YOUTH TENNIS TRAINING CAMP

FLEMING, J.A., NAUGHTON, R.J., HARPER, L.D.
UNIVERSITY OF HUDDERSFIELD

INTRODUCTION: Participation in elite tennis tournaments is occurring at progressively younger ages. In order to compete at the highest-level youth athletes are having to manage high training loads. Developing an understanding of the training demands during tennis, and its impact on performance can allow for research that is both relevant and efficacious to be conducted, and for pertinent recommendations to be made. Accordingly, the aims of the present study were to 1) investigate the physiological load and 2) examine energy expenditure and energy balance during an elite youth tennis training camp.
METHODS: Ten elite youth tennis players (4 males and 6 females; 14 ± 1.1yrs, 53.95 ± 8.5kg, 163.9 ± 5.1cm) competing at National and or International Level (Grade 2 Tennis Europe) participated in the study during an 8-day training camp in LaManga Spain. The training camp consisted of two tennis sessions (on clay courts) and one strength and conditioning session every day, totalling in excess of 30 hours. Training sessions comprised of either tennis drills (TD) or simulated match play (SMP), with afternoon sessions typically combining TD with point play. Actigraph GT9X Link accelerometer watches were worn throughout the training camp to measure individualised energy expenditure whilst training and at rest. Participants also wore a Global Positioning System (GPS) unit (Optimeye S5, Catapult Innovations, Australia) to track external load measures during tennis training sessions. A one-day food diary was also completed by all participants during the training week.
RESULTS: Morning sessions saw significantly more distance covered and PlayerLoad than afternoon sessions (5370 ± 505m v 4726 ± 697m; $p = 0.002$, and 725 ± 109 vs 588 ± 96; $p \leq 0.0005$ respectively). Players covered significantly more distance (5624 ± 897m vs 4933 ± 344m, $p = 0.015$) and achieved higher max velocity (5.17 ± 0.44 m/s vs 4.94 ± 0.39 m/s, $p = 0.03$) during morning SMP sessions compared to morning TD sessions. Energy intake was significantly lower than energy expenditure, with players consuming 2526 ± 183 kcal and expending 3670 ± 635 kcal ($p = 0.01$).
CONCLUSION: The data indicates that players had higher external load during morning sessions, with a higher PlayerLoad and greater distance covered, than afternoon sessions. A contributing factor towards players being unable to match physical outputs in afternoon sessions may have been associated with the reported negative energy balance, impacting player recovery and preparation. Failure to meet the body's needs during high levels of training stress has been shown to increase players susceptibility to injury, impact their growth and maturation, and increase their risk of developing Relative Energy Deficiency in Sport (RED-S). Consequently, more research to corroborate these findings is recommended.

HUMAN TRAINABILITY: EXPLORING THE HERITABILITY AND MODALITY DEPENDENCE OF FITNESS AND STRENGTH ADAPTATIONS IN A RANDOMISED CROSS-OVER STUDY OF TWINS

MARSH, C., THOMAS, H., NAYLOR, L., GREEN, D.
UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: It is recognised that some subjects are more responsive to exercise training than others, and that distinct exercise modalities induce different physiological responses; resistance training primarily induces skeletal muscle adaptation, whilst endurance exercise targets the cardiopulmonary systems. Whilst most previous studies have estimated the contribution of genetics to fitness and strength by performing cross-sectional (CX) analysis of mono- (MZ) and di-zygotic (DZ) twin pairs, few studies have exercise trained twins to assess the heritability of adaptation.
METHODS: We performed a randomised cross-over study investigating strength (1RM leg press) and fitness (treadmill VO2max) responses in 27 pairs (n=54) of untrained twins (22 MZ pairs, 5 DZ same-sex pairs; 27±6yrs). Twin pairs underwent 3 months of supervised centre-based endurance (END; 1hr x 3/wk, running/cycling, 60-90%VO2max) and resistance (RES; 1hr x 3/wk, upper/lower body, 60-90%1RM) exercise training, separated by a 3 month washout period. Twins trained together at identical intensities which were supervised and closely monitored. Change scores were calculated and twin versus twin intraclass correlation analyses calculated by exercise modality and zygosity.
RESULTS: Training specificity was confirmed: strength increased following RES but not END (41.4±4.4 vs 2.5±3.6 kg change; $P<0.001$), and fitness increased following END but not RES (3.3±0.5 vs -0.6±0.3 ml.kg-1.min-1 change $P<0.001$). 85% of subjects increased VO2max following END and 94% were strength gainers following RES. Responders to one modality typically responded to the other; the concordance rate was 92%, but there was no correlation between change in fitness and change in strength within subjects ($r=0.003$, $P=0.98$). At baseline, correlations between twins for strength (MZ=0.9, $P<0.001$; DZ=0.4, $P=0.15$) and fitness (MZ=0.6, $P<0.001$; DZ=0.4, $P=0.15$) suggest a moderate-high genetic contribution to these variables. There were high correlations for MZ, but not DZ, for change in strength following RES (MZ=0.7, $P<0.001$; DZ=0, $P=1$) and change in fitness following END (MZ=0.6, $P<0.001$; DZ=0, $P=1$).

CONCLUSION: These findings indicate that, whilst most individuals respond to some form of exercise training, there is no correlation within individuals in those who respond to endurance versus resistance modality. Our CX twin analysis suggests moderate-high heritability for strength and fitness, in keeping with previous CX twin research. Our novel data pertaining to actual changes when both twins undertake matched training intensities, indicates high correlations in MZ to both forms of training for strength and fitness adaptation, but no correlation for DZ pairs. This suggests that heritability coefficients based on CX analyses may not accurately reflect the actual genetic contribution to trainability in humans.

DIFFERENCES IN VENTILATORY EFFICIENCY BETWEEN CYCLE ERGOMETER AND HALF-SQUAT EXERCISES

GRI-AFIRS, ESCST-UPF

INTRODUCTION: While several studies have focused on evaluating the ventilatory efficiency during incremental (1) and constant-load tests (2), there is a lack of evidence about the oxygen uptake (VO2) efficiency slope (OUES) and the slope of the linear relationship between ventilation (VE) and carbon dioxide (VE/VCO2 slope) in resistance exercises. The main goal of this study was to compare cardioventilatory responses, blood lactate levels, OUES and VE/VCO2 slope between half-squat (HS) and cycle ergometer exercises during a constant-load test at the lactate threshold (LT) intensity.
METHODS: 14 healthy young men were randomly assigned in a crossover design to perform HS or cycle ergometer tests. The order for HS test was: 1) a one repetition maximum (1RM) test to determine the load (kg) corresponding to the 1RM percentages. 2) the incremental HS exercise to establish the load (kg) at the LT intensity. 3) a constant-load HS test at the LT intensity. In cycle ergometer, it was carried out an incremental loading test to determine the intensity in watts corresponding to the LT, followed by a constant-load test at the LT intensity. A rest period of 48 hours between each test was established. During both constant-load test, cardiorespiratory and lactate responses were monitored.
RESULTS: It was detected a significant exercise mode x time interaction effect in VO2, heart rate, and blood lactate responses ($p < 0.001$). No differences were found between the two types of exercise in OUES and VE/VCO2 slope ($p > 0.05$). VE and VCO2 were highly correlated ($p < 0.001$) in the cycle ergometer ($r = 0.91$) and HS ($r = 0.92$) exercises. In the OUES, similarly significant and high correlations ($p < 0.001$) were found between VO2 and log10 VE in the cycle ergometer ($r = 0.88$) and in the HS ($r = 0.86$) exercise.
CONCLUSION: Although the cardioventilatory responses were greater in the cycle ergometer test as compared to HS exercise, ventilatory efficiency was very similar between the two exercise modalities in a predominantly aerobic metabolism. A constant HS test at LT intensity does not induce significant cardiorespiratory stress, while ventilatory efficiency is maintained and muscle strength and local muscular endurance, as well as gross mechanical efficiency (3), may improve.

MORPHOMECHANICAL CHARACTERISTICS OF MUSCLE IN PATIENTS WITH DIABETES MELLITUS

LU, Y.J., WANG, H.K., CHUANG, L.M., LAI, Y.C.

NATIONAL TAIWAN UNIVERSITY

INTRODUCTION: Diabetes mellitus (DM) is characterized by hyperglycemia, increased mortality, and a risk of developing physical disabilities due to muscle dysfunction (1). Ultrasound imaging is a non-invasive method for evaluating the function and morphology of muscles and monitoring muscle modifications resulting from illness (2). Recently, the role of grayscale in ultrasound and elastographic images has drawn the attention of clinicians and been assumed to be related to the fat accumulation in diabetic muscles. The purpose of this study was to investigate the variation in the ultrasound images, morphologies, and mechanical properties of muscles in patients with DM.
METHODS: Patients aged between 20 and 80 years with and without DM were recruited as the DM group and control group. Each subject was assessed by shear wave elastography and B-mode ultrasound imaging (Aixplorer™, Supersonic Imagine, France) for the mechanical properties and 2D images of the rectus femoris (RF) and vastus lateralis (VL) in the supine position with knee flexion of 30 and 60 degrees, and of the medial gastrocnemius (MG) in the prone position. The mechanical properties assessed included muscle stiffness, subcutaneous fat thickness, muscle thickness, fascicle angle, and grayscale in the region of interest (ROI). The independent t test was used to compared the differences in the mechanical properties between the DM group and control group if the normality test (Shapiro–Wilk test) was passed. If not, the Mann-Whitney test was used. The alpha level was set at 0.05.
RESULTS: Ten subjects each were recruited for the DM group (mean age: 65.2 years old) and the control group (59.4 years old), and there was no significant difference in age between the groups. The muscle thickness of the MG was significantly ($p=0.009$) lower in the DM group (1.25±0.21 cm) than the control group (1.62±0.34 cm). The grayscales of the MG (control: 53.06±15.89; DM: 92.32±14.20) and of the RF with knee flexion of 60 degrees (control: 73.36±18.40; DM: 83.24±32.96) were higher in the DM group, with p-values of <0.001 and 0.043, respectively. No significant differences in muscle stiffness, subcutaneous fat thickness, or fascicle angle were found between the groups.
CONCLUSION: The muscles of the DM group exhibited excessive loss of skeletal muscle thickness, especially in the distal lower extremities. The grayscales in the MG and the RF with knee flexion of 60 degrees were greater in the DM group compared with age-matched healthy controls, which may have indicated intramuscular fat infiltration. Furthermore, the grayscale outcomes may have been influenced by the joint angle or muscle length; for example, the greater the lengthening of the muscle, the higher the grayscale values. Ultrasound imaging is a potentially valuable tool for the detection of changes in the morphologic and mechanical properties of muscles in patients with DM.

SLEEP AND APPETITE RESPONSES TO A 6-WEEK TRAINING PROGRAM IN MIDDLE-AGE, INACTIVE WOMEN

SKEIN, M., VINCENT, G., MELEHAN, K., SARGENT, C., LARSEN, P.

CHARLES STURT UNIVERSITY

INTRODUCTION: Exercise has been well advocated for improving general health, however, less is known about how exercise improves sleep and appetite. In addition, despite sleep loss affecting 30-60% of middle-age women and the known links between sleep loss to the risk of diabetes and cardiovascular disease, less attention have been given to the relationship between sleep and exercise in women compared to men. Therefore, this study examined the effects of 6 weeks training on sleep, appetite hormones and eating behaviours in middle-age, inactive women.
METHODS: 25 inactive women (age: 37 ± 7y, mass: 80 ± 17 kg, height: 167 ± 6 cm) with no known sleep conditions, were randomly assigned a) 6-week training attending group-fitness classes 4 times per week (EX; n=13) or b) inactive control group (CON; n=12). Sleep was assessed via Actigraphy and Polysomnography (PSG) pre, during and post interventions. Exercise performance during a 20 min self-paced cycling effort, food cravings questionnaires and appetite hormone responses to a standardised meal were assessed pre and post intervention.
RESULTS: Distance covered during cycling test was significantly longer for EX compared to CONT post-intervention ($P<0.05$). Total sleep time was significantly longer during the EX compared to CON and perceived sleep quality was higher during and post training for EX compared to CON. Sleep efficiency was higher post-training for EX compared to CON ($P<0.05$), while there were no differences between groups for time in bed, latency, wake after sleep onset or number of awakenings ($P>0.05$). PSG revealed no changes in sleep stages due to training ($P>0.05$). Trends were evident for larger reductions in ghrelin pre-to-post meal following EX compared to CON and lower PYY concentrations pre and post-meal following EX ($d=0.5-0.8$). Pre-to-post intervention cravings and attitudes towards sweet and savoury food were augmented following EX, suggesting greater control of sweet and savoury cravings ($d = 0.5-0.9$).
CONCLUSION: A 6 week training intervention improves sleep quantity and quality, however, has no effect on time spent in the respective sleep stages. Greater control of food cravings and appetite hormones were more sensitive to a standardised meal when engaged in habitual exercise training. Therefore, findings from this study advocate the use of exercise training as an intervention to improve and manage sleep, appetite hormones and eating behaviours in women.

BIO-BANDING IN YOUTH ELITE SOCCER PLAYERS – A PILOT STUDY

LÜDIN, D., BORN, D.P., JAVET, M., HINTERMANN, M., KERN, R., ROMANN, M.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN

INTRODUCTION: By the age of 12 to 16 years the biological age (BA) can differ in the same chronological age (CA) group up to five years and affects the athlete's physical and psychological abilities. Early developed players show superior strength, speed, willingness to take responsibility and leadership, which may play a decisive role in the talent identification and development (1). Bio-banding describes the grouping of young athletes based on their BA rather than the CA in order to reduce the differences in maturity. So far, research investigated the qualitative effects of bio-banding on psycho-social parameters (1). The aim of the underlying pilot study was to quantify the effects of bio-banding on technical, tactical and physical parameters in youth elite soccer games.
METHODS: 61 male and two female youth elite soccer players from two Swiss top club's youth academies U13 and U14 participated in the study. All participant's peak height velocity was estimated with the Mirwald-Method and the BA calculated. On a single match-day, 4x20 min matches were played. For two matches, the teams were grouped based on the BA. As a control condition, two matches were played with the conventional CA grouping. All matches were monitored balloriented with video cameras for the subsequent analysis of technical and tactical parameters. Physical parameters were determined using GPS (ASI, Field Wiz). Data between the bio-banded and control condition were compared using a paired t-test and Wilcoxon signed-rank for non-normally distributed samples. In addition, Cohen's d effect sizes were calculated.
RESULTS: Within bio-banding, the number of duels increased ($p=.02$, $d=.89$) and resulted in a reduced time per action on the ball ($p=.01$, $d=.58$). Also, the number of standard situations increased ($p=.03$, $d=1.0$) and the percentage of successful passes decreased ($p<.01$, $d=1.23$). Medium effect sizes indicated a decreased difference of ball possession [%] ($p=.08$, $d=0.68$) within bio-banding. Physical data showed a reduced total running distance ($p<.01$, $d=0.28$).
CONCLUSION: The increased number of duels may indicate a reduced dominance of the early maturing players and consequently may create more opportunities for late maturing players. The reduced time per action on the ball might result from the accelerated match play. Bio-banding created a more balanced and competitive match play and possibly results in a better environment for the development of talented players. From a coach's perspective, bio-banding could improve the talent identification and selection process and help to detect potential future champions.

COMPARISON OF DIFFERENT MEASUREMENT TECHNIQUES FOR QUANTIFYING WHOLE BODY MUSCLE HYPERTROPHY IN MEN

CUPEIRO, R.1, RUBIO-ARIAS, J.Á.2, RAMOS-CAMPO, D.J.2, ALCARAZ, P.E.2, BENITO, P.J.1

[1]UNIVERSIDAD POLITÉCNICA DE MADRID, [2]CATHOLIC UNIVERSITY SAN ANTONIO

INTRODUCTION: Assessing exercise interventions effectiveness frequently requires an accurate quantification of body composition changes. For body fat mass (BFM), significant different values are obtained depending on the measurement procedure used (1). However, to the best of our knowledge, no previous study has addressed the impact of the measurement technique over the free fat mass (FFM) changes after a training program. The aim of this study was to determine if the measurement technique has an effect over FFM change results after hypertrophy training through a systematic review with meta-analysis.
METHODS: A comprehensive literature search was performed using different databases through May 2018. The search was based on the effect of resistance training on muscle mass changes in adult men. Selection criteria can be found in PROSPERO registration nº CRD42018106274. A random effects meta-analysis was conducted to determine the effect of 6 measurement techniques on FFM. The

effects on outcomes between pre and post training values were expressed as mean differences (MD) and their 95% confidence intervals (CI). The techniques were dual X-ray absorptiometry (DXA), bioimpedance (BIA), anthropometry (ANT), air-displacement plethysmography (BOD POD), ultrasound (US) and underwater weighting (UWW).
RESULTS: A total of 61 articles (82 study groups) were selected following PRISMA methodology. The analysis showed no influence of the technique over FFM change (MD in kg: DXA 1.78 [1.27-2.28]; BIA 1.14 [0.41-1.87]; ANT 1.31 [0.66-1.97]; BOD POD 0.79 [-3.56-5.15]; US 0.8 [-3.93-5.53]; UWW 2.19 [1.15-3.23]; I^2 = 0%; sub-group differences p = 0.53). However, gathering the gold standard techniques for fat mass (i.e. DXA and UWW) and comparing them versus the others techniques (i.e. BIA, ANT, BOD POD and US), a trend toward significance was observed (MD in kg: gold standard 1.86 [1.40-2.31]; non-gold standard 1.23 [0.75-1.71]; I^2 = 71.2%; sub-group differences p = 0.06).
CONCLUSION: There was borderline significant interaction between procedure and change in FFM when grouping the techniques in gold standard versus non-gold standard, providing the gold standard group a FFM change 600 g higher than the non-gold standard group. DXA and UWW are considered gold standard for measuring BFM (1,2) and were grouped because we can infer they are also gold standard for FFM (since FFM is the complementary value of BFM). Comparison of all the techniques showed no significant results, although some differences were clinically relevant. Thus, our results are not as clear as those for BFM, where different accuracy among methods is well establish (1), but they suggest a possible influence. More studies are needed, especially with intra-subject comparison designs, and with other forms of hypertrophy (i.e. lean body mass), in order to elucidate the influence of the measurement method on results.

VALIDITY AND RELIABILITY OF VO2 MASTER PRO

DOSTAL, J., HACECKY, V., KIMMEL, E., KUCIRKOVA, I.
CENTER FOR SPORTS MEDICINE

INTRODUCTION: The purpose of this study was to assess the validity and reliability of a novel, wearable VO2 analyzer called the VO2 Master Pro.
METHODS: Four male elite cyclists (25 +/- 3 years) performed an exercise test consisting of two 5-minute steps of respective loads 2W/kg and 4W/kg. Two VO2 analyzers were tested on each athlete: the VO2 Master, and a lab-grade ergospirometry system, the Ganshorn Ergocube. Each athlete took a two-minute break in between tests. The order of VO2 analyzers used was varied in patterns ABBA and BAAB. A 10-second moving average was applied to all data. ANOVA and other statistical analyses were used to assess significance of the results.
RESULTS: Validity testing demonstrates a high correlation 0,90-0,95 (CI 0,84-0,99) for 2W/kg load and 0,92-0,96 (CI 0,80-0,98) for 4W/kg load. Reliability testing demonstrates a very high correlation of test-retest data with correlation 0,97- 0,99 (CI 0,92-0,99) for 2W/kg load and 0,96- 0,98 (CI 0,90-0,98) for 4W/kg load. There are small yet statistically significant differences in the oxygen consumption based on differing physiologic responses. However, these differences are within the standard error of ergospirometry systems and are thus practically irrelevant.
CONCLUSION: Our study concludes that the VO2 Master Pro is both accurate and reliable when compared to a standard lab-based ergospirometry system. Small differences in the VO2 measurements of these systems could be attributed to both physiologic variability and VO2 analyzer repeatability associated with back-to-back testing.

THE EFFICACY OF CONTRALATERAL MUSCLE REHABILITATION EXERCISE ON PERCEIVED AND FUNCTIONAL PERFORMANCE FOLLOWING ANTERIOR CRUCIATE LIGAMENT (ACL) RECONSTRUCTION.

BAILEY, A., GALLACHER, P., ROBERTS, S., BARNETT, A., MINSHULL, C.
RJAH ORTHOP NHS FOUNDATION TRUST

INTRODUCTION: ACL reconstructive surgery is effective in improving knee instability, however it can result in persistent asymmetry of neuromuscular limb function (Lepley 2015), posited to arise partly from post-operative restrictions and arthrogenic inhibition. The cross-education (CE) phenomenon describes the strength gain in the opposite (contralateral), untrained limb following unilateral contralateral resistance training. Despite its potential utility in unilateral injuries, only recently has it been investigated orthopaedic populations, yielding equivocal results. The aim of this study was to investigate the effects of CE on perceived and functional outcomes following ACL reconstruction.
METHODS: 44 patients (n = 18 female; age: 31.8 +/- 9.7yrs) electing to undergo unilateral ACL reconstruction surgery were randomly allocated to one of two groups: CE (n = 22 contralateral limb strength training), or a CONTROL (CON n = 22) (time-matched bilateral upper limb flexibility programme). Both groups followed the same standardised ACL rehabilitation plus 8 weeks of CE or CON that commenced at 2-weeks post surgery. CE comprised of 3 sets 3-5 repetitions maximum of knee extension, knee flexion and leg press resistance exercises, 3 times per week. CON comprised of 5 static upper limb stretches (3 x 20 sec, 3 times per week). International Knee Documentation Committee (IKDC) questionnaires were completed pre- and 10-weeks and 24-weeks post-surgery. Limb symmetry index (LSI) was calculated from the 1-leg hop for distance (operative and non-operative limb) performed at pre- and 24-weeks post-surgery.
RESULTS: IKDC scores did not change from pre- to 10-weeks post-surgery, but increased by a statistically similar amount in both groups at 24-weeks (CE: 33%, CON: 41%). Patients in both groups increased their hop scores from pre- to 24-weeks post surgery; which translated into a statistically similar improvement in LSI of 19% and 24% from pre- to 24-weeks post-post-surgery for CE and CON, respectively. Absolute LSI scores at 24 weeks were 79.2 and 81.5% for CE and CON, respectively.
CONCLUSION: Patents' physical- and self- report of knee-function improved following ACL reconstruction and standardise rehabilitation. Similar to a recent study (Zult et al, 2018), however, these outcomes were not influenced by CE. That recovery of post-operative maximal quadriceps neuromuscular performance has been positively influenced by CE, may reflect the inferior measurement sensitivity of perceived and functional measures and the specificity of the CE intervention.

NEUROMUSCULAR READINESS TO RE-PERFORM IN FEMALE YOUTH SOCCER PLAYERS POST COMPETITIVE MATCH-PLAY

HUGHES, J.D.1, DENTON, K.1, LLOYD, R.S.2,3,4, OLIVER, J.L.2,3, DE STE CROIX, M.B.A.1

1. UNIVERSITY OF GLOUCESTERSHIRE, 2. CARDIFF METROPOLITAN UNIVERSITY, 3. SPORT PERFORMANCE RESEARCH INSTITUTE, NEW ZEALAND , 4. WAIKATO INSTITUTE OF TECHNOLOGY

INTRODUCTION: A greater incidence of non-contact injuries has been reported during the later stages of competitions and training when fatigue is expected. Fatigue can alter neuromuscular function and therefore increase the risk of non-contact injuries. The aim of this study was to explore the potential time frame for neuromuscular function to return to pre-game levels in female youth soccer players following competitive match-play.
METHODS: A repeated measures study design was used that included 33 youth female soccer players aged 12-17 years. The players were sub-divided into three age groups according to chronological age (U13, n = 11; U15, n = 10; U17, n = 12). Measures of relative leg stiffness and reactive strength index (RSI) were taken pre, 80 h, 128 h and 168 h post-competitive match play. Match and training intensity was determined by self-reported ratings of perceived exertion. Self-reported total exposure to physical activity during the testing week was also measured. A two-way repeated measure analysis of variance (ANOVA) with two factors (chronological age (three levels); and time (four levels)) was utilised with statistical significance set at $p < 0.05$. Cohen's d effect sizes were also calculated to interpret the magnitude of change in leg stiffness and RSI: standardised mean differences of 0.2, 0.5, and 0.8 for small, medium, and large effect sizes, respectively.
RESULTS: Significant time effects were reported for reduced leg stiffness at all time points compared to baseline ($p < 0.01$); however, there were no significant between-group differences. Neuromuscular function determined by leg stiffness remained compromised 168 h post-competitive match-play in all age groups (U13, d -1.54; U15 d = -0.45; U17 d = -1.10). Decrements in RSI were evident in the U13 (d = -0.89) and U15 (d = -0.22) age groups 168 h post-match play.
CONCLUSION: In conclusion, seven days may not be sufficient time to enable complete recovery in neuromuscular function in elite youth female soccer players. The reduction in leg stiffness at training sessions and subsequently before the next competitive match may have implications for sprint and jump performance and injury risk. Developmentally appropriate recovery strategies and increased monitoring in between training and match play is required to ensure that athletes are not training when vulnerable to injury and underperformance.

DEVELOPMENT AND VALIDATION OF THE REFEREE TRAINING ACTIVITY QUESTIONNAIRE (RTAQ): TOWARDS A BETTER UNDERSTANDING OF THE TRAINING PRACTICES OF SOCCER REFEREES

MCEWAN, G., UNNITHAN, V., EASTON, C., ARTHUR, R.

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: As the training of soccer referees is predominantly self-led, direct observation and monitoring of training is seldom possible (1). Consequently, relatively little information is readily discernible on the training practices of referees (2). Efficacious and accessible methods of monitoring referee training are therefore required. Accordingly, we sought to develop and validate a novel measurement tool, termed the Referee Training Activity Questionnaire (RTAQ), for assessing the training practices of soccer referees.
METHODS: To develop and validate the RTAQ, we employed a systematic multi-stage process: 1) item generation; 2) assessments of content and face validity; and 3) assessments of criterion validity (3). In stage 1, we generated items based upon a review of the literature, and semi-structured interviews with a sample of refereeing experts (n = 8). In stage 2, items were assessed for content and face validity by a sample of referees and academics experienced in questionnaire design (n = 6), with the content validity index (CVI) calculated (4). In stage 3, a sample of referees (n = 25) completed the RTAQ and subsequently recorded a detailed 7-day training diary. Additionally, we obtained objective estimates of physical training activity through heart rate data which was used to corroborate the self-report data of the training diaries.
RESULTS: Following stage 1, we constructed the preliminary RTAQ to include items pertaining to: 1) general training information (16 items); and 2) specific training practices (66 items). In stage 2, content validity was confirmed for 66 items ($CVI \geq 0.78$) with 16 items being deemed invalid ($CVI < 0.78$). We used participant feedback, in conjunction with content validity indices, to discard or revise problematic items. In stage 3, estimates of training activity derived from the training diaries and heart rate monitors were found to be strongly related ($r > 0.96$; $P < 0.001$). Additionally, negligible mean biases, moderate 95% limits of agreement (LOA), and significant correlations were observed between the RTAQ and training diaries for most items, with those exhibiting insufficient agreement (11 items) subsequently excluded or modified as per participant feedback.
CONCLUSION: The present findings provide initial evidence that the RTAQ is a valid and reliable tool for acquiring insight into the training practices of soccer referees. The development of a self-report measure in the form of the RTAQ will provide practitioners and researchers with a practical means of monitoring the training of soccer referees.

EFFECTS OF LONG-TERM MUSCULAR ENDURANCE VS. POWER TRAINING ON ANTHROPOMETRY, BODY COMPOSITION, AND PHYSICAL FITNESS IN FEMALE YOUNG SOCCER PLAYERS

LESINSKI, M., PRIESKE, O., GRANACHER, U.

UNIVERSITY OF POTSDAM

INTRODUCTION: Previously, it has been recommended that youth should conduct low-to-medium intensity resistance training to promote muscular endurance (Fleck & Kraemer, 2004). However, soccer is an intermittent sport that affords high levels of speed, agility, strength/power to excel. Thus, soccer-specific resistance training programs should include exercises to improve lower limb muscle

power. The objective of this study was to examine the long-term effects of local muscular endurance (LME) versus periodized power training (PPT) on anthropometry, body composition, and physical fitness over the course of a soccer season in young players.
METHODS: The U17 team of the season 2015/2016 (n=17) and the U17 team of the season 2017/2018 (n=16) of the female elite young soccer players (15±1 years; 3±1 years post-peak height velocity) of the 1. FC Turbine Potsdam participated and performed either LME (low-to-medium intensities, slow movement velocities) or PPT (low-to-high intensities, maximal movement velocities). Training was conducted over the course of the season with two sessions per week. Pre-and-post intervention, measures of physical fitness (muscle strength/power, speed, agility, balance), sport-specific performance (kicking velocity), and body composition (lean body mass, fat mass) were assessed. An analysis of covariance (ANCOVA) with baseline data as covariate was used to examine the effects of resistance training programs.
RESULTS: Total training volume was not significantly different between LME and PPT ($p > 0.05$). Significant between group baseline differences were observed in outcome measures. Anthropometric and body composition data were not significantly different between LME and PPT at post-test. The analyses revealed significantly better trunk muscle endurance (i.e., ventral Bourban test) as well as change-of-direction performance (i.e., T-test) ($1.28 \leq d \leq 2.28$; $p<0.01$) following LME compared with PPT. PPT resulted in significantly better drop jump, linear sprint (i.e., 10-m and 20-m sprint), kicking velocity, and maximal muscle strength (i.e., 1 RM leg-press) ($0.85 \leq d \leq 1.44$; $p<0.05$) compared with LME.
CONCLUSION: In accordance with the principle of training specificity, PPT significantly better improved power and linear speed measures, but also maximum muscle strength compared with LME in female young elite soccer athletes. Thus, it is recommended to regularly include lower limb muscle power exercises that are necessary to successfully perform soccer already in female young athletes.

NEURAL CORRELATE OF PROCESSING CAPACITY IN ELITE SOCCER PLAYERS

HUANG, S.W., LIN, C.C., LIANG, C.W., CHENG, Y.C., YANG, C.T., WANG, C.H.
NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: A greater number of studies have demonstrated that athletes outperformed non-athletes on a variety of cognitive tasks. However, the empirical evidence on players practicing strategic sports (e.g., soccer) has provided mixed results. One possible reason may be that processing speed is not the crucial factor that mediates the cognitive mechanism underlying the sporting success in such players. Here we adopted a non-parametric approach, systems factorial technology (SFT), to explore elite soccer players' workload capacity, which has been thought to be a valid index of the changes in information processing capacity when processing multiple sources of target signals. Further, we employed event-related potential (ERP) to explore the potential neural mechanism underlying such cognitive capacity in players.
METHODS: The present study recruited 27 male players (first division, aged 20.30 ± 0.99 years) and 26 age-and gender-matched controls (aged 22.42 ± 1.60 years) who did not participate in any specific sports training and were sedentary for at least 6 months. Participants' task performance was measured when performing a double-dot redundant-target task with concurrent electroencephalographic (EEG) recording. We employed SFT to calculate participants' workload capacity. For the ERP data, the N1 was measured to infer the neural activity underlying visuospatial attentional functioning during the task.
RESULTS: The primarily results revealed that soccer players showed faster responses than the controls ($p = .010$), regardless of single- or redundant-target conditions. However, we did not observe group difference in the Cz value ($p = .235$), suggesting that both groups did not differ with respect to workload capacity for processing multiple information from different spatial. In terms of ERP data, there was a significant main effect for N1 latency ($p = .002$) but not for N1 amplitude ($p = .259$), indicating that the detection of the visual stimuli was faster in the soccer payers relative to the controls, while the amount of attentional resource allocated for visual attention was comparable for both groups.
CONCLUSION: The present study demonstrated that long-term participation in soccer training may be beneficial for the processing speed of visuospatial attention, though no further benefit was observed when processing multiple information. On the other hand, the ERP finding suggests that soccer players had faster attention-related processing speed, and this might be a potential contributor to their superior processing speed. Future research should further address this issue by adopting the redundant-target tasks involving higher-level of cognitive functions to further explore the information processing capacity in strategic sports players.

THE EFFECT OF POST WARM-UP PASSIVE RECOVERY DURATION ON REPEATED SPRINT PERFORMANCE IN FEMALE FOOTBALL PLAYERS

KAWATA, F.1, HORINO, H.1, SUNAMI, S.2
1: WASEDA UNIVERSITY, 2: TOYO UNIVERSITY

INTRODUCTION: While the muscle temperature significantly drops in a duration of 15-20 minutes after warm-up (1), it is reported that professional footballers are required to finish their pre-match warm-up approximately 12 minutes prior to the start of the match (2). Therefore, the aim of this study is to investigate the effect of the passive recovery duration on physiological performance measure in football players.
METHODS: Fifteen female football players (14±0.2yrs) completed three experimental trials. After completing a 10-minute active warm-up, the participants are required to passively recover for either 2, 5, 10 minutes before performing 15 x 20m sprints. 20-m sprint times are observed. The 60-s circuits suggested by Zois et al (3) was selected as the intermittent exercise task in this study. All subjects completed the test on 3 separate occasions under each recovery condition.
RESULTS: Mean 20-m sprint time during the 60-s circuit were significantly faster following 2-minutes passive recovery (3.98±0.2s) compared to following 5-minutes passive recovery (4.05±0.3s, ES: 0.3±0.1, $p<0.01$) and 10-minutes passive recovery (4.18±0.2s, ES: 1.0±0.2, $p<0.01$). Repeated 20-m sprint times were significantly faster following 2- and 5-minutes passive recovery compared to following 10 minutes passive recovery in sprint one to sprint five. There were also significant differences in 20-m sprint time between the first 5 sprints and the last 5 sprints in every recovery condition.
CONCLUSION: Overall, the data would suggest that a passive recovery period of 10 minutes post warm-up may impair the effect of warm-up to 15 x 20m sprint time-trial performance. The present study may indicate that athletes are recommended to apply additional warm-up methods 2-5 minutes prior to the start of the performance.

EVALUATION OF MAXIMAL HEART RATE IN RECREATIONAL FOOTBALL PLAYERS USING LABORATORY AND FIELD TESTING

PÓVOAS, S.1,2, KRUSTRUP, P.3, PEREIRA, R.4, VIEIRA, S.4, CARNEIRO, I.2, MAGALHÃES, J.4,5, CASTAGNA, C.6,7

1:CIDESD , 2:ISMAI , 3:SHSC-SDU , 4:CIAFEL , 5:LAMETEX , 6:ST-FIGC , 7:UTV

INTRODUCTION: Evaluation of maximal heart rate (HRmax) is considered a valid method to assess relative exercise intensity during aerobic exercise, allowing exercise intensity prescription, monitoring and regulation of training interventions and overtraining prevention 1,2. Nonetheless, no information is available in the literature comparing the feasibility of laboratory and field tests and actual match-play in determining HRmax. The aim of this study was to examine the suitability of a standard treadmill test (TT), field tests and small-sided recreational football matches to induce HRmax in recreational football players.
METHODS: In a random order, sixty-six male sedentary untrained participants (age 39.3±5.8 years, VO2max 41.3±6.2 ml·kg-1·min-1, body mass 81.9±10.8 kg, height 173.2±6.4 cm) performed, on different occasions, a progressive VO2max TT, the Yo-Yo intermittent endurance level 1 (YYIE1) and level 2 (YYIE2) tests, the Yo-Yo intermittent recovery level 1 (YYIR1) test, and 7v7 (43x27 m pitch, 83 m2/player) football matches (45 min; 2–4 matches/player). Exercise heart rate (HR) was recorded using the same HR monitors in all the experimental conditions. HRpeak was considered as the maximal value obtained in each selected testing and protocol setting that could coincide or not with the individual HRmax (i.e., the highest value achieved in all the testing protocols and settings).
RESULTS: Players achieved 95±4, 99±2, 97±3, 95±3 and 97±2% of their HRmax in the TT, YYIE1, YYIE2, YYIR1 and match, respectively. During the YYIE1, YYIE2, YYIR1, TT and the small-sided football matches, a total of 73, 24, 18, 17 and 30% of players achieved their HRmax, respectively. Mean time at exhaustion was 10.7±1.5 min, 12.0±4.7 min, 2.9±1.1 min and 5.4±2.4 min for TT, YYIE1, YYIE2 and YYIR1, respectively. The test duration affected proportionally the achievement rate of HRmax with increased chances with durations equal or longer than 7.8 min. The minimum detectable change for the HRpeak value was ±2 b.min-1.
CONCLUSION: The most accurate estimation of a participant's individual HRmax was given by YYIE1 HRpeak, providing much higher probability of HRmax attainment. However, the results of this study suggest caution in considering a reference test for HRmax assessment in this population. When test exhaustion occurs before 7.8 min, it is highly recommended to perform confirmation tests. Field tests appear to be appropriate and accurate for determining recreational football players' individual HRmax.

THE IMPORTANCE OF PERFORMANCE IN COMPETITIONS AS AN INDICATOR OF FUTURE SUCCESS IN CYCLING

MOSTAERT, M.

GHENT UNIVERSITY

INTRODUCTION: The development of the athletes is rather non-linear and dynamic, which can be problematic in the search for the best performers with the potential to excel in sports in the future (Abbott et al., 2005). In the general conviction that gifted youngsters do not automatically end up at the highest performance level, it is important to get insight in the longitudinal career trajectories of young road cyclist until senior (elite) level. One way of identifying talent in young road cyclists is by tracking competitive performance. Furthermore, this can provide opportunities for athletes to further develop their skills and experience over time (Brouwers et al., 2012). The aim of the study was to examine to what extent success at elite level can be predicted by success that athletes achieved in the youth categories.
METHODS: The sample contained of 668 male road cyclists who were born between 1990 and 1993. 54 road cyclists reached senior elite level and were compared to 614 cyclists who did not reach elite level, but achieved at least one top ten result during youth competitions. Results from national competitions (top 10 results) were retrospectively gathered from three youth categories U15, U17, U19. An independent sample T-test was used with reaching elite level or not as independent variable and for each competition category separately. A logistic regression was applied to predict success based on competition performance.
RESULTS: The cyclists who reached the elite status obtained significantly more top ten places in youth competitions compared to cyclists who did not reach elite level (U17 t= -3.993 ; p<0.001 ; U19 t=-7.790 p<0.001), with exception for the U15 category (U15 t=-0.121 ; p=0.904). In the U15 and U17 category no significant predictions were found. The performance level in the category of U19 was a significant predictor to become an elite rider at a later age. Cyclists who achieved top 10 ranks in the U19 category had 13.2 % more chance to attain senior elite level.
CONCLUSION: In accordance with the findings of Brouwers et al. (2012), sports where peak performance is achieved at an older age, such as cycling, the U19 competition results might have a relatively high prediction value for later success. In younger athletes, the focus should not be on competitive performance to estimate future potential.

EMERGENCY NURSES' ACTIVITY ACCUMULATED WITHIN SHIFTS

CHAPPEL, S.E.1, AISBETT, B.1, CONSIDINE, J.2,3, RIDGERS, N.D.1

DEAKIN UNIVERSITY

INTRODUCTION: Within a shift, emergency nurses are required to continually perform tasks with a high physical demand, and therefore is considered a physically demanding occupation. Currently, emergency nurses' physical activity and sedentary time patterns within morning, afternoon and night shifts is poorly understood. Such research would provide insights into whether emergency nurses are able to maintain their on-shift activity levels to continue to provide optimum patient care. The aim of this study was to explore how active emergency nurses' are across their shifts, and to determine how activity undertaken during one 1-hour shift period was associated with their activity in the next hourly shift period.
METHODS: Data were drawn from the observational Physical Activity within Emergency Departments (PACED) Study. Fifty emergency nurses (45 female, five male) from hospitals in Melbourne, Australia, wore a hip-mounted ActiGraph accelerometer and completed a work diary for at least 1 week and a maximum of four weeks during 2018. Forty-two nurses also wore a thigh-worn activPAL inclinometer concurrently. Time spent sedentary and in light- (LPA) and moderate- to vigorous-intensity physical activity (MVPA; ActiGraph) and sitting and standing (activPAL) for each hourly shift period were determined. Multi-level analyses (hour, participant, hospital) examined temporal associations between hourly shift periods for all nurses, and according to shift type (morning, afternoon, night).
RESULTS: ActiGraph and activPAL data showed that emergency nurses spent the majority of each hourly period sedentary (67%) or standing (56%), respectively. Little variation in activity levels were observed across different hourly periods. During any given hourly shift period, every additional 10 minutes in MVPA was associated with 10.4 minutes less MVPA in the following hourly period. During any given hourly period in afternoon shifts, every additional 10 minutes spent in MVPA was associated with 13.6 minutes more LPA in the following hourly period. No other significant associations were observed.
CONCLUSION: Emergency nurses' activity and postural levels remain consistent within their shifts, suggesting they employ pacing strategies to maintain their activity levels during a shift to continually provide care to their patients. However, when nurses engaged in additional MVPA time in one hour they engaged in less MVPA in the following hour, potentially as a mechanism for recovery. Notably, nurses spent over half of their shifts standing, suggesting that hip-worn devices may overestimate sedentary time. Further research is required to investigate what strategies nurses may utilise to maintain their activity levels across a shift, and whether occupational activity affects leisure time activity levels.

PREDICTION OF ATTACKING PATTERNS IN SOCCER GAME USING NLP DEEP LEARNING MODEL

MATSUOKA, H., TAHARA, Y., ANDO, K., NISHIJIMA, T.

UNIVERSITY OF TSUKUBA

INTRODUCTION: A field of natural language processing (NLP) uses text data, and probability of a word appearance or similarity of meaning of words can be estimated from pattern of sequential words. The procedure of NLP already applied in a field of medical sciences to recognise disease patterns from text data of electrical health record (Glicksberg, 2018). The simplest expression of soccer performance is text data which represents ball-related actions such as pass and shot. Approximately 2000 actions in a game are labelled with text in chronological order. Soccer attacking patterns can be predicted from those text data of sequential actions in soccer game by using a procedure of NLP. The purpose of this study was to predict attacking patterns using a NLP deep learning model. Three tasks of this study were 1) to define features which represented technical-tactical actions in text, 2) to architect NLP deep learning model, and 3) to predict successful attacking patterns in soccer games.
METHODS: Forty-five official soccer games' data (ball-event data and tracking data) in 2017 J-League were used and 9,825 possession plays were collected. Each possession play contained players' ball-related actions from beginning to closing of possession. In feature processing phase, technical-tactical actions were defined in terms of actions with specific game situations. Then existing actions in possession plays were replaced to technical-tactical actions. Long-Short-Term Memory (LSTM) of Keras framework was used for training of this model. Sequential text data of possession play was used as input data while attacking outcomes were defined as output data. Softmax function for activation function, categorical-cross entropy for loss function, and Adam for optimizer were used.
RESULTS: To represent soccer game performance, 235 technical-tactical actions were defined. LSTM model achieved 74.16% of accuracy (loss = 0.62). It was possible to predict the best attacking patterns to finish with successful attacking outcomes. The highest probability of attacking pattern finished with shot inside of penalty area was 82.54%. Predicted successful attacking patterns concerned with disciplines of soccer game.
CONCLUSION: This study successfully predicted the attacking patterns of soccer using NLP deep learning model. By defining technical-tactical actions from tracking data and ball-event data, it was possible to represent soccer game performance in the text.

CHANGE IN ANTHROPOMETRIC DATA OF 9-YEAR-OLD SCHOOLCHILDREN BETWEEN 1970 AND 2017

KRUG, J.1, ZINNER, J.2, BECKER, M.2, CRASSELT, W.3, LUDWIG, R.4

1:UNIVERSITY OF LEIPZIG, 2:GERMAN UNIVERSITY OF HEALTH AND SPORTS, 3:FORMER DEUTSCHE HOCHSCHULE FÜR KÖRPERKULTUR, 4:DATENSERVICE LUDWIG

INTRODUCTION: In 1968, a project for the physical development of school youth in the GDR was started (Crasselt et al., 1985). As a result of this study, extensive data were generated over 10 years with a panel design of 3126 pupils with 785 variables of anthropometric, sport, school and social status. At present, several projects for the physical development of schoolchildren are being realized in Germany. In Berlin Zinner et al. (2015) organized the project "Berlin has Talent". From both investigations, the question was deduced which differences exist in the physical performance and in the anthropometric data within the period of more than 40 years. In the present sub-study we focus on anthropometric data of schoolchildren at the age of 9 years.
METHODS: In the study by Crasselt et al. (1985) we analysed 3046 schoolchildren (M = 8.77y, SD = ±0.29) including 1421 boys and 1525 girls as well as with the data up-date of 2017 in the study by Zinner et al. (2015) 3686 schoolchildren (M = 8.38y, SD = ±0.65) including 1847 boys and 1839 girls. The anthropometric variables body mass, body height, sitting height as well as the month age and BMI (Mir-

wald et al., 2002) were used for further statistical analyses with IBM SPSS Statistics, Version 25. In a first step we calculated PCA's, separated for boys and girls in both groups to analyse the similarity of data structure. In a second step a MANOVA with the anthropometric data was calculated.
RESULTS: The PCAs factor analyses showed for all groups similar two-factorial models, with a total of variance explanation > 78 %. The MANOVA with 3 dependent variables (body height, body mass and BMI) and 2 fixed factors (group and sex) yielded following results: Using Pillais trace, there was a significant effect of group V = 0.06,
F(4, 6725) = 97.29, p = 0.001, partial η2 = 0,055. The multivariate test for sex was also significant but with a very small effect (partial η2 = 0.01). However, separate univariate ANOVAs on the outcome variables revealed significant results between the both groups for body height with F(3, 6728) = 139.47, p = 0.001, partial η2 = 0.02, body mass F(3, 6728) = 381.15, p = 0.001, partial η2 = 0,054 and BMI F(3, 6728) = 340.34, p = 0.001, partial η2 = 0,048.
CONCLUSION: The most important result of the study is the increase of body mass from 28.96 kg in 1970 to 32.12 kg in 2017 in both sexes as well as the associated increase of BMI. The difference of body height is significant but has only little meaning. Our findings support the general level of knowledge of increasing in body mass in modern industrialized countries with a special view of schoolchildren at the age of 9 years. For the results of the investigations, however, there are also limitations in the generalization. The study by Crasselt et al. (1985) was representative of the territory of the GDR, the study of Zinner et al. (2015) is limited to the territory of Berlin. Further investigations are needed to generalize the results.

INCREASING PHYSICAL ACTIVITY WITH HEALTH APPS FOR FAMILIES: A QUALITATIVE CONTENT ANALYSIS

BAUMANN, H., MEIXNER, C., FENGER, A., SPRECKELS, C., WOLLESEN, B.
UNIVERSITY OF HAMBURG

INTRODUCTION: Due to precarious life situations and a lack of support, many children are prone to increasing physical health risks (Allender, Cowburn, & Foster, 2006). Even if the different actors in a family tend to clash because of their divergent personalities, a stable family environment, which fulfils its role model function, can be a reducing factor in this respect (Rhee, 2008). Since health apps, at least in individual situations, can be a motivation to improve physical health (Ernsting & Dombrowski, 2017), this study examined whether and how health apps are suitable in a context of family health promotion to increase physical activity.
METHODS: In order to assess the needs of all family members in terms of health apps and their implicit personality structure, both parents and children were interviewed. For the parents (n=40, ♂ =15, ♀ =25), a guided interview was used, which was later evaluated using MAXQDA software and qualitative content analysis. Depending on their age group, the children (n=120, ♂=60, ♀=60) were divided into three focus groups (10-11 years, 12-13 years and 14-15 years) and asked various questions about health apps in a methodological and didactical prepared learning environment.
RESULTS: Including all participants and their diverse personality structures, movement and nutrition were considered as the two essential content areas for health apps. More than 60% of parents would integrate a health app into their family's life even though the individual usage rate of health apps is 35%. The focus groups showed that children between the age of ten to thirteen associated health with playful elements and like to be active with their parents, whereas in adolescents over the age of thirteen, self-expression becomes increasingly important and the time spent with parents is valued less.
CONCLUSION: The results indicate that an intra-familial use of health apps is a possible solution for reconciling family's interests in exercise and nutrition. With an enhanced support of the family, especially preadolescent children could be stimulated to long-term behavioural changes in terms of physical activity increase. Further research will show how the motivational approach in health apps must be implemented so that the divergent personalities within a family echo themselves in it.

OP-SH07 Psychology: Stress and anxiety

A LONGITUDINAL ANALYSIS OF THE RELATIONSHIP BETWEEN MENTAL FATIGUE, FATIGUE AND TIREDNESS IN ELITE AND INTERNATIONAL NETBALL PLAYERS.

RUSSELL, S., JENKINS, D., HALSON, S., JULIFF, L., KELLY, V.
THE UNIVERSITY OF QUEENSLAND, QUEENSLAND ACADEMY OF SPORT AND NETBALL AUSTRALIA

INTRODUCTION: Fatigue is a multi-faceted phenomenon; in addition to fatigue (F), mental fatigue (MF) has been shown to negatively influence aspects of physical and team sport performance (1). Research into MF and sports performance to date has been limited to acute experiments in laboratory-based settings; whether MF and PF can be identified as separate entities over extended periods of training and competition with elite athletes is yet to be examined. Given that outcomes in elite sport are often determined by very small margins,

better understanding the relationships between F, MF and tiredness has the potential to inform athlete preparation and improve individual and team performance.
METHODS: 80 elite athletes competing in Australia's Suncorp Super Netball (SSN) league subjectively rated their MF, F and tiredness (T) on 1-5 anchored Likert scales across six competition rounds and three weeks of finals series matches. 14 of these athletes, who formed the National team, completed the same ratings during international camps and competitions.
RESULTS: Across the SSN rounds a significant difference between MF and F score ($p < 0.001$) was found, r=0.6287, r2=0.395. Similarly, a significant difference between MF and T score ($p < 0.001$) was observed, r=0.4108, r2=0.1688. Comparable results were found over international representative periods; with a significant difference between MF and F score ($p < 0.001$), r=0.6132, r2 =0.3760. A significant difference between MF and T score ($p < 0.001$), r=0.5428, r2 =0.2946 was also identified. Round-by-round analysis revealed significantly higher ($p < 0.05$) subjective ratings of MF, PF, and T, for the 'grand-final' compared to the regular-season rounds. Across the SSN competition, higher than 'normal' perceptions of MF, F and T were reported on 15%, 19% and 26% of the occasions respectively. For international representative period, a higher than normal perception of MF, F and T was reported for 9%, 17 % and 26%, of the total reports.
CONCLUSION: The findings show that elite athletes are capable of distinguishing between perceptual constructs of mental fatigue, general fatigue and tiredness; evidencing each as variables of separate importance. The subjective increases in MF during finals impresses the need to periodise training and recovery practices around MF- similar to the management of physical fatigue in elite sport. Differences in the ratings of MF between SSN and international representation suggest MF may be better managed in a camp or tour setting. Alternatively, international athletes may be more resilient or better able to cope with MF. Given that MF can be identified by athletes as being separate to PF and T, research into susceptibility of particular athletes to MF and strategies to minimise its influence on performance is needed.

A 4-WEEK ENDURANCE TRAINING PROGRAM IMPROVES TOLERANCE TO MENTAL EXERTION IN UNTRAINED INDIVIDUALS

FILIPAS, L., MARTIN, K., NORTHEY, J., LA TORRE, A., KEEGAN, R., RATTRAY, B.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Acute mental fatigue has an adverse effect on cognitive function and endurance performance. Mental fatigue appears to impair endurance performance through an increased perception of the effort during the subsequent physical exercise (van Cutsem et al., 2017). However, a physiological reason for an increase in perceived exertion has only been postulated (Martin et al., 2018). Beyond the physiological mechanism of mental fatigue, it is important to understand whether the ability to resist mental fatigue is relatively stable (e.g., associated with a genetic predisposition) or displays a trainable phenotype. The aim of this study was to investigate whether 4 weeks of endurance training could improve tolerance to mental exertion in untrained participants.
METHODS: Twenty participants completed in a randomised and counterbalanced order, a 6-week experimental protocol. Baseline and follow-up assessment were conducted over three sessions in weeks 1 and 6. During session 1, participants completed an incremental maximal ramp test. During sessions 2 and 3 participants completed a 15 min cycling time trial, once preceded by a mental exertion task, and the other occasion a control task. Following baseline, participants were randomised into a physical training or placebo group to complete thrice weekly interventions for four weeks. Changes in VO2peak, time trial performance, perceived exertion, subjective mental fatigue, motivation and workload were compared between mental exertion and control conditions, physical training and placebo groups, and pre and post intervention.
RESULTS: Following the intervention, the physical training group had a smaller decrease in the distance covered during the time trial after the mental exertion task, compared to the control task ($p = 0.03$). The physical training group also reported that the mental exertion task was less physically demanding ($p = 0.04$) following the intervention.
CONCLUSION: Four weeks of endurance training increased tolerance to mental fatigue in untrained participants. This finding suggests that the ability to tolerate mental exertion is trainable, and highlights the far-reaching benefits of endurance training.

COMPETITIVE AND ORGANISATIONAL STRESSORS FACED BY PROFESSIONAL JOCKEYS IN IRELAND

KING, L.1, CULLEN, S.J.1, WARRINGTON, G.2,3, MCGOLDRICK, A.4, LOSTY, C.1

1: WATERFORD INSTITUTE OF TECHNOLOGY; 2: UNIVERSITY OF LIMERICK; 3: HEALTH RESEARCH INSTITUTE, UNIVERSITY OF LIMERICK; 4: IRISH HORSERACING REGULATORY BOARD.

INTRODUCTION
Elite athletes face various stressors during their careers. One athletic population that is renowned for the demanding lifestyle the sport places on them is professional jockeys. A career as a jockey has implications for physical (Wilson et al., 2014) and psychological (Losty et al., 2019) health. To date, only one study has investigated stressors in jockeys with this sample facing stressors from both the competitive and broader work environment (Landolt et al., 2017). However, research exploring stressors amongst jockeys in Ireland has yet to be conducted. Thus, the aim of this study was to address this gap in knowledge and identify sources of stress to professional jockeys in Ireland.
METHODS
Semi-structured interviews were conducted with 15 jockeys with the sample ranging from 23 to 31 years old (M= 26.6, SD = 2.65), competing on average for eight years (SD = 3.96). Interviews were audiotaped and transcribed verbatim, with data analysed via thematic analysis.
RESULTS
Jockeys identified numerous competitive and organisational sources of stress. Competitive stressors included poor form, managing weight and injury, coping with public scrutiny and an ambivalence over jockey's athlete status. Organisational stressors included job and finance uncertainty, travel, workload and racecourse facilities were the most common reported
CONCLUSION

This is the first of its kind to explore the sources of stress associated with a career as a professional jockey in Ireland with findings suggesting that jockeys face similar stressors to other elite athletes (e.g. managing public scrutiny). However, the data also highlights there are unique sport-specific stressors experienced by jockeys such as managing weight, travelling vast distances on a regular basis for work/competition, and an uncertainty over their athlete status. Understanding the stressors jockeys face will allow for bespoke interventions and support programmes to be developed to minimise the impact of these stressors on performance and well-being. Future research should also explore the positive aspects of a professional career in horseracing.

UTILITY OF A THREE-DIMENSIONAL DYNAMICAL SYSTEMS FRAMEWORK TO BETTER UNDERSTAND STRAIN-PERCEPTION-THINKING-ACTION COUPLING IN THE PHENOMENOLOGICAL EXPERIENCE OF "HITTING THE WALL"

VENHORST, A., MICKLEWRIGHT, D., NOAKES, T.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Traditionally, exercise scientists revert to reductionist perspectives of catastrophic failure in one or other peripheral system when discussing the "hitting the wall" (HTW) phenomenon. However, the phenomenological experience of HTW is better understood as a psychophysiological stress process characterised by (i) discrete and poignant onset, (ii) dynamic interplay between physiological, affective, motivational, cognitive and behavioural systems and (iii) unplanned reduction of pace and performance [1].
METHODS: Utilising a three-dimensional dynamical systems framework of goal-directed exercise behaviour [2,3], a preceding companion article investigated the psychophysiological responses of highly-trained runners to 20-km self-paced treadmill time trials: (i) in a tapered condition and (ii) after producing locomotor muscle fatigue and exercise-induced muscle damage (EIMD) via a standardised drop-jump protocol [4]. Besides defining hallmarks of HTW, medium and large effects were observed in physiological and perceptual variables, respectively. The following cause-effect relationships were proposed: Running with EIMD negatively impacts performance fatigability via (i) amplified physiological demand and non-adaptive distress response and (ii) deterioration in perceived fatigability indicated by increased perceived physical strain, decreased valence and increased action crisis; eventually dissolving the initially aspired performance goal. Here, we applied a five-step structural equation modelling procedure to determine the extent to which the observed data fitted the hypothesised cause-effect relationships.
RESULTS: First, increased haematological indicators of EIMD predicted increased blood cortisol concentration, which in turn predicted increased performance fatigability. Second, increased perceived physical strain predicted decreased valence and was a significant mediator by explaining 44% of the relationship between increased haematological indicators of EIMD and decreased valence. In turn, decreased valence predicted increased action crisis, which in turn predicted increased performance fatigability. The observed data fitted the hypothesised dual-pathway model well with good model-fit indices throughout.
CONCLUSION: The hypothesised cascading interactions between the psychophysiological determinants of goal-directed exercise behaviour were applied, tested and confirmed. The three-dimensional dynamical systems framework comprehensively explained how strain, perception, thinking and action are coupled and how their dynamic interdependencies regulate pacing behaviour and performance. The findings provide novel insights into the psychophysiological mechanisms that underpin the constraint-based emergence of the HTW phenomenon.

ADRENAL STEROID LEVELS, METABOLIC AND CARDIORESPIRATORY PARAMETERS CHANGES IN RESPONSE TO EXTREME PHYSICAL STRESS IN MALE HANDBALL PLAYERS

CSÖNDÖR, É.1, KARVALY, G.2, LIGETVÁRI, R.1, FAR, G.1, MÓRA, Á.1, VÁSÁRHELYI, B.2, TÓTH, M.1,2,4, TÓTH, M.3, STROMÁJER-RÁCZ, T.1, BETLEHEM, J.1, ÁCS, P.1, OLÁH, A.1

1UNIVERSITY OF PÉCS; 2SEMMELWEIS UNIVERSITY; 3EÖTVÖS LÓRÁND UNIVERSITY; 4UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Steroid hormones from the adrenal cortex play a significant role in the regulation of cardiovascular, metabolic and many other functions in stress situations.
METHODS: We investigated the plasma levels of 3 different adrenal specific steroid molecules in a model of extreme acute physical stress and mental stress in male handball players (n=40, mean age=22,5±3,75). The steroid come from the three different layer of the cortex. Steroid levels were measured with a combination of HPLC-Mass Spectrometry technique. Heart rate (HR) and blood pressure (BP) values were monitored in both models whereas metabolic and gas-exchange parameters only in the physical stress situation. All values were measured at baseline, at maximum stress situation and thirty minutes in the restitution phase. The investigations were approved by the ethical committee and the subjects gave informed consent.
RESULTS: BP and HR were elevated in both stress models. The 3 steroid molecules and lactate showed significant ($p<0.05$) elevations in the physical stress model. Mental stress did not have a significant effect on the steroid levels. Aldosterone increased by 106,86% in restitution phase compared to baseline, dehydroepiandrosterone by 89,22% and cortisol increased by 24,16% compared to baseline.
CONCLUSION: According to our results steroid hormones only responded to physical stress and did not change to psychological stress. Our results suggest that all three lines of the adrenal cortex are affected by physical stress. The three elevated steroid molecules originate from three structurally different parts of the adrenal gland pointing to the fact that mineralocorticoid, glucocorticoid and androgenic lines are all involved. The cardiovascular and steroid effects have a different time frame showing maximum levels of BP and HR at the peak of

the stress, while steroid levels are elevated thirty minutes later, and only in the physical stress model. Clarification of the physiological roles of elevated steroid levels in response to acute physical stress requires further investigations.

PL-PS01 Springs and sprinters

THE SPRING IN YOUR STEP: THE IMPORTANCE OF MUSCLE AND TENDON DESIGN FOR HUMAN PERFORMANCE.

LICHTWARK, G.

THE UNIVERSITY OF QUEENSLAND

The human leg is considered to act like a spring when we walk and run; compressing to store energy and then recoiling to release energy. This spring-like function is considered to be energetically favourable because energy can be recycled in elastic tendons and/or ligaments. However, elastic tendons play a much more critical role for muscle function, with their mechanical properties potentially tuned to allow muscles to operate in a manner that can minimise energy consumption, maximise power and protect muscle from damage across the many different tasks we perform. This presentation will explore how muscle and tendon design, in combination with neural control strategies, influences our abilities to perform tasks that have different mechanical objectives – either for maximising economy (e.g distance running), maximising power (e.g. jumping or sprinting) or absorbing impacts (e.g. landing tasks). I will provide an overview of an emerging body of literature demonstrating the importance of tendon compliance in not only determining muscle performance, but also in shaping how movement is controlled and why we select specific movement patterns. I will also provide an overview of the role of muscle function in the spring-like behaviour of the foot and its importance in generating or absorbing power. Finally, I will examine, from a theoretical perspective, how this information can be applied; ranging from optimising the neuro-musculoskeletal system for athletic performance or preventing or treating injuries and for understanding movement dysfunction in ageing or clinical populations (e.g. cerebral palsy).

MAXIMUM SPRINTING: CAN WE TRANSFER OUR BIOMECHANICAL KNOWLEDGE TO IMPROVE ATHLETES' PERFORMANCE

SALO, A.I.T.

RESEARCH INSTITUTE FOR OLYMPIC SPORTS

Biomechanics of sprinting has received plenty of interest in the scientific literature. Perhaps surprisingly it has experienced a renaissance over recent years partly due to various nations investing in scientific support in sport and related facilities and partly due to interest by the scientists involved. At the basic level, running velocity is defined by step length multiplied with step frequency. This is one of the simplest equations in biomechanics, yet so beautifully complicated to master in reality. Researchers have extensively studied areas ranging from kinematics to muscle-tendon interaction in sprinting. However, these have been mainly carried out at discrete distances due to limitations of facilities and equipment. Novel statistical methods (in sports science) like Statistical Parametric Mapping provides further opportunities to analyse the data more comprehensively. As the quest of athletes is to run faster, we need both empirical and experimental data (although true experiments are difficult to carry out on elite athletes) to understand how the performance can be improved. Musculoskeletal modelling and computer simulations have also started to provide new avenues to understand the interaction of muscle characteristics in performance. While biomechanics can find out phenomena behind human locomotion, such knowledge is relevant for sprinters only, if it can be transferred to coaching, athletes' training and consequently to their performance. I will explore all these issues behind this challenging conundrum.

IS-MI02 Advances in athlete development research

MULTI-DISCIPLINARY LONGITUDINAL ATHLETE DEVELOPMENT: KNOWLEDGE ADVANCES FROM THE GRONINGEN TALENT STUDIES

ELFERINK-GEMSER, M.

UNIVERSITY OF GRONINGEN, UMCG

If we look under the surface of elite sport, we know that every elite athlete was once a child and has gone a long way before reaching the top. What characterized their successful development towards expertise? The prediction of long-term success is extremely difficult and the later successful athletes are not necessarily the ones who performed best in youth competitions. The reason for this is that many factors play a role; factors related to both the athlete (i.e., rate of learning, training and maturation of anthropometric, physiological, technical, tactical, and psychological skills) and the environment (i.e., opportunities created by parents, trainers, coaches, talent development program, and the competition structure) along with a component of chance. The Groningen Sport Talent Model gives direction for studying those factors related to the acquisition and maintenance of expertise in three steps: 1. Defining expertise, 2. Studying (the development of) performance and performance characteristics, and 3. The choice of appropriate study methods and statistical analyses (Elferink-Gemser et al., 2018).
In the last decade, over one thousand talented athletes in a variety of sports (e.g., soccer, field hockey players, basketball, volleyball, artistic gymnastics, tennis, cycling, swimming, and speed skating), have been followed throughout adolescence in the Groningen Sport Talent Studies. Multidisciplinary longitudinal athlete monitoring with measures of anthropometry, physiological, technical, tactical and psychological characteristics reveal that to reach expertise, athletes have their own unique development patterns. Still, future successful athletes also have much in common, i.e., their capability to, derive more from the same number of practice hours than less successful athletes. As a consequence, they are better able to constantly improve their performance. They are known to take responsibility for the progress they make and score higher on aspects of self-regulation of learning, such as reflection and effort. Although self-regulation may be considered as a general characteristic of an athlete, which can be applied across domains, the mechanism itself is highly context-specific. In the presentation, this mechanism of self-regulation of learning and its value for reaching expertise will be explained as well as how trainers and coaches can use this information in their training sessions.
Elferink-Gemser, M.T., Te Wierike, S., Visscher, C. (2018). The acquisition and maintenance of expertise. Multidisciplinary, longitudinal studies: A perspective from the field of sports. In: Cambridge Handbook of Expertise (2nd edition). (K.A. Ericsson, R. Hoffman, A. Kozbelt, M. Williams, eds.), pp. 271-290.

MULTI-DISCIPLINARY LONGITUDINAL ATHLETE DEVELOPMENT: KNOWLEDGE ADVANCES FROM TRACKING ADOLESCENT ATHLETES IN UK RUGBY LEAGUE

TILL, K.

LEEDS BECKETT UNIVERSITY

Tracking adolescent performance into adulthood within sport is a complex challenge, especially during this key period of development that may be affected by numerous physiological and psycho-social factors. This presentation examines the relationships between maturity status, anthropometry and physical performance within talent identification, player development and future career attainment within the sport of rugby league. With reference to a large dataset collected on players aged 13-15 years over multiple years, the presentation will showcase the longitudinal and retrospective research methodologies applied to better understand athlete development.
The presentation will illustrate: (1) the longitudinal tracking of players during adolescence and how maturity status influenced physical development; 2) how retrospective analyses of anthropometric and fitness characteristics during adolescence were associated with future adult career attainment (i.e., whether players attained amateur, academy, or professional status); and 3) how examination of relative age, maturity status and playing position in adolescence affected future adult career attainment.
In summary, these research findings highlight the complex interaction of age, maturity, anthropometry and physical performance during adolescence and how they influence athlete development and future attainment. These interactions have to be carefully examined relative to the performance demands within the sport to better understand who are showing promising accelerated trajectories which associate with longer-term career attainment.

ADVANCES IN ATHLETE DEVELOPMENT RESEARCH

COBLEY, S.

THE UNIVERSITY OF SYDNEY

Athlete development systems are consistently confronted by validity concerns and their capability to provide healthy forms of development (i.e., physical, psychological, social or functional). To improve validity and their contribution to individual development, both researchers and practitioners identify the need to better understand the holistic athlete developmental process with the aim to achieve functional individual development. Functional development can be regarded as the recognition and interaction of biological processes, psycho-social conditions and behavioural training stimuli to healthily improve, or accelerate, facets of athletic performance. On this basis, and given existing concerns, research that examines multiple relevant variables longitudinally may prove most insightful. In this invited

symposium, an overview of contemporary research that adopts a multi-disciplinary, multi-variate and longitudinal perspective is provided.
In the third presentation, Assoc. Prof. Stephen Cobley identifies what researchers, sports-systems and practitioners can learn from existing research, highlighting considerations for future research and practice. Alongside the importance of longitudinal tracking, the challenges and confounding factors in athlete development (e.g., growth and maturation) are outlined. Based on studies conducted in rugby league and soccer, Steve highlights methods and strategies for how athletes can be more accurately evaluated. These include the utilization of multivariate z-scoring assessments for individual profiling and corrective adjustment procedures based on maturation status and decimal age. To showcase the latter approach, corrective adjustments in swimming based on longitudinal development profiles is explained. The approach allows sport system practitioners (i.e., coaches, national talent development coordinators) to more equitably compare and evaluate athlete trajectories, and better inform their onward training for functional development. Although at their early developmental stages, these methods and strategies may help facilitate athlete development and improve system validity.

OP-PM14 Physical activity / inactivity I

TELEPHONE-BASED COACHING AND PROMPTING FOR PHYSICAL ACTIVITY PROMOTION: SHORT AND LONG-TERM FINDINGS OF A RANDOMIZED CONTROLLED TRIAL (MOVINGCALL)

FISCHER, X., KREPPKE, J., ZAHNER, L., GERBER, M., FAUDE, O., DONATH, L.

UNIVERSITY OF BASEL

Background: Remotely communicated physical activity (PA) promotion programs entail notable potential to promote health1. However, it remains unknown which intervention components are most effective and result in a sustainable increase in PA2. This study analyzed the short- and long-term efficacy of telephone coaching and SMS prompting for PA promotion in adults reporting low PA levels.
Methods: 288 adults (age: 42 ± 11 years; BMI: 25.9 ± 4. 9 kg/m2) were assigned randomly to three intervention arms: The two intervention groups received 12 biweekly telephone calls with (coaching & SMS group) or without (coaching group) additional SMS prompts (n = 48 SMS). The control group received a single written PA recommendation. The program consisted of evidence-based behavior change techniques and all participants had access to a personal online profile. Self-reported and objective moderate-to-vigorous physical activity (MVPA) were assessed by a structured interview3 and by wrist worn triaxial accelerometer. The assessments took place at baseline, after the intervention (6 months) and after a no-contact follow-up (12 months). Between-group differences of changes in PA were analyzed as intention-to-treat using linear mixed models.
Results: Self-reported and objectively assessed PA levels of the intervention groups were higher compared to the control group in the post and follow-up-test. At the post-test, weekly self-reported MVPA increased by 260 minutes (95% CI 208 to 312) in the coaching group, by 252 minutes (95% CI 196 to 308) in the coaching and SMS group and by 87 minutes (95% CI 28 to 146) in the control group. SMS prompting did not result in a further increase in PA. Changes in self-reported MVPA remained similar in the follow-up-test. Objectively assessed MVPA increased in the post-test in the coaching group (+26 minutes, 95% CI 6 to 47) and coaching and SMS group (+28 minutes, 95% CI 7 to 50) but not in the control group. At the follow-up-test, objectively assessed MVPA in the intervention groups did no longer differ from baseline and declined below baseline in the control group (-26 minutes, 95% CI -50 to -2).
Conclusion: In comparison to a written advice, telephone coaching led to higher PA level and can be considered an effective and well-accepted tool for the adoption and maintenance of a physically active lifestyle.

SOCIO-DEMOGRAPHIC PATTERNING OF OBJECTIVELY MEASURED PHYSICAL ACTIVITY AND SEDENTARY BEHAVIORS IN EIGHT LATIN AMERICAN COUNTRIES: FINDINGS FROM THE ELANS STUDY

FERRARI, G.L.M., KOVALSKYS, I., FISBERG, M., SALAS, G.G., RIGOTTI, A., SANABRIA, L.Y.C., GARCÍA, M.C.Y., TORRES, R.G.P., HERRERA-CUENCA, M., GUAJARDO, M., SOLÉ, D.

UNIVERSIDAD MAYOR

INTRODUCTION: Insufficient moderate-to-vigorous physical activity (MVPA) and excessive time spent in sedentary behaviors (SB) have emerged as key risk factors for cardiovascular disease worldwide, affecting not only high-income nations, but also low- and middle-income countries (LMICs).1 Use of accelerometers has increased in high-income countries. In contrast, relatively few studies have used accelerometers in LMICs, including Latin American countries, and few have implemented the same processing procedures to maximize comparability. Thus, the aim of this study was to use comparable accelerometer data to quantify and characterise socio-demographic patterns of physical activity (PA) and SB in Latin American countries.
METHODS: The Latin American Study of Nutrition and Health (Estudio Latinoamericano de Nutrición y Salud; ELANS) is a household-based multi-national cross-sectional survey of nationally-representative samples from urban populations (Argentina, Brazil, Chile, Colombia, Costa Rica, Ecuador, Peru and Venezuela) and 2,732 participants were included. PA and SB data were collected using accelerometers. SB was defined as time accumulated at ≤100 activity counts/min (1.0METs), ≥101–1951 activity counts/min for light PA (LPA; 1.1–2.9METs), and ≥1952 activity counts/min for MVPA (≥3.0METs).2 Overall and country-specific average levels of time spent in PA and SB were compared by sex, age, socioeconomic and education level.
RESULTS: Overall, the mean time spent on SB was 571.6min/day, ranging from 553.8min/day in Chile to 596.7min/day in Peru. Average levels of LPA, MVPA and total PA were 311.1min/day (95% CI: 307.7; 314.5), 34.9min/day (95% CI: 34.0; 35.9) and 7531.2MET-min/week (95% CI: 7450.4; 7611.9), respectively. MVPA and total PA were higher in men than women. The prevalence of physical inactivity3 was

40.6%, ranging from 26.9% (Chile) to 47.9% (Costa Rica and Venezuela). Women were more physically inactive than men (47.7% versus 33.0%). SB levels were highest among those with higher education; PA graded positively with socioeconomic level.
CONCLUSION: Our findings pose a challenge for the Latin American countries, as physical inactivity and SB are highly prevalent, and show variation across sex, age, socioeconomic level and educational level. Our findings can inform the planning of health policies and programs designed to reduce levels of physical inactivity, as well as inform the local and cultural adaptation of these policies and programs for implementation in Latin America.

SELF-REPORTED FACILITATORS AND BARRIERS OF PRIMARY HEALTHCARE GENERAL PRACTITIONERS AND NURSES TO IMPLEMENT EXERCISE PRESCRIPTION ACCORDING TO EXERCISE IS MEDICINE INITIATIVE

CALONGE-PASCUAL, S.1,2, FUENTES-JIMÉNEZ, F.1, NOVELLA, F.1,2, LÓPEZ-DIÁZ-UFANO, M.L.3, VILLALVILLA-SORIA, D.3, CASAJÚS, J.A.2, BELMONTE, S.3, ARNAL-SELFA, R.3, GONZÁLEZ-GROSS, M.1,2

(1) IMFINE RESEARCH GROUP. FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCES-INEF. UNIVERSIDAD POLITÉCNICA DE MADRID. (2) RED DE INVESTIGACIÓN EXERNET. (3) CONSEJERÍA DE SALUD. COMUNIDAD DE MADRID.

Introduction: Physical inactivity is becoming a serious health threat with worrying perspectives. Together with other measures, promoting PA through the healthcare settings is a worldwide trending strategy; and one of the objectives of the Exercises is Medicine initiative (EIM). The aim of this study was to assess the feasibility of implementing physical activity on prescription (PAP) in Primary Healthcare (PHC).
Methods: A choice-modeling, google-form questionnaire (Q), which had been previously developed according to the focus group methodology and refined and validated in consultation with professionals was sent via e-mail to all GPs and nurses working at PHC in the Region of Madrid. The anonymity of answers was guaranteed. The Q comprised 30 questions. The protocol has been approved by the Central Commission for research of the region of Madrid and the Ethical committee of the Alcorcon Hospital. Differences between health professionals' variables were analyzed by cross tab and one factor ANOVA analysis (SPSS, version 20.0).
Results: A total of 258 GPs (198 females) and 253 nurses (222 females) with 22.27 ±8.73y and 15.35 ±9.51y, respectively, of PHC career experience, answered the Q. 99% admitted health benefits of regular PA. However, 29% considered it only for some specific adult age range and/or sex. 14.3% of GPs and 73.1% of nurses knew correctly WHO PA guidelines. PHC professionals were more confident with PA promotion (70%) than with exercise prescription (39%), with significant differences between both PHC staff ($p < 0.05$). 60.4% had never done previous PAP training courses. Regarding self-perception barriers to implement PAP in PHC, differences were observed between GPs and nurses, respectively (1-6 range values): no space in PHC centers (3.73-4.15, p=0.004); no time (5.47-5.20, p=0.003) and lack of awareness in patients (5.48-5.30, p=0.026). Selected solutions were: need of a specific new space in PHC centers (64.7-81.8%, $p<0.001$); improvement of PA anamnesis (69.8-88.9, $p<0.001$); increased PAP advertising campaigns (96.5-96.0%); progressive PAP implantation in PHC (97.7-95.3%); better use of first-time visit to PHC (81.4-88.5%, p=0.05); collaboration with public external resources (70.9-82.6%, p=0.007); improved PAP materials and economic resources (70.2-81.4%, p=0.002) and more time with each patient (90.3-93.7%). Discrepancies regarding PAP leadership were observed; nevertheless, 64% of PHC professionals agreed to collaborate with Sports Scientists to prescribe exercise in PHC.
Conclusions: Most GPs and nurses are aware of the benefits of regular PA and willing to introduce PAP as a preventive and rehabilitation treatment in PHC. Differences in knowledge and perceived barriers and facilitators were observed. A need for specific PAP education was identified and specific training courses should be offered. The results of this study should help to design a planned strategy to implement effectively PAP in the PHC system.

PREFRONTAL OXYGENATION RESERVE: LINK BETWEEN PHYSICAL ACTIVITY LEVEL AND EXECUTIVE FUNCTIONING DURING COMPUTERIZED STROOP TASK IN HEALTHY YOUNG MALES

GOENARJO, R.

UNIVERSITE DE POITIERS

INTRODUCTION: The recommendation of 150 min of moderate to vigorous intensity physical activity (MVPA) per week from World Health Organization (WHO) is promoted because it has been reported to have significant benefits for health.1 Many studies have reported that physical activity was associated with cognition and more selectively with executive functioning.2,3 There is a growing interest to clarify the neurophysiological mechanisms that underlie this effect. The aim of the current study was to evaluate the neurophysiological changes in cerebral oxygenation that associated with physical activity level and executive functions in healthy young males.
METHODS: Fifty-six healthy young males (n=56, 22.1+2.4yrs) were grouped according to their physical activity level whether they fulfill 150 min of MVPA per week or not by using the Global Physical Activity Questionnaire (GPAQ) (active, less-active). Cerebral oxygenation and changes in concentrations in oxyhemoglobin (ΔHbO2) and deoxyhemoglobin (ΔHHb) in both sides of the prefrontal cortex (PFC) were assessed using fNIRS during computerized Stroop task. On computerized Stroop task, executive function performances were measured by counting the percentage of correct responses and reaction time. Several analyses of variance (ANOVA) with Bonferroni post-hoc tests were conducted to test the interaction of physical activity level by Stroop's performance and cerebral oxygenation.
RESULTS: Physical activity had a moderate effect on reaction time in switching condition (p=0.02; ES=0.77) but not in other condition. There was a significant interaction of physical activity level by Stroop's condition on reaction time [$F(1, 54) = 3.40$, $p = 0.04$]. In the accuracy performance, neither effect of physical activity level nor the interaction of physical activity level by condition were found. From fNIRS data, Physical activity had a large effect on ΔHbO2 in switching condition in right PFC (p=0.04; ES=0.80) and left PFC (p=0.02; ES=0.96), but not in other conditions. A large physical activity effect was found on ΔHHb in inhibition condition in the right PFC ($p<0.01$; ES=0.88) but not in the left PFC nor other conditions.
CONCLUSION: The results indicate that the active individuals performed better in executive function than less active individuals and that this relationship is likely mediated by neurophysiological changes in PFC. Indeed, we did find that active individuals demonstrated greater cerebral oxygenation response in both sides of PFC during switching conditions of Computerized Stroop task in comparison to less active

individuals. Improved executive performance and oxygenation response suggest that fulfilling physical activity recommendation of 150 min MVPA can lead to physiological and behavioral benefits.

THE BRIEF EXERCISE AT WORK (BE@WORK) TRIAL: EFFECTS OF WORKPLACE-BASED HIGH-INTENSITY INTERVAL TRAINING ON PHYSICAL FITNESS, CARDIOMETABOLIC HEALTH AND WELLBEING IN OFFICE WORKERS

BURN, N., WESTON, M., ATKINSON, G., MAGUIRE, N., WESTON, K.L.

TEESSIDE UNIVERSITY

INTRODUCTION: High-intensity interval training (HIT) can improve markers of physical fitness and cardiometabolic health (MacInnis & Gibala, 2017).The chronic impact of HIT on psychological variables is understudied (Stork et al. 2017) and the effectiveness of HIT in workplaces is unclear.We quantified the effects of our Brief Exercise at Work (BE@Work) intervention, comprising 8-weeks of workplace-based HIT, on outcomes related to physical fitness, cardiometabolic health and wellbeing in office workers.
METHODS: Using a controlled trial design, 55 office-based employees (mean age ± standard deviation [SD] 46 ± 11 years) were recruited from two workplaces in Northeast England; one as an intervention site (n = 31), the other as no-treatment controls (n = 24). The 8-week intervention comprised of thrice-weekly workplace-based HIT sessions consisting of 4 to 7 60-s maximal effort intervals interspersed with 75-s rest, based on stair stepping, stair climbing and non-contact boxing. Outcomes assessed at baseline and post-intervention were cardiorespiratory fitness (VO2max), leg extensor muscle power, handgrip strength, body mass index, waist circumference, blood pressure, blood lipids and glucose, eight domains of health related quality of life (HR-QoL) (Short Form 36 HR-QoL questionnaire; Hays et al. 1993), psychological wellbeing (Warwick Edinburgh Mental Wellbeing Scale; Tennant et al. 2006) and perceived stress (Perceived Stress Scale; Cohen & Williamson, 1988). Data were analysed using an ANCOVA model (covariates; sex, age, outcome baseline value and hours fasted [blood variables only]). Using magnitude-based inferences, we calculated the probability of intervention effects as beneficial, trivial, and harmful against a threshold of the minimum clinically important difference of 1mL·kg-1·min-1 for VO2max and 0.2 between-subject SDs for all other outcomes. Effects were only declared clear when the probability likelihood for the effect was ≥75% (i.e. likely). Data are presented as mean ±90% confidence limits.
RESULTS: Mean HIT session attendance was 83%. Post-intervention there was a likely beneficial increase in VO2max (3.9 mL·kg-1·min-1 ±3.4 mL·kg-1·min-1) in intervention participants compared to controls. For domains of HR-QoL, there was a likely beneficial effect on energy/ fatigue (8.5 arbitrary units [AU] ±5.8 AU) and general health (4.6 AU ±4.1 AU), and a likely negative impact on bodily pain (-7.9 AU, ±10 AU). There was a likely beneficial decrease in perceived stress (-2.5 AU ±2.5 AU). There were no clear changes in any other outcomes post-intervention.
CONCLUSION: This is the first trial to show that novel workplace-based HIT has clinically relevant beneficial effects on VO2max, and positively impacts on domains of HR-QoL and perceived stress. An increase in bodily pain may be due to muscle soreness from the HIT intervention. Improvements in markers of employee wellbeing may be particularly meaningful to organisations planning to implement similar programmes in the future.

ADHERENCE TO PHYSICAL EXERCISE TREATMENT BY PATIENTS WITH, OR AT RISK OF, TYPE 2 DIABETES MELLITUS: A SYSTEMATIC REVIEW AND META-ANALYSIS

JABARDO, G.1,3, DONAT-ROCA, R.1, MILÀ-VILLARROEL, R.2, SITJÀ-RABERT, M.2, BORT-ROIG, J.1,3

1: UNIVERSITY OF VIC-CENTRAL UNIVERSITY OF CATALONIA, 2: RAMON LLULL UNIVERSITY

INTRODUCTION: Evidence has demonstrated that physical exercise interventions improve health-related outcomes and the quality of life of patients with type 2 diabetes mellitus. However, although both moderate- and high-intensity exercise have been demonstrated useful to control the pathology (1), less is known about patient's participation and adherence to the programme. Related to this, high-intensity has been grown popularity in the last years as a time-efficient protocol to avoid the lack of time barrier and improve exercise adherence. Therefore, the aim of this study is to examine the extent to which exercise interventions impact dropout risk in patients with, or at risk of, type 2 diabetes mellitus.
METHODS: A systematic review and meta-analysis of adherence to aerobic exercise training interventions of varying intensity was conducted according to the PRISMA guidelines. Randomised controlled trials were searched in MEDLINE, PEDro and WOK, up to December 2017. Studies with exercise interventions on patients with, or at risk of, type 2 diabetes were included. The intervention had to last a minimum of three months, and the studies had to include at least two groups, one with moderate and other with high-intensity exercise.
RESULTS: Twenty-one studies were selected for both systematic revision and meta-analysis. Overall, exercise protocols demonstrated a higher dropout risk than other treatment approaches in this population group (OR 2,08[CI95% 1,49-2,91] p=0,0001). No difference in exercise adherence between intensities groups have been detected (OR 1,13[CI95% 0,85-1,50] p=0,41). In contrast, high-intensity protocols seem to have a higher dropout risk than moderate intensity when both are conducted over a similar time period (OR 1,81[CI95% 1,13-2,90] p=0,01). A significant risk of bias has been observed due to only one study reported the minimum amount of adherence required of participants.
CONCLUSION: Although exercise programmes are effective at improving health-related outcomes among patients with, or at risk of, type 2 diabetes mellitus, exercise protocols demonstrated a higher dropout risk than other treatment approaches in this population group. Moreover, it seems that high-intensity protocols did not improve adherence despite requiring less time. Thus, lower intensity interventions may enhance patients' adherence more than intense programmes. Further research is needed to explore barriers and enablers to better understand patients' participation.

OP-PM05 Lifestyle: Ageing

BODY AGE ASSESSMENT – MOTIVATION FOR HEALTHIER LIFESTYLE IN 3844 DANISH EMPLOYEES

HUSTED, K., DANDANELL, S., PETERSEN, J., HELGE, J.W.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: A paradox exists between the perception of workplaces being the ideal setting for health promotion, and the relative moderate effect seen on workplace health interventions so far. As the aging population expands and unhealthy lifestyle continues to progress, it is highly relevant to investigate how to motivate to healthier lifestyle by adequate interventions. Body Age is a composite score (in years) based on risk factors related to metabolic syndrome, physical inactivity and smoking habits.
The objective of this study is to investigate whether getting the results of a health tests incorporating Body Age influences lifestyle. We hypothesized that Body Age health test motivates to a healthier lifestyle.
METHODS: This cohort study involve 3844 Danish employees from different private and public companies. The Body Age health test protocol consisted of: blood pressure, lipid profile and glucose measurements using standard bedside equipment, waist circumference (WC) and height were measured and weight, body mass index (BMI), fat free mass (FFM), fat mass (FM) and fat percentage (fat%) using bio impedance. The protocol also included assessment of activity level: fitness level measured by submaximal cycle test, push- ups, handgrip strength, wall sit and sit and reach test. Finally, smoking habits were clarified. As test result, participants got their Body Age and advice on how to improve if necessary. Data consist of baseline and follow up test results. We used two-sided paired t-test for continuous observations and chi-square test for categorical observations and the level of significance was set at 0.05.
RESULTS: At baseline 59% had BMI 18.5-25, 34% had BMI >= 25 and 7% had BMI >= 30 with corresponding Body Ages diverting with -2.5 (±3.6), 1.1 (±4.1) and 6.5 (±4.3) years, respectively from mean chronological age. On average time to follow up were 1.5 years (3 month-5.6 years) and 1.6 years (3 month- 5.5 years) for women and men, respectively. At baseline 6.5% of women and 6.3% of men smoked, compared to 4.2% and 4.2%, respectively at follow up. Overall fitness level improved for women (0.5 ml/min/kg; p= 0.003) together with WC (-0.8cm; p<0.0001) and blood glucose levels (-0.04mmol/l; p= 0.008). For men an overall improvement was seen in total cholesterol (-0.04 mmol/l; p=0 .007), blood glucose (-0.036 mmol/l; p= 0.01) and WC (-0.5 cm; p<0.0001). Both men and women lost weight (-0.5 kg p=<0.0001 and -0.3 kg p=<0.0001), and improvements in wall sit and sit and reach test were observed at follow up.
CONCLUSION: This study demonstrates that risk factors related to unhealthy lifestyle improves after Body Age assessment. These improvements are likely mediated by a positive change in physical activity level and/or weight loss. Interestingly, being older than your birth certificate states seems to have impact on smoking habits as well.

SIT-TO-STAND MUSCLE POWER TEST IS A SENSITIVE AND CLINICALLY RELEVANT TOOL TO MONITOR CHANGES IN LOWER-LIMB MUSCLE POWER THROUGHOUT THE LIFESPAN

ALCAZAR, J.1, AAGAARD, P.2, HADDOCK, B.3, ARA, I.1, ALEGRE, L.M.1, PRESCOTT, E.4, HOVIND, P.2,4, SUETTA, C.4,5

1: UNIV. OF CASTILLA-LA MANCHA, SPAIN; 2: UNIV. OF SOUTHERN DENMARK, DENMARK ; 3: RIGSHOSPITALET-GLOSTRUP, DK; 4: BISPEBJERG-FREDERIKSBERG UNIV. HOSPITAL, DK; 5: HERLEV-GENTOFTE UNIV. HOSPITAL, DK

INTRODUCTION: Muscle power is a stronger predictor of mobility limitations among aged individuals compared to muscle endurance or muscle strength, yet muscle power is rarely assessed in the clinical setting. Further, the temporal change in maximal muscle power with increasing age has not been fully elucidated. The aims of this study were: 1) to assess the validity and relevance of an easy-to-implement functional muscle power test in older adults; and 2) to evaluate the time course of changes in muscle power throughout the adult lifespan.
METHODS: A total of 1305 subjects (729 women, 576 men; 20-93 years) were evaluated for body mass and height, handgrip strength, maximal gait speed (10 m), leg lean mass (iDXA) and lower-limb muscle power. Absolute, relative (normalized to body mass) and specific (normalized to leg lean mass) sit-to-stand (STS) muscle power were assessed by using the subjects' body mass and height, the chair height and the number of repetitions completed in the 30-s STS test, and compared with leg extensor power (LEP) assessed by Nottingham power rig testing.
RESULTS: STS power and LEP did not differ among older adults (≥60 y; N=628) (186±81 vs 185±89 W) and were strongly correlated (r=0.75; p<0.001). Maximal gait speed was more strongly related to relative STS power than handgrip strength or relative LEP (r=0.53 vs. 0.35-0.45; p<0.05). Relative STS power peaked between 20 and 30 years of age in both women (0.08±0.05 W·kg-1·y-1; p=0.08) and men (0.14±0.07 W·kg-1·y-1; p<0.05), while declining during the fourth and fifth decades of life in both sexes (–0.05±0.05 and –0.06±0.08 W·kg-1·y-1, respectively; p>0.05). After the fifth decade, relative STS power declined at an accelerated rate in men (–0.09±0.02 W·kg-1·y-1) and women (–0.09±0.01 W·kg-1·y-1) (p<0.001), with an attenuated decline rate in women aged •75 (–0.04±0.02 W·kg-1·y-1; p<0.05). Age-related changes in relative LEP followed an identical pattern. Up to the age of 65 in men and 75 in women the decline in absolute STS power was solely due to a decline in specific STS power, while changes at older age were caused by concurrent decrements in both specific STS power and leg lean mass.
CONCLUSION: The STS muscle power test appears to provide a valid, feasible, clinically relevant and inexpensive tool to monitor changes in lower-limb muscle power throughout the adult lifespan. Reduced skeletal muscle mass profoundly affects the loss in STS muscle power from the age of 65 in men and 75 in women.

THE EFFECTS OF A 12-MONTH STRUCTURED EXERCISE PROGRAMME ON THE PROGRESSION OF MILD COGNITIVE IMPAIRMENT

STUCKENSCHNEIDER, T.1,2, ASKEW, C.2, ABELN, V.1, SCHNEIDER, S.1,2

1> GERMAN SPORT UNIVERSITY; 2> UNIVERSITY OF THE SUNSHINE COAST

INTRODUCTION: A lack of physical exercise plays a major role in the pathophysiology of vascular, metabolic, and metastatic diseases and is a major risk factor for the development of cognitive decline during ageing. Initial research indicates enhanced cognitive performance following exercise training in people with mild cognitive impairment (MCI), which is defined as the preclinical stage of Alzheimer's disease. Evidence to date has been limited by short intervention periods, the lack of standardized neuropsychological testing and the use

of only one exercise mode (e.g. aerobic exercise). So far, no standardized treatment for people with MCI exists and it is not known whether other intensities are also of benefit. The multi-centered NeuroExercise study [1] aimed to compare the effects of aerobic exercise with a stretching and toning program on cognitive performance.
METHODS: 75 (mean age: 74 ± 4) participants with diagnosed MCI were recruited in Germany and randomized to one of two intervention groups (IG; consisting of aerobic exercise or a stretching and toning program), or a control group (CG). The interventions consisted of 3 supervised sessions per week for 12 months. Quality of life, exercise capacity, and cognitive performance were determined before and after the 12 months intervention and were compared between groups and across time using repeated measures ANOVA.
RESULTS: Data analysis showed differences between the intervention group and the control group, but not between the two intervention groups. When the intervention groups were considered together an effect of session frequency was found. Participants, who participated • 2 times/week showed an increased exercise capacity ($p < 0.001$), an increased cognitive performance ($p < 0.001$), and an increased quality of life ($p < 0.001$). Participants, who participated in an average only one session per week showed no changes in exercise capacity ($p = 0.715$) or in cognitive performance ($p = 0.812$), but there was an increase in quality of life ($p = 0.017$). The control group with no exercise showed a decrease in exercise capacity ($p = 0.001$), but no other significant changes.
CONCLUSION: Participants with MCI improved their quality of life and cognitive performance, regardless of the intensity of the exercise program. The results show that regular physical exercise, i.e. two exercise classes per week are sufficient to counteract further progression of MCI. Given the increasing number of older adults with cognitive impairment, successful strategies for the promotion of physical exercise are needed.

THE TIME COURSE OF PHYSIOLOGICAL ADAPTIONS TO HIGH INTENSITY INTERVAL TRAINING IN HEALTHY OLDER ADULTS.

HERROD, P.J.J., BLACKWELL, J.E.M., BOEREBOOM, C.L., WILLIAMS, J.P., LUND, J.N., PHILLIPS, B.E.
UNIVERSITY OF NOTTINGHAM

INTRODUCTION: High intensity interval training (HIIT) has been shown to be more effective than moderate continuous aerobic exercise for improving cardiorespiratory fitness (CRF) in a limited timeframe. HIIT may therefore be suited for use as exercise prehabilitation before major surgery, however, the length of time required for HIIT to produce a clinically significant improvement in CRF is not known. This study aimed to evaluate the changes in CRF of older adults completing HIIT protocols of different durations.
METHODS: Healthy, recreationally active older adults aged 65-85 years were invited to participate. Participants completed a ramped incremental cardiopulmonary exercise test (CPET) on a cycle ergometer, before and after 2, 4 or 6 weeks of fully supervised HIIT on a cycle ergometer. A final group acted as a no intervention control. All data are displayed as mean(SD) with analysis via 2-way ANOVA.
RESULTS: Forty participants aged 71(5) years (21 males) were recruited. Peak power at termination of CPET, a measure of physical function, was increased after 2-weeks (+15(15)W), 4-weeks (+17(11)W) and 6-weeks (+16(11)W) of HIIT (all $p<0.001$), with no significant difference between groups. However, anaerobic threshold was increased only after 4 weeks (+1.9(1.1)ml/Kg/min; $p=<0.001$) and 6-weeks (+1.9(1.8)ml/Kg/min; $p=<0.001$) of HIIT (2-weeks: +1(1.1)ml/kg/min; $p=0.08$). Six weeks of training was required to elicit significant improvements in VO2 peak (+3.0(6)ml/Kg/min; $p=0.04$), with no significant changes after 2 (+1.7(2.4)ml/Kg/min; $p=0.43$) or 4-weeks (+2(2.5)ml/kg/min; $p=0.3$). There were no significant changes in any parameter in the control group.
CONCLUSION: Improvements in exercise performance after HIIT appear to precede changes in CRF. Just 4-weeks of training was required to produce significant and clinically relevant changes in anaerobic threshold, fitting within the 31-day time to first treatment cancer target in the UK. A further 2 weeks of training improves the volitional VO2 peak but it is not known whether this confers additional benefit over improvements in AT and is likely not a sufficient reason to delay clinical pathways.

HEALTHEBIKES: INDIVIDUAL E-BIKE POWER REGULATION APPLIED IN HEART PATIENTS AND HEALTHY TRAINED STUDENTS

SCHÜTZENHÖFER, M., BIRNBAUMER, P.H., FALGENHAUER, M., MODRE-OSPRIAN, R., TRANINGER, H., HOFMANN, P.
UNIVERSITY OF GRAZ

INTRODUCTION: To improve the sustainability of therapies, the use of a power-controlled HEALTHeBIKES prototype was investigated. As a hypothesis, it was assumed that a special developed control system of the HEALTHeBIKE enables an individual outdoor group training at the same individual strain regardless of the route and speed.
METHODS: 10 trained students (S) and 10 patients (P) from a cardiovascular outpatient rehabilitation participated in this study. All subjects in groups of 2-3 persons completed a flat two times (17.4 km, 25 m alt.) and a hilly (24.4 km, 230 m alt.) track one time. A safe target power of 105% of the power at PLTP1 from a spiro-ergometry (S) and 40 % of Pmax (P) was specified. Before, during and after each trip blood samples (20 µl) were taken from the earlobe for lactate determination. The target speed was set at 20-23 km/h.
RESULTS: 10 students (5 women:26.3 ± 4.4 yrs; BMI: 23.46 ± 2.02 kg/m2; Pmax: 261.8 ± 54.7 W; HRmax: 187.6 ± 9.1 bpm) and 10 patients (5 women: 65.2 ± 8.3 yrs; BMI: 29.2 ± 4.58 kg/m2; Pmax: 175 ± 64.7 W; HRmax: 142.4 ± 11.6 bpm) completed the tracks with a target power (Ptarget) of 102.2 ± 22.7 W (S) and 70.26 ± 26.1 W (P) corresponding to 66.7 % (S) and 70.0 % (P) of HRmax. For a total of 59.1 km at 21.7 ± 0.7 km/h (S) and 20.02 ± 0.74 km/h (P) a HRmean of 103.7 ± 14.6 bpm (S) and 92.0 ± 9.2 bpm (P) with a pedal power (Pcrank) of 108.6 ± 22.5 W (S) and 99.1 ± 23.5 W (P) were measured. Lamean at all tracks was 1.26 ± 0.19 mmol/L (S) and 2.18 ± 0.49 mmol/L (P). Ptarget and Pcrank were significantly correlated ($r = 0.904$, $p <0.0001$) in S but the correlation was low ($r = 0.166$, $p <0.0001$) in P which was caused by an unrhythmical driving style.
CONCLUSION: HEALTHeBIKES enables safe training of performance-heterogeneous groups with uniform speed in both flat and hilly terrain, while respecting individual performance limits. All subjects were in a safe range of their individual target heart rate. Because of the special developed control system, riding the HEALTHeBIKE requires specific instructions and training. Furthermore, the control system needs adaptions for low performing subjects and unrhythmical driving.

THE PHYSIOLOGICAL AND MECHANISTIC EFFECTS OF CHEMICAL ENDOGENOUS TESTOSTERONE DEPLETION DURING RESISTANCE EXERCISE TRAINING IN YOUNGER MEN: A DOUBLE-BLIND PLACEBO-CONTROLLED CLINICAL TRIAL

GHARAHDAGHI, N., RUDRAPPA, S., PHILLIPS, B.E., FARRASH, W., AZIZ, H., IDRIS, I., BROOK, M.S., WILKINSON, D.J., SZEWCZYK, N.J., SMITH, K., ATHERTON, P.J.

UNIVERSITY OF NOTTINGHAM

INTRODUCTION: The role of endogenous testosterone (T) in mediating hypertrophic responses to resistance exercise training (RET) remains contentious with correlative studies suggesting a limited role [1], and others a more central role [2]. We thus investigated the mechanistic effects of chemical endogenous T depletion adjuvant to 6-wk of RET on muscle mass, function, myogenic regulatory factors and muscle anabolic signalling in younger men.
METHODS: Sixteen non-hypogonadal healthy young men (18-30y, BMI≤30kg.m-2, serum T>230 ng·dl-1) were randomised in a double-blinded fashion to receive either: placebo (P, saline n=8) or the GnRH analogue, Goserelin (Zoladex (Z) (3.6-mg, n=8)) injections before undertaking 6-wks of whole-body RET (6-muscle groups, 3-sets, 8-10 reps at 80% 1-RM). Participants underwent Dual-energy X-ray Absorptiometry (DXA), ultrasound of m.vastus lateralis (VL), knee-extensor Maximal Voluntary Contraction (MVC) and Oral Glucose Tolerance Testing (OGTT); finally, m.vastus biopsies were taken to quantify myogenic gene expression and anabolic pathways.
RESULTS: Provision of Z during RET suppressed endogenous T (Z: 273±14 to 58.7±21 ng·dl-1 P=0.005 vs. P: 240±19 to 277±30 ng·dl-1, P=0.6). The Z group exhibited blunted whole-body (Z: 55±3 to 56±3kg, P=0.6 vs. P: 56±2 to 58±2kg, P=0.006), appendicular (Z: 8.2±0.3 to 8.4±0.4kg·m-2, P>0.9 vs. P: 7.6±0.3 to 8.3±0.3kg·m-2, P=0.07), and VL (Z: 1±0.04-fold, P>0.99 vs. P: 1.06±0.03-fold, P<0.0001) lean mass gains, and composite strength gains (Z: +40±2 vs. P: +50±3%, P=0.03). Reductions in body fat were only evident in the P group (Z: 23±2 to 24±2%, P=0.2 vs. P: 24±3 to 23±3%, P=0.04). The P group exhibited augmented gene expression related to T metabolism (e.g. Androgen Receptor: +1.8-fold; HSD17B3: +2.8-fold, P<0.05); anabolism/myogenesis (e.g. IGF-1EA (+3.3-fold), IGF-1EC (+4.6-fold), Myogenin (+2.6-fold), Myf5 (+2.6-fold), c-Met (+2.7-fold), P<0.05) in addition to RNA/DNA (P: 0.5±0.1 to 0.6±0.1, P=0.0003 vs. Z: 0.5±0.1 to 0.5±0.1, P=0.3), and RNA/ASP ratio (P: 6.5±0.2 to 8.9±1.1, P=0.008 vs. Z: 5.8±0.4 to 6.8±0.5, P>0.9). Also, acute RET-induced phosphorylation of AKTser473 (Z: +4.9±1.6-fold, P=0.7 vs. P: +10.1±5.3-fold, P=0.003) and mTORC1ser2448 (Z: +2.5±1.3-fold, P>0.9 vs. P: +4.8±2.1-fold, P=0.03) were attenuated in the Z group. Finally, only the P group enhanced insulin sensitivity (Cederholm: Z: +2.1±0.4 vs. P: +14.5±4.9 mg·L2·mmol·L−1·mU−1·min−1, P=0.04)
CONCLUSION: Chemical T depletion during RET blunted muscle insulin/anabolic signalling, T processing enzyme and pro-myogenic gene expression, perhaps explaining attenuated muscle growth and insulin sensitivity in this group. Thus, decreasing endogenous levels of T coupled to RET attenuates numerous positive adaptations to RET - thereby, demonstrating the, at least, permissive importance of endogenous T in regulating muscle hypertrophy.

EFFECTS OF A TIME-MATCHED ENDURANCE AND CONCURRENT TRAINING ON CIRCULATING SEX HORMONES AND BODY COMPOSITION IN OBESE POSTMENOPAUSAL WOMEN

GONZALO-ENCABO, P., DE COS, A.I., CALVO VIÑUELAS, I., SANTACRUZ LOZANO, J.A., GARCÍA-HONDUVILLA, N., VALADÉS, D., PÉREZ-LÓPEZ, A.

UNIVERSITY OF ALCALA

INTRODUCTION: A dysregulated sex hormones production has been identified as a signal of obesity-driven cancer in postmenopausal women. Endurance training has been revealed as an effective strategy to reduce circulating estrogens and androgens in this population, however, there is no clear evidence regarding the effects of other types of exercise. Moreover, it remains to be elucidated if after menopause the role of exercise on sex hormones regulation is mediated by a fat mass loss or is caused by exercise practice per se. Thus, the aim of this study was to evaluate the effects of a time-matched endurance vs concurrent training on circulating sex hormones levels in postmenopausal women.
METHODS: Thirty-nine sedentary and obese postmenopausal women were recruited and randomly divided into an endurance training (EN, n=10), concurrent training (CON, n=13) or a control group (CT, n=12). Participants took part in a 12-weeks supervised intervention training 3 days/week and 60 min/session of endurance (EN) or endurance plus resistance exercise (CON). EN was performed at 70-75%HRR, while CON was composed of 40 min of resistance training performed in a circuit involving major muscle groups (6 exercises, 3 sets, 8-12 repetitions at 65% 1RM), followed by a 20min endurance training (at 70-75%HRR). Body composition was assessed, and blood samples were obtained before and after the 12-weeks intervention. Circulating sex hormones: estradiol and SHBG were analyzed using radioimmunoassay, testosterone and DHEA levels were measured by chemiluminescent immunoassay.
RESULTS: A significant decrease in total fat mass was observed in EN (-2 kg) and CON (-2kg) but not in the CT group (ANOVA interaction, P=0.036), while a significant increase in muscle mass was found in the CON group (0.7 kg, P=0.018). In the CON group, total (25%) and free testosterone (21%) were increased (P<0.05), while in EN group were decreased (-40% and -41%, respectively) (ANOVA interaction, P<0.01). Moreover, DHEA was diminished in response to endurance training (-13%, P<0.01). In contrast, no significant changes were found for total and free estradiol or SHBG, however, when the training groups were stratified according to fat mass loss (>2kg), SHBG was increased by 21% (ANOVA interaction, P=0.039).
CONCLUSION: Despite the differences in body composition remodeling observed after 12 weeks of endurance or concurrent training, circulating levels of estrogens remained unaltered while androgens showed an opposed response according to the exercise type. Furthermore, those participants who lost more fat mass (>2 kg) showed a significantly reduced expression of circulating SHBG. Since sex hormones have been extensively related to breast cancer pathophysiology, exercise-induced fat loss and the type of exercise should be considered to regulate estrogens and androgens metabolism, respectively, in postmenopausal women.

ANGIOTENSIN CIRCULATING LEVELS AFTER MAXIMAL EXERCISE IN ELITE CYCLISTS

MOTTA-SANTOS, D.1,3,4, GONÇALVES, R.1,4, PRADO, L.1,4, GERALDI, C.1, PAPOTTI, M.2, SZMUCHROWSKI, L.1,4, SANTOS, R.3

1.UFMG, BELO HORIZONTE, MG, BRAZIL; 2. USP, SÃO PAULO, SP, BRAZIL 3. INCT NANOBIOFAR, BELO HORIZONTE, MG, BRAZIL; 4. SPORTS TRAINING CENTER, CTE, BELO HORIZONTE, MG, BRAZIL

INTRODUCTION: Cardiac and metabolic diseases as well as high volumes of training may alter the regulation of the renin angiotensin system (RAS). The renin-angiotensin system is a key regulator of many metabolic aspects including physical performance. It is unknown the angiotensin peptides response in athletes, especially immediately after a maximal exercise test. We aimed to investigate the levels of angiotensin peptides in elite cyclists after a maximal incremental test.
METHODS: Our study included 08 professional cyclists (23.14 +- 5.55 years, 67 +- 6.23 kg) who performed a maximal incremental test (MIT) in CompuTrainer. Blood was collected using specific inhibitors cocktail (Alamantec®) at baseline and immediately after MIT for angiotensin peptides analysis (Mass Spec, Xevo TQ-S, Waters®).
RESULTS: The estimated VO2 max was 72.13 +- 5.15 ml.kg.min-1, maximal power 384.38 +- 26.52 watts and the relative power was 5.76 +-0.41 watts/kg. The MIT affects the levels of Ang I (baseline: 375.8 +- 51.23 and after MIT: 833.2 +-101.8 pg/mL, p=0.0001) and Ang II (baseline: 6.52 +- 0.54 and after MIT: 17,21 +-1.98 pg/mL, p=0.0001). No significant differences were noted for Ang-(1-7) and Alamadine after MIT.
CONCLUSION: During intense exercise and MIT the activation of the sympathetic nervous system increasing heart rate and blood pressure are essential for maintaining cardiac output. Angiotensin II, formed from Angiotensin I is an important vasoconstrictor of the RAS system and as expected, these peptides were significantly increased after MIT. However, the levels of the systems counter-regulatory peptides, Angiotensin-(1-7) and Alamandine did not change after maximum effort indicating a shift to the vasoconstrictor axis after a maximal effort . Additional studies in non-athletes are necessary to further determine the effects of training in the angiotensin responses after a maximal effort.

EFFECTS OF STRENGTH TRAINING ON BODY COMPOSITION, BIOCHEMICAL PARAMETERS AND PHYSICAL PERFORMANCE IN HYPOGONADAL PATIENTS

KRALIK, M.1, CVECKA, J.1, PUTALA, M.1, BUZGO, G.1, TIRPAKOVA, V.2, BUJDAK, P.2, KOLLARIK, B.3, UKROPCOVA, B., UKROPEC, J.4, PAYER, J.5, KILLINGER, Z.5, RAASTAD, T.6, SEDLIAK, M.1

1: FSPORT CU , 2: SMU , 3: SCMUH , 4: BMC SAS , 5: FMED CU , 6: NIH

INTRODUCTION: Male hypogonadism is a clinical syndrome that results from failure of the testis to produce physiological levels of testosterone (TST)(1). Symptoms include decline in lean mass, muscle strength, increased adiposity. Low TST is highly related to insulin resistance, visceral obesity and metabolic syndrome (2). There are very few studies dealing with effect of physical activity on hypogonadal males (3). The aim of the study was to examine the effect of 12-week strength training program on body composition, selected biochemical parameters and physical performance in hypogonadal males.
METHODS: The study compared the effect of strength training (ST) on hypogonadal patients (HP, n=8, 47.81±6.38 yrs, TST= 8.5±1.75 nmol/l) and control group of eugonadal males (EM, n=8, 49.31±5.84 yrs, TST= 15.81±3.99 nmol/l). The subjects performed ST twice a week, the training program consisted of 6 exercises at an intensity from 60-80% of 1RM. Body composition was measured by DXA, muscle strength was measured by predicted dynamic leg press 1RM from multiple repetition maximum, handgrip strength using hand dynamometer and cardio-respiratory fitness by The Single Stage Treadmill Walking Test. Fasting morning venous blood samples were collected. The parameters analysed from serum were glucose, total cholesterol, LDL cholesterol, HDL cholesterol, SHBG, insulin, homeostasis model assessment of insulin resistance (HOMA-IR), total testosterone, and cortisol.
RESULTS: Subjects from both the HP and EM groups significantly decreased fat mass, ($p>0.05$ and $p<0.01$, respectively). Muscle strength of lower extremities increased in both group ($p<0,01$). Only the EM group also improved predicted VO2max ($p<0.05$). When we used correlation from all test of subjects and TST, a negative correlation between TST and fat mass ($p<0.01$), TST and body mass ($p<0.01$) before and after intervention was found. We also found positive correlation between TST and lean mass ($p<0.05$) before and after the intervention in both groups. When effect size with Cohen D was calculated, we found that ST influenced glucose (d= -0.54) and LDL cholesterol (d= 0.56).
CONCLUSION: 12 weeks of strength training protocol caused, that all subjects significantly improved muscle strength and reduced body fat regardless of the testosterone levels. Even though the training sessions took on average 60 minutes twice per week, eugonadal males improved also their cardiovascular fitness. We could see fat mass and lean mass still correlated with TST. On biochemical level, we found ST had positive but not statistically significant impact on predictors of obesity, but studies with a longer period need to be done to confirm these findings.
The study was funded by the VEGA no. 1/0714/16. Trial registration: ClinicalTrials.gov: NCT03282682

EFFECTS OF OESTROGEN AND PROGESTERONE ON SUBSTRATE OXIDATION AND RESPIRATORY VARIABLES

BENÍTEZ, J.A., ALFARO-MAGALLANES, V.M., BARBA-MORENO, L., BENITO, P.J., CUPEIRO, R., ROMERO-PARRA, N., RAEL, B., PEINADO, A.B.

FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCE . UNIVERSIDAD POLITÉCNICA DE MADRID.

INTRODUCTION: Respiratory parameters seem to be influenced by oestrogen and progesterone.1,2 Because of that, it is possible to assume differences in carbohydrates (CHO) and fat oxidation during exercise if the hormonal levels change.1,2 However, unclear results are found in the literature.2 This probably occurs due to the different doses of exogenous and endogenous sex hormones used in the previous studies.1,2 Therefore, the purpose of this study was to explore the association between substrates oxidation and endogenous hormonal levels in female athletes.
METHODS: Fifteen eumenorrheic endurance-trained females (35.6±4.2 yrs; 58.1±5.2 kg; 163.9±5.9 cm; VO2max:50.3±3.6 ml·min-1·kg-1) performed three continuous running sessions of 40 min at 75% of the VO2max velocity throughout early follicular phase (EFP), mid-follicular phase (MFP) and luteal phase (LP). Respiratory variables were measured breath by breath during the exercise protocol in each phase. Blood samples were taken pre-exercise in the three phases in order to obtain baseline hormonal levels. Pearson´s correlation

was used to study the association between oestrogen and progesterone levels with respiratory parameters (oxygen uptake: VO2; ventilation: VE; and respiratory exchange ratio: RER) and CHO and fat oxidation.
RESULTS: Pearson´s correlation showed no association between oestrogen and respiratory variables or substrate oxidation (p>0.005). Progesterone also presented no association with respiratory variables (p>0.05). Conversely, attending to substrate oxidation, progesterone and fat oxidation were positively correlated (p=0.001; r=0.46). On the contrary, progesterone and CHO oxidation showed a negative and low correlation (p=0.011; r=-0.377)
CONCLUSION: Hormonal levels do not seem to influence respiratory parameters. However, we have observed a positive and moderate correlation between progesterone and fat oxidation and a negative but low correlation between this hormone and CHO oxidation. These results suggest that high levels of progesterone could enhance lipolysis increasing fatty acid oxidation and CHO sparing in the muscles .2 Some studies show an influence of oestrogen on fat oxidation,2 however we did not find this association since in this study oestrogen was measured in the MFP instead of late follicular phase when the highest levels of oestrogen are found. The fact that women depends on fat oxidation more than men1 could be explained in part by the association of progesterone and fat oxidation.

ACUTE HORMONAL RESPONSES TO AN INTENSE RESISTANCE EXERCISE PROTOCOL IN UNTRAINED MEN AND WOMEN

MARESH, C.
THE OHIO STATE UNIVERSITY

INTRODUCTION: Testosterone (TEST) and cortisol (CORT) represent important anabolic and catabolic signals, respectively, and are involved with exercise-induced adaptations in skeletal muscle and other tissues (1). Importantly, glucose (GLU) and insulin (INS) contribute to meeting the metabolic demands of exercise (2). The primary aim of this study was to better understand the acute response patterns of these humoral factors to an intense resistance exercise protocol, conducted at the beginning of a training program, and to determine any sexual-dimorphism in response to this profound exercise challenge.
METHODS: Healthy untrained men (n=14, 22.9 ± 3.6 yrs, 181.2 ± 3.4 cm, 81.9 ± 4.5 kg) and women (n=14, 22.9 ± 3.8 yrs, 166.9 ±4.2 cm, 65.1 ± 3.9 kg) completed 6 sets of 10 repetitions back squat at 80% of their one-repetition maximum (1RM) with 2 minutes rest between sets. Blood was collected pre-exercise (Pre), at immediate post- (IP), and at 15, 30, and 60 min post-exercise. Descriptive analyses were examined, and repeated measures ANOVA were used to analyze differences between males and females across all time points. Significance was set at $p<0.05$.
RESULTS: The men produced substantially greater total work, than the women, during the exercise protocol (p=0.00). There was no difference (p>0.05) in Pre lactate values between men and women, but values were higher in men than women at IP (12.8 vs 7.4 mmol/L, p = 0.000), 15 (8.5 vs 4.2 mmol/L, p = 0.000), 30 (5.4 vs 2.7 mmol/L, p = 0.000), and 60 (2.5 vs 1.8 mmol/L, p = 0.028) min. TEST values were higher in men than women at all time points ($p < 0.05$). There were no gender x time interactions for INS, CORT, and GLU ($p > 0.05$), but there were gender specific time effects ($p < 0.05$). TEST increased from Pre (29.8 mmol/L) to IP in men (35.5 mmol/L, p = 0.001) with no changes from IP to 15 min (35.3 mmol/L, $p > 0.05$), decreased from 15 to 30 min (31.3 mmol/L, p = 0.028), with no change from 30 to 60 min (27.1 mmol/L, $p > 0.05$). In contrast, there were no differences in TEST in women across time (mean = 5.3 ± 1.8 mmol/L, $p > 0.05$). INS increased from Pre to 60 min for both genders. Compared to Pre values, CORT remained elevated in both men and women at IP, (p=0.00), 15 (p=0.021), 30 (p=0.00), and 60 min (p=0.00) post-exercise. GLU increased from pre-exercise to IP (p=0.00) in both genders, remained unchanged at 15 min (p=0.10) and 30 min (p=0.10), and decreased (p=0.00) from 30 min to 60 min post-exercise.
CONCLUSION: The higher lactate levels in men largely reflect their greater total work capacity. Indicative of sexual dimorphism, our data showed greater levels of TEST in untrained men than women in response to the intense resistance exercise protocol. Otherwise, the men and women had similar INS, CORT and GLU responses.

OP-BN02 Balance and stability

TASK-SPECIFIC ADAPTABILITY BUT DIMINISHED RETENTION OF FALL-RESISTING SKILLS IN OLD AGE

KÖNIG, M., EPRO, G., WERTH, J., SEELEY, J., POTTHAST, W., KARAMANIDIS, K.
LONDON SOUTH BANK UNIVERSITY

INTRODUCTION: Effective and safe human bipedal locomotion requires continuous corrective motor actions in response to a constantly varying mechanical environment. Given the reduced ability to cope with sudden disturbances to gait with increasing age (1), we asked whether, similar to findings from visuomotor learning (2), age also affects other aspects of locomotor plasticity (i.e. short- and long-term adaptation and transfer of adaptation). We therefore used a gait perturbation paradigm in young, middle- and older-aged adults to investigate acute adaptations to gait, the retention of these adaptations over prolonged time periods and their transfer to untrained motor tasks.
METHODS: 26 young, 27 middle- and 22 older-aged adults (24±4, 52±5 and 72±5 yrs respectively) were recruited either to a perturbation training group (eight separate unexpected trip-like perturbations during treadmill walking; N=35) or a control group (unperturbed walking only; N=40). Gait perturbations resulted from a resistance unexpectedly applied to the swing phase of the right leg via an ankle strap connected to a custom-built brake-and-release system. Before and after treadmill walking all participants were exposed to a sudden loss of balance from a forward-leaning position (transfer task). For both tasks and for retention-test walking after 14 weeks, movement kinematics were tracked by a motion capture system (120 Hz; Vicon Motion Systems, UK) and the anteroposterior margin of stability (MoS)

was calculated as the difference between the anterior boundary of the base of support and the extrapolated centre of mass at foot touchdown (TD) of the recovery steps (3).
RESULTS: Older adults showed reduced ability to cope with sudden balance perturbations compared to young and middle-aged adults (lower MoS at TD of the first recovery step during the initial trial for both tasks; P<0.05). After a single perturbation training session, all age groups rapidly improved their recovery response (increased MoS at TD of the first recovery step; P<0.001) to the trip-perturbation task and sudden forward fall, with the latter showing no differences between intervention and control groups. Furthermore, we found significant (P<0.01) retention of acquired reactive gait stability improvements after 14 weeks irrespective of age group, with a detectable decay over time (P<0.05) in older but not in young or middle-aged adults.
CONCLUSION: We conclude that the aged human neuro-motor system remains capable of rapid adaptation in its locomotor behaviour due to merely a single perturbation training session, allowing it to cope better with external perturbations, but shows a diminished ability to retain those gait adaptive changes over prolonged time. Further, we found evidence for task-specific locomotor plasticity, suggesting that transfer of acquired fall-resisting skills may not solely explain improvements in untrained motor tasks.

INCREASED KNEE VARUS ANGLE AS A RISK FACTOR FOR LATERAL ANKLE SPRAINS DURING SINGLE-LEG LANDINGS - 16-MONTH COHORT STUDY

MINETA, S.
WASEDA UNIVERSITY

INTRODUCTION: New knowledge on preventing lateral ankle sprains (LAS) is needed as incidences of LAS has remained unchanged over the past 30 years. LAS occurs rapidly after initial contact during high-intensity motions, such as single-leg landings and cutting maneuvers. However, previous studies revealing risk factors were only measured during low intensity and continuous motions, such as single-leg balance tasks. In other words, risk factors were only determined during motions that rarely cause LAS. To determine the injury mechanism for effective prevention, risk factors associated with high-risk motions, such as single-leg landings, must be measured. Therefore, we conducted a prospective cohort study to reveal the motion characteristics that increase LAS risk.
METHODS: We performed a 16-month prospective cohort study and recruited 216 college athletes. Joint movement and moment were measured during a single-leg landing task (SLL). Subjects with LAS during the SLL were categorized as the injured group (IG) and those without LAS as the non-injured group (NG) after a follow-up period. Those with LAS due to other mechanisms were excluded from analyses. First, we performed Shapiro-Wilk tests and then assessed group differences between the IG and NG group with Mann-Whitney U tests and Student's t-tests. Next, we extracted risk factors for LAS using Cox regression analyses. In this process, we used only variables that had significant differences between IG and NG groups as independent variables. Additionally, we assessed the relationship between the extracted risk factors and ankle inversion angle using Pearson correlation coefficients and relationships between extracted risk factors and other joint kinematics using multiple regression analyses.
RESULTS: Fifteen participants sustained LAS injury during the follow-up period. An increasing knee varus angle at 100 ms after initial contact was a risk factor for LAS (Hazard ratio: 1.196; 95% confidence interval: 1.103-1.297; $P < 0.001$). Additionally, a positive correlation was found between the knee varus angle and ankle inversion angle ($r = 0.42$-0.44, $P<0.001$), and an increasing hip internal rotation angle was related to an increasing knee valgus angle (standardized $\beta = 0.705$, standardized $R2 = 0.494$, $P<0.001$).
CONCLUSION: Normally, an increasing hip internal rotation angle is related to an increasing knee valgus angle; however, past research has shown that increased hip internal rotation angles with contralateral pelvic rotation towards the support leg is related to increased knee varus angles. Additionally, contralateral pelvic rotation can lead the trunk outside the base of support, with this posture more vulnerable and increasing the ankle inversion angle. Hence, those who have an increased knee varus angle after landing may be categorized as having a high risk of LAS.

THE PROFILE AND DEVELOPMENT OF THE TIBIOFEMORAL ANGLE IN SETSWANA CHILDREN BETWEEN THE AGES OF 2 TO 9 YEARS.

VAN ASWEGEN, M., CZYZ, S.H., MOSS, S.J.
NORTH WEST UNIVERSITY

INTRODUCTION: The act of mothers back-carrying their children, often deep into toddlerhood, is a normal and widely accepted cultural behaviour of Setswanas (1). Back-carrying has a positive impact on hip development as it prevents developmental hip dysplasia (DDH) (2), but it is unknown whether back-carrying will impact knee development. Profile data on the normal development of the tibiofemoral joint in black Setswana, South African children is lacking. This study aimed to provide profiles and the development of the tibiofemoral angle (TFA), hip anteversion or -retroversion and tibial torsion.
METHODS: Measurements were obtained clinically, with a goniometer or tape measure, from 691 healthy 2 to 9-year-old Setswana children. Frontal plane assessments included the TFA and intercondylar distance (ICD) for genu varum or intermalleolar distance (IMD) for genu valgum. The ICD or IMD was measured in standing, as the distance between the femoral condyles or medial malleoli, respectively. The TFA and Quadriceps angle (Q-angle) were measured in standing. In the transverse plane, the prone Craig's test was used to determine hip anteversion or –retroversion, and tibial torsion was measured in prone, with the child's knee flexed to 90°.
RESULTS: Two year olds presented closest to genu varum at -3.4° (±3.4°). At three years a peak of -5.7° (±2.3°) genu valgum was seen, which then plateaued at -4.5° (±2.1°) at age 9 years. Significant differences in TFA were observed between 5-, 8- and 9-year-old males and females. In 6-year-old males and females statistically significant differences were measured for Q-angle (p=0.04) and hip anteversion (p=0.05) development. Very small Q-angles were observed in the 2-year-old group, (-3.81°±3.77°) which increased to a mean peak of -9.2° (±4.4°) in 9 year olds. Hip anteversion was the largest in 2 year olds at 75.8° (±18.9°), and decreased to a mean angle of 70.8° in 9 year olds.
CONCLUSION: The TFA of Setswana children developed similar to developments reported in European, Asian and Nigerian children. Anteversion angles were however greater in the Setswana population than angles reported in children of other ethnicities. The developmental profiles assist in identifying out of normal ranges in knee development of Setswana children to enable corrective interventions early in life.

ALTERATIONS OF MOVEMENT QUALITY JOINT LOADING AND MUSCLE ACTIVITY DURING A CROSS- COORDINATION MOVEMENT ON STABLE AND UNSTABLE SURFACES

POHL, T., WEARING, S., BRAUNER, T., HORSTMANN, T.

TECHNICAL UNIVERSITY MUNICH - FACULTY OF SPORTS- AND HEALTH SCIENCES

INTRODUCTION: Dynamic balance training that includes cross-coordination movements (CCM) is thought important for the acquisition of complex motor skills and is commonly used to prevent musculoskeletal injury and rehabilitate athletes with movement coordination impairments [1,2]. At a clinical level, the intensity of dynamic balance training with CCM is typically progressed by changing the stability of the support surface. However, movement patterns evoked by undertaking CCM on stable and unstable sources has not been quantified and is important for optimal progression of balance training exercises [3]. This study investigated differences in whole body kinematics, knee joint moments, centre-of-mass (CoM) movement and muscle activation patterns of the support leg during CCM undertaken on a stable and unstable surface.
METHODS: 23 healthy young adults (23 ± 2 years, 169.0 ± 8.8 cm, 67.8 ± 12.5 kg) performed the same CCM on a stable surface and a sensorimotor training device (Posturomed, Haider Bioswing, DE). CCM was undertaken during single limb stance and involved synchronous cyclic movement of the knee of the swing leg and the elbow of contralateral arm towards the center line of the body. Participants were instructed to move with a constant but self-chosen velocity for 50 s while whole-body 3D kinematics were collected with a 10 camera infrared motion capture system (Vicon Motion Systems, GB). Myoelectrical activity of 10 muscles of the support leg were also synchronously recorded using surface electromyography (Myon 320, Myon, CH). Statistical comparisons were made using paired t-tests (α=.05).
RESULTS: Participants performed a significantly greater number of movement repetitions on the stable than on the unstable surface (18.5 ± 4.3 vs. 14.2 ± 4.3) and adopted a more internally rotated hip position (5.2 ± 13.0° vs. -0.2 ± 13.5°) and a more flexed knee (14.2 ± 6.8° vs. 9.6 ± 7.6°) and ankle (8.4 ± 4.3° vs. 6.0 ± 4.1°) posture throughout the CCM on the unstable surface. CCM on the unstable surface where characterized by a significantly greater AP (162 ± 50 cm vs. 110 ± 46 cm) and ML (208 ± 105 cm vs. 32 ± 12 cm) CoM displacement and a reduced sagittal range of motion of the swing hip (101.8 ± 7.2° vs. 109.3 ± 6.9°) but not shoulder. Peak knee adduction moments were significantly higher on the unstable surface, as was muscle activity in selective muscles of the shank (soleus, tibialis anterior, peronues longus) and thigh (semitendinosus, vastus medialis and vastus lateralis).
CONCLUSION: CCM movements performed on an unstable surface present a greater challenge to balance and coordinated movement and can be used to progress the intensity of dynamic balance training. However, they are also characterized by a more flexed knee posture and greater knee adduction moment and, as such, may require judicious use in people with medial compartment knee osteoarthritis.

THE IMPACT OF A PASSIVE UNILATERAL LOWER LIMB EXOSKELETON ON HUMAN BALANCE CONTROL

RINGHOF, S., EHRENBERGER, I., BEIL, J., ASFOUR, T., STEIN, T.

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: Exoskeletons are wearable devices closely coupled to the human, which interact with the musculoskeletal system, e.g., by applying assistive forces in order to regain or augment physical and functional capabilities [1]. A main prerequisite for the development and application of exoskeletons is to investigate the human-exoskeleton interaction in terms of potential inferences with motor control, especially balance. Therefore, the purpose of the present study was to investigate whether a passive unilateral lower limb exoskeleton has an impact on static and dynamic reactive balance control.
METHODS: Eleven healthy subjects (22.9 ± 2.5 yrs, 5 females) volunteered for this study and performed three balance tasks: (i) quiet standing in bipedal stance, (ii) quiet standing in single-leg stance, and (iii) compensating perturbations applied randomly to a swinging platform in single-leg stance. In counterbalanced order, participants performed all the balance tasks with and without a passive unilateral lower limb exoskeleton (a modified version of [2]). To assess static and dynamic balance, AMTI force plates and a Vicon motion capture system were used to capture the center of pressure (CoP) path length and the time to stabilization (TTS), respectively. Dependent t-tests were separately run for both static balance tests, and a repeated-measures ANOVA with factors exoskeleton (EXO, No-EXO) and direction of perturbation (anterior, posterior, medial, lateral) was calculated for the dynamic reactive balance task.
RESULTS: The exoskeleton did not significantly influence postural sway in bipedal stance. However, in single-leg stance, the mediolateral path length of the CoP was significantly shorter for the EXO condition when compared to the No-EXO condition (p=0.018, d=1.13). For the dynamic reactive balance task, the ANOVA found no statistical main effect (p=0.154) but a large effect size (ηp^2=0.19) for the exoskeleton. Specifically, the participants tended to regain stability less quickly when wearing the exoskeleton, indicated by larger TTS for all directions of perturbation.
CONCLUSION: The study showed that the exoskeleton did not affect balance in bipedal stance, but increased mediolateral stability in single-leg stance. This indicates that the exoskeleton provides some additional mechanical support under static conditions, which may disappear when sufficient stability is available (bipedal stance). Besides, the exoskeleton tended to impair dynamic reactive balance, potentially by impeding adequate compensatory adjustments via the ankle strategy. These are important findings considering the human-exoskeleton interaction, which have strong implications for the future design and application of exoskeletons, emphasizing the significance of taking into account the mechanisms of human motor control.

COMPARISON OF POSTURAL CONTROL IN CANCER PATIENTS WITH MATCHED HEALTHY CONTROLS

MÜLLER, J.1, RINGHOF, S.2, VOLLMER, M.2, SCHNEEWEISS, A.1, STEIN, T.2, WISKEMANN, J.1
(1) HEIDELBERG UNIVERSITY HOSPITAL, (2) KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: Chemotherapy-induced peripheral neuropathy (CIPN) is a serious side effect deriving from neurotoxic chemotherapeutic agents. The underlying nerve damage can cause changes in proprioception, which may have a negative impact on balance ability [1]. The aim of this study was to analyse the temporal course of postural control in cancer patients during chemotherapy and to compare these data to healthy controls.
METHODS: Participants were 35 cancer patients (PAT: 2 males, 33 females; age 53.8±9.6 years, height 166.0±5.5cm, weight 69.8±12.2kg) and 35 gender, age, height and weight matched healthy controls (MC: 2 males, 33 females; age 53.3±8.7 years, height 167.4±4.9cm, weight 71.5±11.3kg). Postural control of MC was tested once, whereas PAT were tested prior to (t0) and 23±7 days after completion of neurotoxic chemotherapy (t1), which lasted 17.6±5.4 weeks on average. Mean sway velocities (VEL) were calculated using center of pressure data obtained from a force plate (AMTI AccuSway). The following balance conditions were analysed: bipedal stance with eyes open (BPEO) and eyes closed (BPEC), and semi-tandem stance with eyes open (STEO) and eyes closed (STEC). CIPN symptoms were assessed via questionnaire (EORTC QLQ-CIPN20). Time and group differences were determined by using dependent t-tests. Cohens d was used to demonstrate clinical relevance. Linear regression was applied to analyse associations between severity of CIPN symptoms and postural control.
RESULTS: After completion of chemotherapy (t1), PAT showed sig. higher CIPN symptoms ($p<.001$, $d=.78$) and increased VEL in all standing conditions ($p<.05$, $d>.53$) compared to t0. These results were reproduced in comparison to MC at t1, with the exception of STEO. The differences were greatest in conditions with eyes closed: BPEC (PAT: 13.4±7.1mm/s, MC: 10.4±3.9mm/s; $p=.021$, $d=.41$) and STEC (PAT: 34.4±16.4mm/s, MC: 26.7±8.6mm/s; $p=.021$, $d=.39$). Detailed analyses of VEL revealed that the differences between PAT and MC were more pronounced in AP than ML direction. Regressions models did not show sig. correlations between CIPN symptoms and balance performance.
CONCLUSION: About three weeks after completion of chemotherapy, PAT showed significant and clinically relevant balance deficits compared to MC. Especially the deficits in the standing conditions with closed eyes may indicate an impaired proprioception, which might be compensated by visual control in the other trials. It can also be hypothesized that this impairment may lead to a greater use of the hip strategy to maintain balance, resulting in larger AP movements. However, severity of subjectively reported CIPN symptoms was not significantly correlated with balance performance. Further studies need to objectively assess the degree of nerve damage and take further influencing factors on postural control into account (e.g. strength) in order to generate effective rehabilitation measures.

OP-BN07 Skill acquisition

IDENTIFICATION OF ELITE PERFORMANCE CHARACTERISTICS IN A SMALL SAMPLE OF TAEKWONDO ATHLETES

NORJALI WAZIR, M.R.W., VAN HIEL, M., MOSTAERT, M., DECONINCK, F.J.A., PION, J., LENOIR, M.
UNIVERSITEIT GENT.

Introduction
Along with the increasing popularity of taekwondo, coaches and federations are in need of evidence-based talent identification (TID) and development programs based upon profiles of future elite athletes. This study first aims to investigate the differences between elite and non-elite youth taekwondo athletes in anthropometry, physical performance and motor coordination. The second aim was to demonstrate the applicability of z-scores in TID research to overcome statistical limitations with respect to sample size in specific populations that are small in number by definition, like elite athletes.
Methods
In this cross-sectional study, 98 Taekwondo athletes between 12 and 17 years old were tested using a generic (i.e. non-sport specific) test battery consisting of four anthropometrical, six physical performance and three motor coordination tests. Based on the individual success at international competition level, 18 were categorised as elite athletes and 80 were considered as non-elite.
T-tests (step 1) on raw test scores and MANOVAs on z-scores (step 2) were conducted to examine differences between the elite and non-elite taekwondo athletes for anthropometry, physical performance and motor coordination tests. A large reference base of > 600 well trained youth elite athletes was used to calculate z-scores of this particular sample. Finally, z-scores were reconverted to raw scores to demonstrate practical significance for coaches.
Results
Overall, elite taekwondo athletes score better compared to the non-elite group on body composition (fat percentage), sprint speed, lower limb explosivity, and general body coordination. The potential value of reconverting z-scores to raw scores for a hypothetical individual taekwondo athlete that was not part of the original sample is discussed.
Conclusions
This study adds to our current knowledge on the physical profile of youth elite athletes in taekwondo. More specifically, this study underlines the hypothesis that general motor coordination is a characteristic that discriminates between athletes of different expertise levels, which has already been show in sports like soccer, female artistic gymnastics, or volleyball (Vandendriessche et al., 2012; Vandorpe et al, 2012, Pion et al, 2015). As a result, an evaluation of motor coordination should be a standard component of TID test batteries. The use of z-scores in the context of talent characteristics in small groups is shown to be of practical value, however not without limitations.

REAL-TIME MUSCLE CONTRACTION FEEDBACK SYSTEM FOR PEDALING ANALYSIS BASED ON SURFACE EMG AND LOWER LIMB MUSCLE LENGTH

ABE, N., MURATA, T., TSUMUGIWA, T., YOKOGAWA, R.

DOSHISHA UNIVERSITY

INTRODUCTION: In recent years, a feedback system capable of displaying the lower limb muscle activation patterns during pedaling exercise has been developed (1). However, few studies have been focused on a system that can describe cyclists' lower limb muscle contraction during the pedaling exercise. In the previous studies, the muscular strength and muscle fatigue can be changed depending on a type of muscle contraction (2). Therefore, the purpose of this study is to develop a real-time muscle contraction feedback system that can describe cyclists' lower limb muscle contraction to improve pedaling performance in real-time. This paper presents that the pedaling performance of a cyclist has been improved based on the muscle contraction information obtained from the proposed system.
METHODS: An amateur cyclist participated in this experiment. The surface EMG was recorded from rectus femoris(RF) and ham-strings(HAM), and the pedaling force and efficiency were measured using a power meter. Furthermore, the lower limb motion was measured by the 3D motion capture system and the muscle length of each muscle was computed. Then, the muscle contraction of each leg was estimated every 10 crank angle degrees based on the analysis results from the surface EMG and the muscle length. At the same time, the types of muscle contraction (Eccentric / Concentric contraction) were shown with visualized pie charts on the monitor, the cyclist could recognize his types of muscle contraction in real-time and improve his pedaling skill immediately based on the visual feedback. Two experimental conditions were set: pedaling cadence 80-90 rpm and 110-120 rpm. To evaluate the intervention effect of the proposed system, the cyclist participated in the same pedaling analysis experiment after 4 weeks of training from the first experiment.
RESULTS: The experimental results show that the lower limb muscle contraction and the pedaling efficiency were improved under each pedaling cadence condition after 4 weeks of training. In 110-120 rpm, the concentric contraction range of HAM was increased by 31.3 %, and the pedaling efficiency was increased by 4.4 % (t-test: $p < 0.05$). Similarly, in 80-90 rpm, the concentric contraction range of HAM was increased by 33.3 % and the pedaling efficiency was increased by 3.4 % (t-test: $p < 0.05$). Therefore, the cyclist could acquire the skill to pedal mainly with HAM under the concentric contraction and improve the pedaling performance.
CONCLUSION: In this study, we developed a real-time muscle contraction feedback system that can describe cyclists' lower limb muscle contraction during the pedaling exercise. The present results show that the proposed system improves the pedaling performances of cyclists.

INTERFERENCE OF BALANCE TASKS REVISITED: LEARNING OF NON-POSTURAL TASKS SEEMS TO IMPAIR CONSOLIDATION OF BALANCE TASKS

EGGER, S., WÄLCHLI, M., SCHAERER, N., TAUBE, W.

UNIVERSITY OF FRIBOURG

INTRODUCTION: It is well-documented that a simple motor learning tasks can disrupt consolidation of another motor task and therefore lead to interference (2). However, Giboin and colleagues (2018) tested recently the interference paradigm in two consecutive balance tasks and reported no interference. However, it remains unclear whether non-postural tasks like visuomotor tracking or an explosive force task can impair consolidation of a previously learned balance task.
METHODS: 40 healthy young adults (25 women, 15 men) were randomly assigned to one of two intervention groups. For the balance training, all subjects were standing on a custom-made "seesaw" balance device that moved in the anterior-posterior direction (8 series of 8 trials of 8 s). Immediately after the learning phase, subjects performed either a visuomotor tracking task (8 series of 8 trials of 8 s) or a rate of force development task (8 series of 8 trials). Both tasks were executed isometrically on the isokinetic device while contracting the calf muscle. On the following day, all subjects performed a retention test on the balance device (3 series of 8 trials of 8 s) after a short period of re-familiarization (6 trials of 8 s).
RESULTS: Subjects improved their performance significantly when learning balance ($F1, 38 = 32.987$; $p < .001$; $n2p = .465$), visuomotor tracking ($t19 = 6.953$; $p < .001$; $r = .85$) or ballistic contractions ($t19 = -5.885$; $p < .001$; $r = .80$). More importantly, the performance on the balance device decreased significantly from the last series of the training phase to the first series of the retention test ($F1, 32 = 12.045$; $p = .002$; $n2p = .273$). No main effect for GROUP and no interaction (GROUP x TIME) were observed.
CONCLUSION: The performance improvements in balancing, visuomotor tracking and ballistic contractions indicate that learning has occurred in all three tasks. Most noteworthy, the performance on the balance device was significantly decreased at the beginning of the retention test, which probably indicates interference. However, as the results of a control group, performing no interference task after balance training, are not analyzed yet, the decrease in performance may theoretically also be caused by the normal decline of motor memory over time. It seems reasonable to assume that this effect is, however, much less pronounced without an interference task. In this sense, the current results imply that typical interference tasks like visuomotor tracking or ballistic contractions impair balance performance and should not be performed shortly after balance training.

EFFECTS OF EXTERNAL VERSUS INTERNAL FOCUSED INSTRUCTIONS FOR KNEE ALIGNMENT ON WHOLE BODY KINEMATICS OF LANDING AND JUMPING MOVEMENTS

WERNER, I., PEER-KRATZER, M., HAID, T., FEDEROLF, P.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Studies confirm the advantage of external focused training instructions on motor learning and performance. In contrast, internal focused feedback is often used in training therapy. Immediate adaptations in whole body movement coordination caused by instructions using different attentional foci are rarely explored (1). This study aims to observe short term effects of attentional focus on movement patterns in landing and jumping controlling knee alignment.

METHODS: Twenty-three well trained young ski racers (15 to 16ys old; 12 male, 11 female) performed 3 sets of 5 jumps from a 40cm platform combining a smooth landing with a submaximal jump. The first set was without instruction, the second and third with external and internal focus to knee position control in a cross over design. All athletes were free of knee injuries. They were equipped with 41 markers over all body segments and filmed with 8 cameras of a Vicon system. Movement trajectories were exploited from the first to the last ground contact. Data were centered and time normalized. A Principal Component Analysis (PCA) was conducted and the relative subject specific variance of different principal components (PC) was calculated (2). Differences in variance between not instructed, internal and external focused trials were analysed (alpha level 5%) using repeated measure ANOVA (focus, trials) or Friedman test.
RESULTS: The first 10 components of PCA explained more than 99% of variance. Relative subject specific variance differed between uninstructed and internal focused trials in the first 3 PC-components ($F(1,22)=6.28$, $p=.02$, $eta^2=.22$; $F(1,22)=6.71$, $p=.017$, $eta^2=.23$; $chi^2(9)=26.5$, $p=.002$ respectively) with higher percentages in PC1 and lower ones in PC2 and PC3. Internal and external focused trials did not differ but showed the same direction of change compared to uninstructed trials.
CONCLUSION: Results confirmed effects of movement instructions giving a special focus. External focus and to a greater extent internal focus revealed a shift to higher fraction of the first component and lower ones to the second and third component of PCA supporting the constrained-action hypothesis (3).

THE WALK-RUN TRANSITION IS NOT AFFECTED BY ADDED COGNITIVE LOADING

HANSEN, E., HYTTEL, M.K., JAKOBSEN, L.S., JENSEN, M.K., BALLE, H., VOIGT, M.

AALBORG UNIVERSITY

INTRODUCTION: Walk-run transition can be predicted from stride rates (1, 2), based on the assumption that the human acts as a complex system (3), which can be described with Dynamic Systems Theory (4). Besides, two research groups have investigated the hypothesis that added cognitive loading affects the walk-run transition. One of the groups confirmed the hypothesis (5) while the other rejected it (6). To clarify this, we re-tested the hypothesis in the present study.
METHODS: Healthy individuals (13 men, 5 women) participated. First, two pressure-sensitive sensors were placed under the insole of the participant's right shoe at, respectively, a position corresponding to the midpoint of the underside of the heel and at a position corresponding to the midpoint between 1st and 2nd metatarsal heads. The sensors were used for determination of stride characteristics. Then, 10-min warm up was done on a treadmill. For this, the treadmill speed was initially 1 km/h and increased by 1 km/h each min, until the final speed of 10 km/h was completed. After 4 min of rest, the reference walk-run transition test began. For this, the initial treadmill speed was 5 km/h and increased by 0.1 km/h each 10th s, until transition occurred, or a final speed of 9 km/h was reached. This was followed by 4 min of rest. Then, the dual task walk-run transition test began. This test was similar to the reference test. But, in addition to walking, the participant had to perform mental arithmetic, which added cognitive loading. The arithmetic task began with the number 911. From this, 7 were repeatedly subtracted. To increase the cognitive loading, the participant was regularly cheered to perform the arithmetic fast. Data were evaluated with paired samples t-tests. Two subjects were omitted from the evaluation since they did not transit to running in the dual task test.
RESULTS: In the reference test, the speed and stride rate at the transition were 7.5±0.5 km/h and 67.0±3.1 strides/min, respectively. In the dual task test, the matching values were 7.6±0.5 km/h and 68.4±3.7 strides/min, respectively. There were no differences between the two types of tests ($p>0.05$).
CONCLUSION: The addition of cognitive loading in a walk-run transition test with monotonous increasing walking speed did not change the speed and stride rate at the transition. We consider this finding to be consistent with the idea that the walking human acts as a self-organized dynamic system, without influence of a central control centre.

IS SKIN TEMPERATURE RELATED TO PHYSIOLOGICAL STRESS AFTER A HALF MARATHON?

PRIEGO QUESADA, J.I.1,2, PÉREZ-GUARNER, A.2, OFICIAL-CASADO, F.2, CIBRIÁN ORTIZ DE ANDA, R.2, CARPES, F.P.3, SALVADOR PALMER, R,2

1 RESEARCH GROUP IN SPORTS BIOMECHANICS . UNIVERSITAT DE VALÈNCIA. SPAIN. 2 RESEARCH GROUP IN MEDICAL PHYSICS . UNIVERSITAT DE VALÈNCIA. SPAIN. 3 APPLIED NEUROMECHANICS RESEARCH GROUP. F

INTRODUCTION: Analyses of asymmetries in skin temperature are discussed as an approach to detect the risk of injury (1). However, other approaches have been suggested such as monitoring basal skin temperatures to detect higher values that could be related to the training workload (2). Theoretically, muscle damage and inflammation resultant of exercise could increase skin temperature (1). The objective was to determine the association between basal skin temperature and physiological stress produced by a half marathon competition.
METHODS: 17 runners were measured 48 h before, 24 h before, 24 h after and 48 h after completing the 2018 Valencia Half Marathon. On each measure, creatine kinase (CK; Reflotron system), perception of pain (visual analogue scale), jump performance (countermovement jump test - Chronojump platform), and skin temperature (FLIR E60 thermographic camera) from 10 regions of interest of the full body was determined. Data are showed by the p values, Cohen's effect sizes (ES) and 95% confidence intervals of the differences (CI95%).
RESULTS: On 24 h after the half marathon, CK ($p<0.001$, $ES=2.1$ and CI95%[291.6, 922.9 U/L]) and perception of pain ($p<0.001$, $ES=1.7$ and CI95%[1.5, 5.7 cm]) increased, whereas jump performance decreased ($p<0.01$, $ES=0.4$ and CI95%[-2.7, -0.5 cm]). Comparing 48 h before and 24 after the competition, skin temperature increased in the posterior upper limb ($p<0.001$, $ES=0.9$ and CI95%[0.3, 1.3ºC]) and in the

anterior leg (p<0.01, ES=1.0 and CI95%[0.2, 1.3°C]). However, skin temperature was higher 24 h before the half marathon for most of the ROIs (p<0.05) compared to 48 h before the competition.
A bivariate correlation was found between the 24 h variation (pre - 24h) of CK and the skin temperature of the posterior upper limb (p=0.04 and r= 0.5), and between the 48 h variation (pre – 48h) of pain perceived and the skin temperature of the knee (p<0.01 and r= 0.6). However, no multiple regression model was able to predict CK using skin temperature.
CONCLUSION: The analysis of CK, jump performance and pain perception confirmed the presence of stress in response to the competition.
Variation in skin temperature two days before the competition highlighted that the interpretation of skin temperature in a sport club is complicated because an increase in the skin temperature could also be due to different factors (e.g.environmental or psychophysiological), and not only to the training workload of the previous sessions.
Correlations obtained were moderate and isolated. We considered that following up basal skin temperatures does not seem to be an adequate method to detect the stress produced by a half marathon. Future studies with competitions with higher stress (e.g.marathon) and using other methodologies such as the analysis of the skin temperature recovery after cold stress are necessary.

EFFECTIVENESS OF SELF- VERSUS EXTERNALLY-CONTROLLED HEAT STRAIN DURING HEAT ACCLIMATION

PROUT, J.R.P., GIBBONS, T.D., KISSLING, L.S., AKERMAN, A.P., LAMBERTS, R.R., CORBETT, J., SIMS, S.T., HARGREAVES, E.A., CAMPBELL, H.A., COTTER, J.D.

UNIVERSITY OF OTAGO

INTRODUCTION: Humans adapt effectively to heat. Repeated bouts of clamped/controlled hyperthermia are deemed the 'gold standard' approach to heat acclimation (HA) in research, however in practice, athletes typically self-regulate exposure, i.e., based on perceived thermal and total strain. Conceivably, self-regulation may be safer and highly efficacious. The purpose of this study was to compare the effectiveness of these two conceptually contrasting approaches to exercise-based HA. Effectiveness was assessed using standard physiological and perceptual markers of HA.
METHODS: Six endurance-trained participants (24 ± 6 y; 2 female) completed two HA regimens in cross-over fashion, 6-wk apart. One involved core temperature clamped 1.5 °C above baseline (CLAMP) and one was self-regulated (SELF) with no feedback on core temperature. Both regimens involved 9-d cycling-based HA (60 min/d) in controlled humid heat [40 °C, 50% RH (3.7 kPa)]. Days 1, 5 and 9 involved controlled exercise at 1.75 W/kg for the first 30 min to assess thermoregulatory adaptations to a matched exercise load.
RESULTS: HA resulted in lower resting core temperature and increased plasma volume, as well as lower mean exercising core temperature and heart rate, and higher affect (Cohen's d = 0.18 to 1.12, p = 0.02 to 0.12). These improvements across HA occurred to a similar extent between regimens (d = 0.11 to 0.41, p = 0.22 to 0.85). HA reduced thermal discomfort and increased sweat rate (d = 0.48, 0.32; p = 0.06, 0.01, respectively), but these outcomes tended to be larger in SELF (d = 1.3, 1.9; p = 0.08, 0.06) than in CLAMP. Thermal sensation and rating of perceived exertion did not change regardless of regimen (d = 0.09, 0.08; p = 0.85, 0.81). Five of the six participants preferred SELF.
CONCLUSION: SELF was as effective as CLAMP in eliciting the standard markers of HA. We therefore preliminarily recommend self-regulated heat acclimation for athletes, especially as it is more practically viable, whereas researchers would use whichever suits their question(s).

EFFECTS OF IN-PLAY COOLING INTERVENTIONS DURING TENNIS MATCH PLAY IN THE HEAT ON PERFORMANCE, PHYSIOLOGICAL, AND PERCEPTUAL MEASURES

WIEWELHOVE, T., CONRADT, F., FERRAUTI, A.

FACULTY OF SPORT SCIENCE, RUHR UNIVERSITY, BOCHUM, GERMANY

INTRODUCTION: Competitive tennis is often played in hot environments (Kovacs, 2006). The resulting heat stress is associated with impaired tennis performance and increased risk of heat-related health issues. Therefore, in-play cooling interventions are recommended by the International Tennis Federation (Schranner et al., 2017). Most common include a combination of ice-cold drinks, electric fans, and the application of ice wrapped in a wet towel around the neck with damp, cold towels simultaneously placed on the thighs. However, there is no evidence that these cooling interven-tions are actually mitigating thermal strain when only applied during short in-play breaks (90-120 s) typically permitted by tennis rules. Accordingly, the objective of this study was to investigate whether cooling during tennis match play in the heat could affect players performance, physiology, perception of effort, and well-being.
METHODS: After an initial familiarization session, eight competitive male tennis players (age 20.6 ± 5.0 y, height 181.6 ± 6.4 cm, body mass 77.1 ± 12.3 kg, mean ± SD) performed two testing sessions (one day apart), comprising a 90-minute standardized tennis match play on a hard court at 31.8 ± 2.1°C and 48.5 ± 9.6% relative humidity. During breaks, the currently used cooling strategy (COL) - cold water ingestion (ad libitum) and an electric fan facing the players from 1 m combined with an ice-filled damp towel around the neck and on the thighs - or no cooling (CON) were applied. Measures of performance, heart rate, blood lactate concentration, ear and skin temperature, sweat loss, perceived exertion, and rating of fatigue and recovery were obtained in both trials.
RESULTS: COL resulted in significantly higher blood lactate concentrations and ratings of recovery (p<0.05), but no significant difference (p>0.05) was observed between COL and CON for total points won, serve velocity, jump performance, heart rates, ear or skin temperature, sweat loss, perceived exertion, or ratings of fatigue. However, effect sizes indicated trends to lowered resting heart rates, skin temperature, and ratings of fatigue in the cooling condition.
CONCLUSION: The intermittent use of COL during tennis match play in hot conditions has no effect on tennis performance, physiological measures of heat strain, or perception of effort, although heart rate recovery and ratings of well-being were improved. Blood lactate concentration was higher in the cooling condition. Consequently, it is possible that the players who felt less fatigued and better recovered due to COL presented a willingness to push themselves harder during the tennis match.

PREPARATION FOR THE TOKYO OLYMPIC GAMES: IS THERE AN ERGOGENIC POTENTIAL OF COMBINING HEAT AND HYPOXIC ACCLIMATION?

SOTIRIDIS, A.1,2, DEBEVEC, T.1,3, CIUHA, U.1, MILIOTIS, P.4, MCDONNELL, A.C.1, MLINAR, T.1,2, ROYAL, J.1,2, KOSKOLOU, M.4, MEKJAVIC, I.B.1

1: JOZEF STEFAN INSTITUTE, LJUBLJANA, SLOVENIA, 2: IPS JOZEF STEFAN, LJUBLJANA, SLOVENIA, 3: UNIVERSITY OF LJUBLJANA, SLOVENIA, 4: NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE

INTRODUCTION: A combined stressor heat and hypoxia acclimation protocol has been proposed as a "conditioning cocktail" for aerobic performance in thermoneutral conditions (1). Heat acclimation-elicited thermoregulatory benefits have been shown not to be negated by adding daily exposure to hypoxia (2). These observations may lure athletes to incorporate such protocols on the road to the Tokyo Olympics. Whether a combined stressor approach could indeed enhance aerobic performance in hot environments remains unresolved.
METHODS: Eight trained males (VO2max: 54.3 ± 5.8 mL·min-1·kg-1, Wpeak: 343 ± 30 W) underwent a 10-day normobaric hypoxic confinement interspersed with daily 90-min normoxic controlled-hyperthermia (target rectal temperature: 38.5°C) exercise sessions (live high (13.5% FiO2)-train warm (35°C) and low: LH-TWL). Prior to and following the confinement, the participants were tested on a cycle ergometer in normoxic (23°C, 50% RH, 20.9% FiO2; NOR), hypoxic (23°C, 50% RH, 13.5% FiO2; HYP) and hot (35°C, 50% RH, 20.9% FiO2; HE) conditions in a randomized and counterbalanced order. The exercise tests consisted of two stages; a 30-min steady-state exercise followed by incremental exercise to exhaustion. The steady-state exercise was performed at 40% NOR Wpeak to evaluate thermoregulatory function and exercise economy. Hematocrit and hemoglobin concentration were assessed from venous blood samples obtained immediately before and after the confinement. The anaerobic threshold was defined as the oxygen uptake that corresponded to the deflection point of the end-tidal PETCO2 confirmed by the nadir in the VE/VCO2 when plotted as functions of the workload during the incremental test. Ten control participants (VO2max: 57.9 ± 6.2 mL·min-1·kg-1, Wpeak: 375 ± 49 W) completed the same test in the same environments before and after 10 days comprising daily volume-matched training sessions in thermoneutral normoxic conditions without hypoxic exposure (CON).
RESULTS: VO2max and the anaerobic threshold did not increase in any environmental condition following LH-TWL. In contrast, Wpeak increased by 6.3 ± 3.4% in NOR and 4.0 ± 4.9% in HE, respectively. The forehead sweating response was augmented in HE as reflected on the higher values of peak sweat rate and the gain of the sweating response. Similar thermoregulatory and performance gains were observed in the CON group. Exercise economy increased post-acclimation in NOR after LH-TWL only. The estimated plasma volume contracted by 15.1 ± 8.5% after LH-TWL, whereas it expanded by 10.7 ± 7.2% in CON.
CONCLUSION: A 10-day combined heat and hypoxia acclimation protocol did not confer any additional benefit over training in normoxic thermoneutral conditions. Thus, adoption of such a training protocol as an ergogenic aid in preparation for the Tokyo Olympics does not seem warranted.

INFLUENCE OF HYPEROXIA ON TIME TRIAL PERFORMANCE IN HOT AND COOL CONDITIONS

PÉRIARD, J.D.1, HOUTKAMP, D.1,2, BRIGHT, F.1, DAANEN, H.A.M.2, ABBISS, C.R.3, THOMPSON, K.G.1,4, CLARK, B.1

1UNIVERSITY OF CANBERRA, 2VRIJE UNIVERSITEIT AMSTERDAM, 3EDITH COWAN UNIVERSITY, 4NEW SOUTH WALES INSTITUTE OF SPORT

INTRODUCTION: Thermal and cardiovascular strain are exacerbated during self-paced exercise in the heat and power output progressively decreases compared with cooler conditions (1). Although it has been shown that breathing air with a fractional oxygen content (FiO2) between 0.25 and 1.0 enhances time trial performance in cool conditions through increased oxygen availability and delivery to locomotor muscles (2), it remains unknown whether hyperoxia can enhance time trial performance under heat stress. The purpose of the study was to investigate whether supplementing with a hyperoxic gas mixture during the final 25% of a 40-min cycling time trial in hot and cool conditions would similarly enhance performance (i.e. power output) and compensate for the impairment in performance observed under heat stress.
METHODS: Ten well-trained male cyclists performed incremental VO2max tests in normoxia (FiO2: 0.21) and hyperoxia (FiO2: 0.45) and then four 40 min cycling self-paced time trials, all on separate days. Two time trials were undertaken in 18ºC and 40% relative humidity (COOL) and two in 35ºC and 60% relative humidity (HOT). For the first 30 min in each time trial participants breathed ambient air and for the remaining 10 min either normoxic (FiO2: 0.21) or hyperoxic (FiO2: 0.45) air.
RESULTS: VO2max was 6.9 ± 4.3% (mean ± SD) higher in hyperoxia than normoxia (P=0.001) and accompanied a 24 ± 17 W higher peak power output (P<0.005). During the first 30 min of the time trials power output was lower in the HOT (~229 W) compared with COOL (~248 W) trials (P<0.05). Mean power output was higher during the final 10 min in COOL hyperoxia (307 ± 36 W) than normoxia (279 ± 27 W; P=0.004). Mean power output was also higher during the final 10 min in HOT hyperoxia (261 ± 25 W) relative to normoxia (241 ± 31 W; P=0.016), however did not reach that of COOL normoxia (P=0.047). SpO2 was higher when breathing hyperoxic air in each condition (P<0.05), increasing to a greater extent in the COOL trial (P<0.05). Heart rate was higher throughout the HOT compared with COOL trials (P<0.05). Rectal temperature reached higher values in the HOT (~39.4ºC) compared with COOL (~38.8ºC) trials (P<0.05). Thermal discomfort was higher in the HOT compared with COOL trials (P<0.05), whereas ratings of perceived exertion increased similarly in all trials (P<0.05).
CONCLUSION: Compared with normoxia, acutely increasing FiO2 and SpO2 during the final 10 min of a 40 min time trial increased power output similarly in COOL (~28 W) and HOT (~21 W) conditions. Hyperoxia appears to partly offset the increase in thermal and cardiovascular strain experienced under heat stress, although not to the extent whereby it is fully compensated, as demonstrated by the failure to reach a performance level similar to that of normoxic exercise in COOL conditions.

TOKYO 2020 OLYMPIC GAMES: THE EFFECTS OF HOT CLIMATE ON CYCLIST'S PHYSIOLOGICAL PARAMETERS

CUPIDO SANTOS, A.1, AFONSO, J.1, SEBASTIÃO, F.1, NUNES, A.1, JOÃO VIEIRA, M.2, MENDES, B.2, TEIXEIRA, R.2, GONÇALVES, L.2, GAMEIRO DA SILVA, M.3

(1) FCDEF, (2)DEPARTMENT OF CARDIOLOGY, COIMBRA UNIVERSITY HOSPITAL CENTRE & FACULTY OF MEDICINE , (3) ADAI, LAETA, DEPARTMENT OF MECHANICAL ENGINEERING, UNIVERSITY OF COIMBRA

INTRODUCTION: Tokyo, the city where the next Olympic Games will take place in July and August 2020, has a higher risk of heat illness than the three cities where the Games were held before. The values of the Wet Bulb Globe Temperature (WBGT) index, used to assess the risk of thermal stress are typically, at least, for the Games season, 3 ºC above the Beijing and Rio de Janeiro values1. It is well established that the increase in temperature and humidity aggravates WBGT index and consequently impairs human performance altering physiological values at various levels, such as heart rate, sudation rate, core temperature and s˙O2. The main purpose of this study was to evaluate the impact of the expected WBGT index in Tokyo on the athletes physiology parameters comparing with the WBGT index provoked by laboratory standard conditions (21ºC, 60%RH).
METHODS: The present study compares physiological variables related to cycling performance, such as heart rate, lactic acid, ventilation rate, r˙O2, blood pressure, urine temperature, haemoglobin and haematocrit, plasma volume, urine specific gravity density, urine osmolality and body mass variation searching differences between the WBGT index for the standard laboratory environment at 21ºC and 60% RH and the predicted WBGT index to Tokyo. The study included 16 male athletes from the XCM and road categories aged from18 to 43. It was performed, a VO2máx and anaerobic lactate threshold test at WBGT index characteristics of laboratory standard conditions. The two following tests were realized at the power load corresponding to 2mmol/L lactic acid during 1 hour of cycling practice, under two different conditions: I) WBGT index characteristics of laboratory standard conditions and II) predicted WBGT index to Tokyo (34ºC with 55% RH). The tests ended when the athlete was unable to maintain power load, or reach the 60-minute mark.
RESULTS: At condition I) all cyclists finished the protocol although, through test II) 6 cyclists were not able to finish it. There were significant differences (sig ≤0.05) between the I) and II) moments, respectively: heart rate at the end was 154.50±11.42 bpm and 175.89±9.40 bpm, ventilation at the end was 80.68±15.41 L/min and 93.75±11.97 L/min, oxygen consumption was 52.05±4.99 and 54.45±6,33 ml-1.kg-1.min-1, systolic blood pressure was 186±49.39 mmHg and 285±35,59mmHg, the lost plasma volume was 3.33±4.58% and 7.54±4.19%, urine temperature was 37.59±1.30ºC and 38.68±0.45ºC, body mass variation was 2.03±0.4% and 3.09±0.7%.
CONCLUSION: Overall, these data suggest that evaluating athletes in laboratory conditions and then compete or train in hot environments with this specific data will lead to erratic training intensities, since the increase in central temperature, arterial systolic pressure, decrease in plasma volume and metabolic efficiency will affect drastically how athletes will perform under these circumstances, Therefore, our study suggests that an acclimatization process is needed in these adverse climatic conditions

YOU ARE AS FAST AS YOUR MOTOR NEURONS: SPEED OF RECRUITMENT AND MAXIMAL DISCHARGE OF MOTOR NEURONS DETERMINE THE MAXIMAL RATE OF FORCE DEVELOPMENT IN HUMANS

DEL VECCHIO, A., NEGRO, F., HOLOBAR, A., CASOLO, A., FOLLAND, J.P., FELICI, F., FARINA, D.

IMPERIAL COLLEGE LONDON

INTRODUCTION: During rapid contractions motor neurons are recruited in a short burst and begin to discharge at high frequencies, up to 200 Hz (1). We assessed the behaviour of populations of motor neurons during rapid contractions in humans applying a new approach to accurately identify motor neuron activity concurrently with measures of rate of force development.
METHODS: The activity of spinal motor neurons was assessed by high-density EMG decomposition (2) from the tibialis anterior muscle of 20 men during isometric explosive contractions. We introduce a novel metric to assess the validity and reliability of the motor unit decomposition during rapid contractions. The speed of motor neuron recruitment, the instantaneous motor unit discharge rate, and the average number of discharges per motor unit per second were analysed as a function of the impulse (the time-force integral) and the maximal rate of force development (3,4).
RESULTS: The peak of motor unit discharge rate occurred before the onset of force and discharge rates decreased thereafter. The maximal motor unit discharge rate was associated to the rate of force development and impulse, at the whole population level ($R2 = 0.71$ (0.12), $P<0.001$). Moreover, the peak motor unit discharge and explosive force variables were correlated with an estimate of the efferent corticospinal input, that was measured as the speed of motor unit recruitment before the generation of afferent feedback ($P<0.05$).
CONCLUSION: We show for the first time the full association between the effective neural drive to the muscle and human rate of force development. The results obtained in this study indicate that the maximal contractile speed capacity of the human tibialis anterior muscle is determined by the discharge rate of motor neurons preceding force generation.

EFFECTS OF THREE DIFFERENT RATES OF FORCE DEVELOPMENT ON ALPHA MOTOR INHIBITION AT DISTINCT TORQUES

FLÜTHMANN, N., KATO, K., BLOCH, O., KANOSUE, K., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Recent research on consecutive voluntary movement sequences suggests alpha-band oscillations to play an important role in muscle (de-)activation tasks and, thus, in the progressive inhibition of motor-related cortical areas. This regulatory domain may coordinate complex muscle activities in daily movement performances (e.g. pacing, timing, inhibiting perturbation); however, it has yet been poorly understood. Therefore, the aim of this study was to investigate alpha-band activity (7-13 Hz) in fast vs. intermediate vs. slow isometric muscle contractions at distinct lower torques of maximum voluntary contraction (MVC) when combined with subsequent instant muscle relaxations.
METHODS: In the proposed study, 15 healthy subjects performed three series of ten submaximal isometric palmar flexions (i.e., motor tasks). While meeting different rates of force development (RFD) (i.e., fast, intermediate or slow), participants were asked to reach distinct torque levels (i.e., 20% and 40% MVC) and relax instantly after achievement. Synchronized recordings of EEG (32 Ag/AgCl-electrodes

mounted over motor-related areas), right-limb EMG (i.e., flexor carpi radialis, FCR) and torque served to detect electrocortical oscillations at muscle activation onsets.
RESULTS: Main findings revealed increased alpha activity in fast RFD (in 20% and 40% MVC: p<.001) whereas alpha activity decreased during both intermediate and slow RFD (in 20% and 40% MVC: p<.001) resulting in a continuous decreasing alpha activation pattern from fast to slow RFD. As soon as muscle relaxation set in, alpha activity returned to its baseline regardless of the RFD level.
CONCLUSION: We suggest alpha to desynchronize in proprioceptive demanding motor tasks whereas task-specific alpha synchronization is characteristic for ballistic movements. The reliable post-stimulus alpha rebound may indicate an inhibitory baseline.

OPTIMISATION OF A TECHNIQUE TO ESTIMATE PERSISTENT INWARD CURRENTS IN SPINAL MOTOR NEURONES

MESQUITA, R.N.O., KIRK, B., TAYLOR, J.L., BLAZEVICH, A.J.

EDITH COWAN UNIVERSITY

INTRODUCTION: Motor neurones (MNs) are nerve cells originating in the spinal cord that signal the muscle fibres to contract. Persistent inward currents (PICs) are activated in MN through voltage-dependent channels. PICs amplify the gain of synaptic input, increasing the likelihood of MN firing (1). Combined tendon vibration (TV) and electrical muscle stimulation (ES) induces sustained MN firing, which may reflect the activation of PICs (2). This study aimed to determine the optimum method for the technique by altering ES parameters.
METHODS: Plantarflexor torque was recorded during trials of 33-s periods of Achilles tendon vibration at 115 Hz simultaneous with brief 20-Hz bouts of ES on the gastrocnemius muscle (n=20; 7 men, 13 women). ES started 10 s after TV. ES parameters were varied between trials. Intensity was set to elicit 10, 20 and, if tolerated, 30% of maximal voluntary contraction torque (MVC), pulse width was narrow (0.2 ms) or wide (1 ms), and the stimulus pattern varied (5 x 2-s and 10 x 1-s bouts, with ES ending 5 or 4 s before the end of TV, respectively). Thus, up to 12 different trials were performed in a randomised order. An additional block of trials in the same order was performed in those who responded to the technique (i.e. produced an involuntary torque at the end of the trial). Estimates of PIC activity were analysed with a repeated measures ANOVA with intensity, pulse width, stimulus pattern and block as independent factors.
RESULTS: Six of 7 men but only 5 of 13 women produced sustained motor unit firing during the test (responders). Eight of 20 participants (3 of 11 responders) perceived the 30% trials as painful and thus did not complete trials at this intensity. Involuntary torque during vibration at the end of ES (Tvib), as well as a sequential increase in torque throughout the trial (wind-up effect) were significantly higher in 20% trials compared to 10% trials (n=11; 9.7±9.0 vs 7.1±6.1% MVC, P=0.013, and 4.3±4.5 vs 3.6±3.5% MVC, P=0.016, respectively). Tvib was significantly higher if a combination of wide pulse width and 5 rather than 10 ES bursts was used (P=0.006). Sustained involuntary torque observed 3 s after cessation of TV (Tsust) was significantly higher in trials with wide pulse width (5.4±5.9 vs 4.1±4.3% MVC, P=0.033). Estimates of PIC activity were not different between 20% and 30% trials (P>0.05, n=8). Although there was no significant main effect of block, low levels of reliability were shown for the estimates of PIC activity between blocks.
CONCLUSION: When estimating the strength of PIC activity in MNs innervating the plantar flexors through a combination of Achilles TV and ES on the plantar flexors, 5 x 2-s bouts of ES with a wide pulse width eliciting a 20% MVC seem to provide the most robust responses. However, performing 8 or 12 trials in a row variably influences the strength of PIC activity, and may compromise measurement reliability.

CHANGES IN SUPRAMAXIMAL M WAVE INDUCED BY ECCENTRIC EXERCISE ARE SITE-DEPENDENT IN THE BICEPS BRACHII MUSCLE.

CABRAL, H.V.1, MEIBURGER, K.M.2, MOLINARI, F.2, OLIVEIRA, L.F.1, VIEIRA, T.M.2

(1) UNIVERSIDADE FEDERAL DO RIO DE JANEIRO, RIO DE JANEIRO, BRAZIL; (2) POLITECNICO DI TORINO, TORINO, ITALY

INTRODUCTION: The accomplishment of eccentric exercises with unaccustomed intensity induces muscle damage. Regardless of the method used to quantify this exercise induced muscle damage (EIMD), attention is typically focused on a single muscle site [1]. Previous evidence suggests however the EIMD may manifest in different muscle regions [2]. Here we combine nerve stimulation with high-density surface EMG to investigate the electrophysiological topography of biceps brachii EIMD.
METHODS: Ten male subjects were submitted to following measures during five consecutive days (before and four days after EIMD): (i) perceived soreness of right elbow flexors during passive stretching; (ii) monopolar surface EMGs from biceps brachii with a 64 grid of electrodes while 10 supramaximal current pulses were applied transcutaneously to the musculocutaneous nerve; (iii) two isometric, elbow flexion maximal voluntary contractions (MVC) on a dynamometer. After measurements have been taken at the end of the first day, participants performed 3x10 eccentric, maximal elbow flexions. Single-differential EMGs were computed and for each of the resulting 59 signals, M waves were averaged and their peak-to-peak amplitude was computed. Innervation zone (IZ) was identified visually and, separately for proximal and distal regions from the IZ, the number of active channels (EMGs with greatest amplitude), their relative longitudinal position and their averaged EMG amplitude [3] were assessed to characterize EIMD induced changes on M waves. The one-way repeated measures ANOVA and Tukey post-hoc tests were applied to compare the variables across days.
RESULTS: The MVC significantly decreased at 24, 48, 72 and 96 h after EIMD (P<0.001), while the perceived muscle soreness increased progressively from 24 to 96 h after EIMD (P<0.001). The number of proximal active channels significantly decreased and the longitudinal coordinate of the proximal centroid shifted towards the IZ at 24, 48 and 72 h after EIMD (P<0.007 in both cases). No time effect was observed for the distal number of active channels, the distal centroid location and the average amplitude of EMGs (P>0.146 for all cases).
CONCLUSION: EIMD consistently changed supramaximal M waves elicited from the biceps brachii muscle. With respect to baseline, M waves with largest amplitude were detected from a smaller biceps brachii region up to 72 h from EIMD, possibly because EIMD took place predominantly proximally. While this possibility urges further testing, our results suggest muscle tissue damage manifests locally within biceps brachii, within three days from EIMD.

SEX-AND AGE-RELATED DIFFERENCES IN EMG-THRESHOLD, DETERMINED VIA AN INTERMITTENT ISOMETRIC CONTRACTION PROTOCOL

WOODS, S., DOTAN, R., JENICEK, N., MAYNARD, J., FALK, B.

BROCK UNIVERSITY

INTRODUCTION: The electromyographic threshold (EMGTh) is defined as the point of non-linear increase in EMG amplitude during progressive exercise and is presumed to reflect the onset of accelerated recruitment of higher-threshold (type-II) motor units (MUs). Children have been shown to have higher EMGTh than adults, likely reflecting lesser activation of type-II MUs and supporting the child–adult differential muscle activation hypothesis. Women have lower maximal strength, rate of force development, and greater muscle endurance, compared with men. Such sex-related differences have not been shown in children. There is limited evidence to suggest that adult sex-related differences are associated with muscle-activation differences, but such differences have not been demonstrated in childhood. Therefore, the purpose of our study was to use the EMGTh as a proxy for muscle activation and assess the sex effect on age-related differences in EMGTh.
METHODS: Thirty-five adults (14 women, 21 men) and 31 children (13 girls, 18 boys) completed one-repetition-maximum (1RM) knee-extension and an intermittent, progressive, isometric-contraction (IPIC) protocol to determine EMGTh. The IPIC comprised sets of five 5-s isometric contractions with 3-s rest intervals. Starting at 25%1RM, loads were increased by 3%1RM for each successive set, with 30-s rest between sets, until volitional exhaustion. Vastus-lateralis surface EMG was used to determine EMGTh.
RESULTS: Children's EMGTh occurred at higher relative exercise intensities (57.1±10.0 %1RM) compared with adults (45.3±7.4 %1RM; p<.001). Smaller, statistically non-significant differences were found between boys (55.6±9.2 %1RM) and girls (59.3±11.1 %1RM), while no differences could be shown between men (45.5±7.4 %1RM) and women (44.93±7.9 %1RM). Body-mass-corrected maximal strength was higher in adults (3.9±.6 Nm/kg) compared to children (3.0±.5 Nm/kg; p<.001) and in males (3.7±.7 Nm/kg) compared to females (3.1±.6 Nm/kg; p<.001).
CONCLUSION: Higher EMGTh in children than in adults is consistent with previous findings, suggesting lower type-II MU activation in children and supporting the child–adult differential muscle activation hypothesis. The similar men–women EMGTh values raise the question of whether the known differences in muscle performance stem from other factors (e.g. muscle composition), rather than differential muscle activation.

NEUROMUSCULAR MOTOR UNIT ADAPTIVE STRATEGY IN THE VASTUS MEDIALIS MUSCLE OF YOUNG AND OLD ADULT

HU, C.H., BUI, L., TU, S.J., GUO, L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Older adults with sarcopenia, which is an ageing related phenomenon of muscle mass loss, usually suffer from decreases in both strength and functional performance. Some, therefore, have attempted performing resistance training to prevent sarcopenia before discovering the actual mechanism. However, the causality between function loss and physiological changes is unclear; muscle mass loss cannot fully explain ageing related strength and functional descent. A study suggested that the neuromuscular activation pattern could be a determinant of muscle strength loss in the elderly. This study was aiming to explore difference of the other neurological factors, such as adaptive strategy and neuromuscular re-innervation, between young and older adult to contribute to discovering the neurological mechanisms and may ultimately to help to improve current elderly training principle.
METHODS: Surface electromyography (sEMG) signals of vastus medialis were collected from eight young (age: 20.5 ± 0.8) and six elderly (age: 64.5 ± 4.5) participants when performing seated knee extension exercises at 25% level of their Max voluntary isometric contraction, which was required from a leg extension machine. During data collection, participants performed sub-maximal contraction following real-time output feedbacks displayed on a monitor. sEMG were processed with a decomposition method to extract information of motor unit firing. Mann–Whitney U test was used to compare the difference in recruited amounts of MU and average firing rates between elderly and young participants. Cross-correlations were calculated to estimate within individual MU synchronisation, and the difference between the elderlies and youngers was compared with an independent t-test.
RESULTS: The average firing rate of the elderlies was significantly higher than younger group while performing the same level of sub-maximum exercise (Young: 12.45 ± 2.04, Old: 16.83 ± 3.50 pulse per second, p = 0.02). Irrespectively, no difference was found in the total amount of MU recruitment during the task (elder: 19.67 ± 3.67, younger: 21.75 ± 7.85, p = 0.36) nor the median MU firing synchronisation (Young: 0.29 ± 0.03, Old: 0.31 ± 0.03, p = 0.15).
CONCLUSION: This study demonstrated different neuromuscular characters between young and elders when performing the same level of leg exercise task. This difference may provide some hints for discovering ageing-related strength and function loss. For example, increased motor unit firing rate may represent worse efficiency in neuromuscular control despite the same recruitment amount and quality. Future study should consider combining in vivo measurement of muscle size to clarify if this EMG difference is related to the loss of muscle strength or mass before recruiting symptomatic elder participants for further investigation.

OP-MI04 Youth football

A MULTIDIMENSIONAL INSIGHT INTO THE DIFFERENCES BETWEEN BOYS AND GIRLS WITHIN AUSTRALIAN SOCCER

O'BRIEN-SMITH, J., BENNETT, K.J.M., FRANSEN, J., SMITH, M.R.

UNIVERSITY OF NEWCASTLE

INTRODUCTION: Developmental differences play a large role in the disparities between male and female athletes. However, research in female soccer is scarce, little is known about the key performance characteristics of female players throughout adolescence. Therefore, this case study aimed to examine the performance characteristics of female soccer players within different age cohorts, comparing them with their male counterparts.
METHODS: Following a cross-sectional study design, 77 female athletes (10-17 y) and 182 male athletes (9-16 y) from a high-level Australian soccer academy under the guidance of a professional club participated in generic and soccer specific assessments. Three develop-

mental stages (sampling stage: 9-11 y; specialisation stage: 12-14 y; and investment stage: 15-18 y) grouped the athletes as they undertook assessments of anthropometry (height, body composition, biological maturation), physical fitness (lower limb power, speed and acceleration, change of direction and intermittent running), motor competence (Körperkoordinations Test für Kinder), dribbling performance (UGent dribbling test) and decision-making (video-based task).
RESULTS: MANOVA revealed significant interaction effects for age and sex on anthropometry, motor competence & physical fitness ($p < 0.001$, $\eta 2p = 0.131$-0.216); while only main effects of sex and age were revealed for decision-making and dribbling performance ($p < 0.001$, $\eta 2p = 0.053$-0.250). Females had better mean scores for several variables in the sampling stage (motor competence and intermittent running), whereas males in the investment stage outperformed the females in all areas of physical fitness and some motor competence. Males had greater performance scores for decision-making and dribbling performance at all ages.
CONCLUSION: There are contrasting differences of males' and females' generic and soccer-specific performance-related characteristics at a young age. Hence, this study argues that, in order to maximise the size of talent pools in Australian soccer and enhance skill development, young male and female players should train and play together until the end of the sampling stage (~12 y). Additionally, female athletes in the current cohort have a physical advantage in the specialisation stage, however, this advantage disappears for females' in the investment stage, a finding dissimilar to previous research. This contrast between the females of these different stages may represent the loss of talented females during late adolescence, either by deselection or due to drop out; potentially signifying a lack of development and support for females in Australian soccer. Further research is needed to understand the development pathway of female soccer players.

A PROFILE OF THE PHYSICAL, TECHNICAL AND TACTICAL SKILLS, AND PATHWAYS THAT UNDERPIN EXPERTISE IN AUSTRALIAN YOUTH SOCCER PLAYERS

BRUCE, L.1, RAYNOR, A.J.2, KELLER, B.S.2

1. DEAKIN UNIVERSITY. 2. EDITH COWAN UNIVERSITY

INTRODUCTION: Understanding the development of expertise is complex due to the interacting factors accelerating or inhibiting talent pathway progression. As such, contributing factors are often studied in isolation with little understanding of the interactions that may occur between them. The aim of the current study was to identify the physical, technical, tactical and developmental profiles of Australian youth soccer players that discriminate between three different skill levels.
METHODS: 36 male soccer players (age = 17.06 ± 0.49 years) from three playing cohorts completed eleven physical, four technical and one tactical skills test along with the Developmental History of Athlete Questionnaire (Hopwood, 2013). Initial multivariate ANOVA analyses within each separate skill testing battery revealed four physical (height, yo-yo intermittent recovery test level one (yo-yo IRT1), 30m sprint, 20m flying sprint), the four technical (Loughborough Soccer Passing Test, the long passing test, shooting test and the ball control test) and the decision making skill tests were able to reveal differences in performance between the playing cohorts. A decision tree analysis was undertaken using R Studio, with the significant factors from the previous analyses included along with selected DHAQ factors (based upon previous research in high performing team sport athletes) to determine those variables that were most indicative of being selected in the top playing cohort.
RESULTS: Initial analyses showed that performance on the yo-yo IRT1 and dominant foot performance from the long passing test were the greatest indicators of cohort selection. Neither decision making performance or any factors from the DHAQ were indicative of selection in the top cohort in the current model.
CONCLUSION: Findings from the current study provide an indication of the interactive nature of physical, technical, tactical and developmental factors in athlete development. Whilst decision making and developmental variables from the DHAQ were able to differentiate between cohorts when examined in isolation, when combined with physical and technical skill assessments, they did not contribute to the overall model of cohort selection. This research body provides evidence that a smaller number of tests could be utilised in athlete testing to identify players who could be placed into talent development environments to further their pathway progression.

HOW TO IMPROVE YOUR NON-PREFERRED FOOT? TRAINING TRANSFER FROM TASK-SPECIFIC SKILLS TO SMALL-SIDED GAMES IN YOUNG SOCCER PLAYERS. THE INEX PROJECT.

FERNANDES, T.1, BARREIRA, D.1, BAGATIN, R.1, PADILHA, M.1, RIBEIRO, J.1, ABARGHOUEINEJAD, M.1, GUIMARÃES, E.1, FERNANDES, R.1, BAXTER-JONES, A.2, MAIA, J.1

1.CIFI2D, FACULTY OF SPORTS, UNIVERSITY OF PORTO; 2.COLLEGE OF KINESIOLOGY, UNIVERSITY OF SASKATCHEWAN

INTRODUCTION: Previous research has shown that non-dominance of feet is an important factor in a soccer players´ expertise and should be developed from early ages. This type of training is performed in decontextualized conditions or in isolated drill settings which raise issues related to its efficiency. Therefore, this study aimed to investigate whether right-foot (RF) or left-foot (LF) passing and shooting specific tasks, chronological age and years of training were linked to greater efficacy of specific skills in a game setting.
METHODS: The University of Queensland Football Skill Assessment Protocol [1], along with the System of Assessment of Functional Asymmetry of the Lower Limbs in Football [2] were used to assess right-or-left foot accuracy in task-specific shooting/passing over 20 meters, and to assess the efficacy index of the same skills in five-a-side soccer games, respectively. We tested 96 young male soccer players (mean age 3.7±0.81 yrs; mean years of training: 6.9±2.30) recruited from six clubs of the Porto Soccer Association (north of Portugal). All players were recruited from the In search of excellence in sport - a mixed-longitudinal study in young athletes (INEX) study. Robust Generalised Linear Models developed in STATA software (alfa=5%) were used to predict the influence of right-or-left passing/shooting accuracy over 20 meters, chronological age and years of training in passing/shooting efficacy index.
RESULTS: Descriptive statistics were: for passing accuracy over 20 meters (RF=4.16±1.69; LF=3.51±1.46), shooting accuracy over 20 meters (RF=3.33±1.69; LF=2.97±1.47), passing efficacy index (RF=6.36±2.80; LF=1.84±2.67) and shooting efficacy index (RF=5.84±3.51; LF=2.04±2.95). Results indicated that RF and LF passing accuracy over 20 meters statistically improved, on average, the RF (b=0.59±0.16; p<.01) and LF (b=0.17±0.86 p<.05) passing efficacy index in five-a-side soccer games, respectively. Also, the LF passing efficacy index was negatively associated with chronological age (b=-3.8±.16; p<.02). On the other hand, years of training and right-or-left foot shooting accuracy were not statistically significant to right-or-left shooting efficacy index (p>.05).
CONCLUSION: Players with higher right-or-left foot passing accuracy over 20 meters presented greater right-or-left efficacy index of the same motor skills in five-a-side soccer games. Also, older players used the LF less successfully in the five-a-side soccer games. Years of training did not explain the right-or-left efficacy index in five-a-side soccer games, which could be due to the type of practice or training

quality. This study suggests that the 20 meters passing specific task could be employed as an exercise training regime to increase the right-or-left foot efficacy of players and could be used to identify young players passing abilities.

RELATIONSHIP BETWEEN CHANGES IN AEROBIC FITNESS AND A TRAINING INDUCED FATIGUE RESPONSE IN ELITE YOUTH FOOTBALL PLAYERS

FITZPATRICK, J.F., MUSHAM, C., HICKS, K.M., HAYES, P.R.
NORTHUMBRIA UNIVERSITY

INTRODUCTION: With the demands of training and matches increasing and time for recovery decreasing, methods for reducing fatigue and/or increasing the rate of recovery are of paramount importance to elite football players. It has been suggested that improvements in aerobic fitness will enhance the ability to recover between repeated bouts of high intensity exercise (1). An increase in aerobic fitness could therefore reduce the fatigue associated with football training and match play. Recent research has established an association between the time spent above maximal aerobic speed (MAS) in training and improvements in aerobic fitness (2). The aim of this study was to determine whether, in elite youth male football players, an accumulative time above MAS (t>MAS) would increase aerobic fitness and attenuate the fatigue response following a standardised training session.
METHODS: Eleven elite youth male football players, completed a 1500 metre time trial to estimate MAS (km.h-1) at the start and the end of a five week intervention. Players were randomly assigned to either a MAS training group (n=5) or a repeated sprint (RS) training group (n=6). The MAS group completed an interval training protocol targeting 13 minutes t>MAS per week. Based on previous research (2) this would predict an improvement in aerobic fitness of 4.7%. Players fatigue response following a standardised training session was measured pre and post intervention by assessing; subjective ratings of fatigue and muscle soreness, drop jump reactive strength index (DJ-RSI), and a sub-maximal run measuring PlayerLoad™ mediolateral (PLML) and percentage contribution PlayerLoad™ vertical (PLV).
RESULTS: Clear improvements in aerobic fitness were observed for the MAS group (+3.0%, ES = 0.42; 90% CI 0.14 to 0.70) but not the RS group. Furthermore, a clear between group difference for changes in aerobic fitness was observed (+2.3%, ES = 1.74; 90% CI 0.09 to 3.38). A clear attenuation of the fatigue response following a standardised training session was observed for the MAS training group for all fatigue measures, apart from PLML. Furthermore, these improvements where substantially greater than changes within the RS training group.
CONCLUSION: Results indicate clear improvements in aerobic fitness were elicited from a five week intervention targeting weekly increases in t>MAS. Consequently, this improvement in aerobic fitness facilitated a clear attenuation of training induced fatigue. This has important implications for the management of training load and fatigue in elite football players.

ATHLETE MONITORING ACROSS A COLLEGIATE FOOTBALL (SOCCER) PRE-SEASON

FIELDS, J.B., SHORT, J.L., LAMEIRA, D.M., MERRIGAN, J.M., BISCARDI, L.M., WHITE, J.B., JONES, M.T.
GEORGE MASON UNIVERSITY

INTRODUCTION: Sport training requires a balance between periods of overload and recovery if adaptations are to be engendered and overtraining prevented. Inadequate recovery can lead to nonfunctional overreaching and overtraining, which may result in a reduced performance and heightened risk of injury (1). Comprehensive load monitoring may help in understanding how athletes adapt to training, yet this area remains understudied in American elite collegiate athletes. The pre-season phase is of particular concern because training loads are often 2-4x greater than in-season (2). The purpose was to examine the relationship between external and internal load markers within a collegiate football (soccer) pre-season.
METHODS: Elite male football (soccer) athletes (n=20; mean±SD age: 20.3±0.9 yr; body mass: 77.9±6.8kg; body height: 178.87±7.18cm; body fat: 10.0±5.0%; VO2max: 65.39±7.61mL/kg/min) participated. Fatigue, soreness, sleep, and energy were collected daily using Likert scales. Total distance (TD), player load (PL), high-speed distance (HSD, >6.04 m/s), high inertial movement analysis (IMA, >3.5m/s/s), and repeated high intensity efforts (RHIE) were collected in each training session using GPS/GNSS technology. At 5 minutes post-training, athletes reported their rate of perceived exertion (RPE; Borg CR-10 Scale). Session RPE (sRPE) was calculated via multiplying RPE by training session duration. Multilevel models assessed the bi-directional prediction of load markers on fatigue, soreness, sleep, energy, and sRPE ($p<0.05$).
RESULTS: Morning ratings of soreness and fatigue, respectively, were predicted by previous afternoon practice's TD ($p=0.001$), PL ($p=0.001$), HSD ($p=0.003$), IMA ($p=0.005$), RHIE ($p=0.002$), and sRPE ($p=0.005$). Morning soreness negatively predicted that day's afternoon practice TD ($p=0.002$), PL ($p<0.001$), HSD ($p=0.028$), IMA ($p=0.002$), RHIE ($p=0.005$), and sRPE ($p<0.001$). Morning fatigue negatively predicted afternoon practice's TD ($p=0.002$), PL ($p=0.001$), IMA ($p=0.006$), RHIE ($p=0.002$), and sRPE ($p=0.003$). Perceived energy was not affected by previous day's training load, but positively predicted TD ($p<0.001$), PL ($p<0.001$), HSD ($p<0.001$), IMA ($p=0.048$), RHIE ($p<0.001$), and sRPE ($p<0.001$) for same day practice. Duration of previous night's sleep positively predicted TD ($p=0.02$), HSD ($p=0.02$), and RHIE ($p=0.046$) for the following day's practice. Further, IMA positively predicted sleep duration later that night ($p=0.002$).
CONCLUSION: Measures of training load were highly related in pre-season. Training loads exhibited at practice were successful in predicting next day's ratings of soreness and fatigue. In turn, soreness, fatigue, and energy predicted load measures at same day's practice. Utilizing self-assessment scales with positional monitoring technology may enhance the understanding of training responses and inform training program development.

SEDENTARY LIFESTYLE, BODY ECOLOGY, AND SUSTAINABLE DEVELOPMENT

LOLAND, S.

THE NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction
In post-industrial societies, sedentary lifestyle is considered one of the main challenges to public health and individual well-being. Increase in physical activity (PA) is viewed as a main preventive measure (World Health Organization (WHO) 2018). For adults, WHO recommends a minimum of 150 minutes of moderate-intensity activity throughout the week, and for children and adolescents the recommendation is 60 minutes of moderate to vigorous-intensity activity daily.
Method
Typically, public PA recommendations are based on instrumental justification. Balanced dosages of PA promote public and individual health, and insufficient PA has become one of the leading risk factors for global mortality (WHO 2018). As an alternative, and in line with phenomenological analyses outlined in the literature on body ecology (Sirost et al 2018), a holistic justification is developed with the ideal of natural movement within a sustainable environment.
Results and discussion
Firstly, natural human movement is portrayed as implying both spontaneous and planned exploration of human embodied possibilities in time and space and in depth and width. Evolutionary speaking, the human body is designed for an optimal balance between movement and rest. It is demonstrated how the challenge of sedentariness can be met with facilitating for natural movement in everyday life.
Secondly, and with reference to urban space (Sallis et al 2016), an examination is made of possibilities and boundaries of urban environments for playful exploration of movement. With several practical examples, it is argued that such exploration is enhanced in environments that meet requirements on sustainability.
In a final section, potential criticism is addressed of sustainable body ecology perspectives as utopian. It is argued that emerging cultural and political trends support the perspectives, and that development of movement-friendly and sustainable urban environments is a realistic future scenario.

GLOBALIZATION AND PROSPECT OF SPORTS TOURISM IN EAST ASIA

JUN, H.M., KIM, K.S., CHO, S.R.

MOKPO NATIONAL UNIVERSITY

The purpose of this study is to propose globalization plans and prospects of Sports Tourism in East Asia. For this purpose, the study looked into the current state of sports tourism, benefit of sports tourism, and then I looked at cases of sports tourism in Asian countries and examined globalization plans and prospect of sports tourism in Asian countries. As a research method, case study and literature survey were conducted. The subjects of this study are Korea, Japan, China, Vietnam, Thailand and others such as united state and australia. Data collection was done through literature data and cases from each country. Data analysis was analyzed by case and content analysis. he findings were as follows: First, sports tourism has economic value, socio-cultural effect, environmental effects. Second, sports tourism contributes to national and community development. Third, In recent Sports tourism in East Asia is regarded as a sustainable tourism resource and receive much policy support. The last, in order to globalize sports tourism, we must utilize local resources, storytelling through sports heritage, linkage with local festivals, and above all, the unique brand image of each country. Future sports tourism will become popular with special interest tourism. The future prospect of sports tourism is very bright. This can be found from the fact that sports tourism can be accessed in various forms such as tourism for sports and tourism through sports, and has potential and potential in terms of development of tourism resources and sports.

THE ROLE OF SPORT EXCHANGES IN PROMOTING CHINA'S INTERNATIONAL RELATIONS

YUAN, Z.

BEIJING SPORT UNIVERSITY

24th annual ECSS Congress Prague/Czech Republic, 3 - 6 July 2019
The Role of Sport Exchanges in Promoting China's International Relations
Yuan, Z.
Beijing Sport University
Introduction
Based on the principle of "Amity, Sincerity, Mutual Benefit and Inclusiveness", people-to-people exchanges have become the third pillar of promoting China's international relations along with political-security cooperation and economic cooperation. The exchanges can be in a variety of forms, like education, culture, and sport. Sport exchanges as a tool play an important role. What is sport exchange? Why is it important in China's international relations? How has China utilized it and what will China do to promote its international relations with developed and developing countries?
Methods
The paper analyzes how sports exchanges promote China's international relations with both developed and developing countries. Previous studies will be reviewed; historical and current situations will be studied; future possibilities will be predicted.
Results and Discussion
China's sports exchanges with developed and developing countries take different forms. The activities with developed countries are on a fuller scale of exchanges, such as knowledge sharing, well-known sports stars as "ambassadors", with bilateral benefits. In contrast, the

sport exchanges with developing countries often focus on providing financial aids; for example, the wrestling rings in Senegal built by China have become a symbol of friendship between the two countries. In recent years, China has reshaped its international image through hosting sports competitions like the 2008 Beijing Olympics and 2013 Nanjing Youth Olympics Games. China is now confident to use 2022 Winter Olympic Games as a propeller to improve its multilateral relations and influence the world in the near future.

A MIXED METHODS FIDELITY ASSESSMENT OF A MENTAL SKILLS TRAINING PROGRAMME FOR DISADVANTAGED YOUTH

TIDMARSH, G., WHITING, R., THOMPSON, J.L., CUMMING, J.

UNIVERSITY OF BIRMINGHAM

Introduction: Mental skills training (MST) programmes have been used by athletes to develop techniques, skills and qualities that promote successful performance (2, 3). MST programmes have been adapted and applied to community-based programmes. Homeless youth often lack the mental skills required to transition from an unstable period to one of stability. This study assesses fidelity of delivery style of an MST programme for homeless youth (MST4Life™), consisting of 10 sessions and four days of outdoor adventure education (OAE), which is vital to ensuring measured improvements in youth health, wellbeing and employment/education status can be attributed to the intervention.

Methods: A mixed methods study design was employed. A pilot study aided development of a 29-item tool, rating facilitator behaviours around basic psychological needs (1) and facilitation skills. Following the pilot study, observations were carried out across four project sites by three observers. Facilitators (N=7) completed a self-report rating scale and reflection post session. Quantitative data were analysed using descriptive and non-parametric statistics; qualitative data were analysed via inductive thematic analysis.

Results: Quantitative results showed the programme was delivered with high fidelity (average observation score 87%, average self-report score 89%; no significant difference p>.05). Two higher-order themes were developed highlighting enabling factors (e.g. communication, positive participant behaviour) and barriers (high support needs of young people and deviation from strengths-based approach by service provider staff) to delivering sessions with high fidelity.

Discussion: Scores showed high adherence to intended delivery style; Improvements in participants' health, wellbeing and employment/education status can thus be correctly attributed to the intervention. Highly experienced facilitators can overcome barriers to delivering MST4Life™ in a need supportive style through communication and support from instructors during OAE. It is recommended that interventions include fidelity evaluations as part of their design, and that observers and facilitators undergo extensive training to increase the likelihood of adherence to intended delivery style.

CLASSROOM STANDING DESK AND TIME-SERIES VARIATION IN SEDENTARY BEHAVIOUR AND PHYSICAL ACTIVITY AMONG PRIMARY SCHOOL CHILDREN

KIDOKORO, T., SHIMIZU, Y., EDAMOTO, K., SUZUKI, K., ANNEAR, M.

INTERNATIONAL CHRISTIAN UNIVERSITY

INTRODUCTION: Sedentary behaviour (SB) is associated with increased risk of all-cause mortality. Previous studies have reported that children spend more time in SB during school hours than non-school hours (Abbott et al, Obesity, 2013). Environmental intervention within classroom settings may reduce children's SB. Preliminary evidence suggests that the introduction of the standing desks has potential to reduce SB among primary school children (Clemes et al., J Public Health, 2016; Minges et al., Pediatrics, 2016), although evidence in this area is scarce. It is not known how introduction of the standing desks in classroom settings influences daily and hourly variations in activity. The purpose of the present study was to examine the effects of the standing desks on time-series variation in SBs and PA among primary school children.

METHODS: Thirty-eight children aged 11-12 years (22 boys and 16 girls) from two classrooms at a primary school in Nagano, Japan participated in this study. One class was allocated as the intervention group, and the other was allocated as the control. In the intervention class, participants were provided individual, height-adjustable standing desks for 7 months. Participants were also instructed to change their posture as frequently as possible during school hours. The control class were requested to continue with their usual practice. Time spent in SBs, light-intensity physical activity (LPA), and moderate to vigorous intensity physical activity (MVPA) at baseline and follow-up

was measured with using accelerometers (ActiGraph) in the both classes. Two-way ANOVA was used to examine the effects of the classroom standing desks on daily variation in SB and types of PA.
RESULTS: There were significant interaction (class*time) effects in SB (F (1, 36) = 4.95, p = 0.035, eta squared = 0.082), suggesting that time spent in SB in the intervention class was significantly decreased by on average, 18.3 min/day, while there was no change in the control class. Additionally, there were significant interaction effects in MVPA (F (1, 36) = 9.22, p = 0.005, eta squared = 0.213), suggesting that time spent in MVPA in the intervention class was significantly increased by on average, 19.9 min/day, while there was no change in the control class. There was no significant interaction effect in LPA. Our time-series analysis showed that time spent in SB during morning classes (9am and 10am) was significantly decreased while time spent in MVPA during the same period was significantly increased after introduction of the standing desks.
CONCLUSION: Introduction of classroom standing desks may significantly decrease SB and increase MVPA among primary school children. In particular, SB reduction in the morning classes (9am and 10am) seems to be accounted for by an increase in MVPA.

A GORDIAN KNOT: THE SELECTION PROCESS FOR PERMANENT PHYSICAL EDUCATION TEACHING POSITIONS IN SPAIN

GONZÁLEZ-CALVO, G., VAREA, V., HORTIGÜELA-ALCALÁ, D.
UNIVERSITY OF VALLADOLID, ÖREBRO UNIVERSITY, UNIVERSITY OF BURGOS

Teaching is a profession in which personal past experiences are particularly relevant, as they are based on concrete relationships and situations. The events lived by teachers are often so intense that they may influence their personal and professional subjectivities. This possibility is even more problematic among long-term interim teachers, who are usually treated as 'new teachers' by the executive board of school, despite having several years of teaching experience. Similar to the Gordian knot, the selection system for permanent teaching positions in public schools in Spain often generates challenging circumstances which shape teachers' personal and professional subjectivities and their pedagogical practices.
This paper explores the ways in which a cohort of long-term interim Physical Education (PE) specialist teachers with more than 14 years of teaching experience respond to, live and negotiate their personal and professional subjectivities according to the selection system for permanent teaching positions in Spain. Specifically, the paper aims to: (a) explore the possible influences of the selection process system in the personal and professional subjectivities of teachers; (b) examine the professional development among long-term interim teachers; and (c) investigate how interim employment influences pedagogical practices.
Semi-structured interviews were used to collect data. Participants were asked to reflect on their perceptions and experiences of employment as long-term interim teachers; and their feelings towards themselves, their work and the people with whom they interacted.
The results reflect the pressure of the Spanish educational system on these educators who, to a large extent, undermined their commitment to teaching and their enthusiasm towards the profession. Although the participants each had more than fifteen years of teaching experience, they were still employed in interim positions – a situation which is very common in Spain. Their interim appointments prevented their full recognition within the education system, as teachers with 'full rights', which resulted in conflicts and dilemmas. These included compromised interpersonal relations with their colleagues and executive boards, and feelings of insecurity, incompetence, isolation and loneliness, which influenced their professional and personal subjectivities.
It is necessary, therefore, that we understand neoliberal discourses and practices, how they work and their possible effects, so that their normalising and naturalising features, such as considering normal to hold an interim position in PE for life, can be interrupted. This paper hopes to contribute to a fruitful dialogue around the 'competitive system' and neoliberalism, and to show how this scenario has altered the essence of teaching that can lead teachers to feelings of worry, exhaustion, and disenchantment with their profession.

CARDIORESPIRATORY FITNESS, COGNITIVE FLEXIBILITY AND SCHOLASTIC PERFORMANCE IN CHILDREN: EXPLORING MEDIATION MECHANISMS

YANGUEZ ESCALERA, M.1,2, HILLMAN, C.H.3, CHANAL, J.1,2
1: UNIVERSITY OF GENEVA, 2: DISTANCE LEARNING UNIVERSITY SWITZERLAND, 3: NORTHEASTERN UNIVERSITY

INTRODUCTION: Research in children indicates that physical activity (PA) and enhanced cardiorespiratory fitness (CRF) have a positive relationship with executive functions (EF) and scholastic outcomes (Donnelly et al., 2016). However, little is known about how CRF acts on EF to explain academic performance. This study aimed to understand how CRF and scholastic performance might be mediated by cognitive flexibility, one component of EF.
METHODS: Preliminary data were analyzed from a large study that will be completed in 2019. During the 2017-18 school year, 67 children (8 to 12 years) were recruited from Geneva (Switzerland) schools. To evaluate cognitive flexibility, we used 3 cognitive tasks (two task-switching paradigms and the trail making test). To evaluate CRF, children completed the 20 meter shuttle run test. This test requires continuous running between two lines spaced 20 meters apart, with increasing speed each minute (+0.5 km/h, starting at 8 km/h). Structural Equation Modelling (SEM) was performed to evaluate the relationship between CRF, cognitive flexibility and school grades.
RESULTS: The first model showed that CRF was significantly related to grades in Reading & expression (β=.22, p=.06), Grammar & vocabulary (β=.34, p<.05) and Math (β =.52, p<.05). A second model showed that CRF significantly predicted cognitive flexibility (β=−.55, p<.05), showing that higher CRF is related to lower switching cost across cognitive flexibility tasks. We then performed a third model to test whether the link between CRF and grades were mediated by enhanced cognitive flexibility, with the results confirming the mediation of cognitive flexibility on Reading & Expression (β=-0.82, p<.05), Grammar & Vocabulary (β=-.86, p<.05) and Math (β=-.72, p<.05).
CONCLUSION: The relationship between CRF and academic performance has been observed in previous studies; however, the current findings extend prior work by showing that this relationship is mediated by children's cognitive flexibility, an important aspect of EF.

EDUBALLS - AN INNOVATIVE INTERDISCIPLINARY TEACHING APPROACH TO PHYSICAL EDUCATION FOR PRESCHOOL AND ELEMENTARY SCHOOL

ROKITA, A., CICHY, I., WAWRZYNIAK, S.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION WROCŁAW

Introduction
The interdisciplinary teaching is a current trend in elementary school education. Interdisciplinary education is a process in which two or more subject areas are integrated with the goal of fostering enhanced learning in each one (Cone, Werner, & Cone, 2009). In Poland, EDUball - an innovative, interdisciplinary teaching approach to physical education (PE) in preschool and elementary school education has been developed since 2002. The EDUball approach combines physical education and academic learning. The EDUball method uses a didactic teaching aid in the form of EDUballs to integrate a variety of subjects such as language studies and mathematics into PE. The set of EDUballs consists of 100 balls for small team sports games with letters of the alphabet, numbers, and signs of mathematical operations (Rokita & Cichy, 2013). The concept relies on the development and improvement of children's academic and motor performances through movement, play and having fun. The aim of this paper is to present the effectiveness of PE program with EDUballs on childrens academic and motor skills in preschool and elementary schools in Poland.
Methods
The research were carried out between 2002-2018 and involved over 1000 children. All the studies obtained the written consent from the school's headmasters and children's parents/guardians. The research used a pedagogical experiment method and a parallel groups technique (experimental and control groups). Studies lasted from 6 months to 3 school years. The academic and motor performances of all children were assessed before and after the implementation of the experimental program. Experimental groups followed a PE program enhanced with EDUballs twice per week at the sports hall. The experimental factor was the integration of literacy and numeracy content using EDUballs in an effort to reinforce lessons previously taught in regular classes.
Results
Children participating in PE with EDUballs significantly improved language (reading and writing), math and graphomotor skills after experimental program. Participation in PE integrated with EDUballs had a positive influence on measures of physical fitness, motor coordination, eye-hand coordination and temporal-spatial orientation.
Discussion & Conclusion
Integrating PE with enhanced academic content with EDUballs had a positive influence on the academic and motor performances of the children. The findings suggested that the EDUball approach may also serve as a therapeutic teaching aid for dyslexic children. The interdisciplinary model for PE with EDUballs is an effective teaching approach to improving motor and academic performances.

EVALUATION OF AN INCREASED NUMBER OF PHYSICAL EDUCATION LESSONS

REIF, A.

UNIVERSITY OF VIENNA

Introduction
The daily sports lesson is a much-discussed topic in Austria. The aim is to increase the number of physical education (P. E.) lessons in school to lead children and adolescents across all social classes to a more active lifestyle. The present study aims to evaluate the effect of two additional P. E. lessons on the development of motor skills as well as on self-esteem and analyzes childrens' movement behavior outside school.
Methods
The sample consists of 140 pupils at the age of 12 to 14 years including an observation group (n=57) with five P.E. lessons and a control group (n=83) with three P.E. lessons per week. The Deutscher Motorik-Test has been used to measure the motor skills, self-esteem was tested using the ALS-Test, and to analyze the movement behavior outside school a specific questionnaire was created. The observation period of 1.5 years includes three data-collection-points.
Results and discussion
Based on lower baseline results, the control group, having fewer weekly P.E. lessons, achieved a significantly better development of their motor skills ($p<0.01$), while regular participation in sports clubs lead to a significantly higher development of motor skills at all three data-collection-points ($p=0.02$). There is no significant difference in the development of self-esteem between the observation and control group. The results regarding extracurricular physical activity show that more frequent P. E. lessons do not compete with sports club participation, but rather form an effective complement.

IS-SH01 Athletes mental health - FEPSAC Symposium

FROM A FIRST INSIGHT TO A DEEPER KNOWLEDGE OF DEPRESSION IN ELITE ATHLETES

NIXDORF, I.

TECHNICAL UNIVERSITY OF MUNICH

Although depression among elite athletes is a topic of interest and empirical data on prevalence rates are recorded, research on mechanisms and underlying psychological variables is still rare. Reviews on this matter suggest depression in elite athletes to be a severe challenge and indicate a connection to sport specific factors such as injuries, overtraining, exceeding stress or the engagement in individual sport disciplines (Frank, Nixdorf, & Beckmann, 2013; Wolanin, Gross, & Hong, 2015). Therefore, the lecture will present research on psychological mechanisms explaining these sport specific factors. In regards to higher levels of depressive symptoms in individual sport disciplines (Nixdorf, Frank, Hautzinger, & Beckmann, 2013; Schaal et al., 2011) negative attribution after failure mediates the relationship

between individual sports and depression scores and appears to be an important psychological variable explaining this effect (Nixdorf, Frank, & Beckmann, 2016). Regarding to specific stressors relevant for depressive symptoms in athletes, results suggest stressors within the sport (e.g. pressure to perform well) to have the most negative impact (Nixdorf, Frank, & Beckmann, 2015). Due to the lack of longitudinal studies, mechanisms leading to depression are just discovered. Consequently, the lecture will present findings based on such longitudinal studies uncovering vulnerabilities increasing the likelihood of higher depression scores in elite athletes.

PERFECTIONISM AND ATHLETE BURNOUT: REVIEW, CRITIQUE, AND RECOMMENDATIONS

MADIGAN, D.

YORK ST JOHN UNIVERSITY

Burnout syndrome is an extreme form of sport disaffection that can afflict athletes. It is comprised of three symptoms, namely, a reduced sense of accomplishment, sports devaluation, and physical and emotional exhaustion. Burnout is a relatively prevalent syndrome among athletes and is a significant threat to an athlete's physical and mental health. To help prevent burnout, it is essential that sport and exercise scientists understand its aetiology. One factor that has been implicated in the development of burnout is perfectionism. Perfectionism is a complex multidimensional personality construct that broadly comprises high personal standards which are accompanied by overly critical evaluations of behaviour. Researchers have used cross-sectional, longitudinal, and meta-analytic techniques to examine the relationship between perfectionism and athlete burnout. In the present talk, I will summarise, discuss, and critique the past 10 years' worth of research on this relationship. In doing so, I aim to provide athletes and coaches with essential information to help prevent burnout.

PROMOTING WELL-BEING AND PREVENTING MENTAL HEALTH DISORDERS: NATURE CONTACT AS A PATHWAY TO RESTORATION AMONG ATHLETES

MACINTYRE, T.

UNIVERSITY OF LIMERICK

INTRODUCTION
Nature based solutions to well-being have been suggested as a means of jointly tackling several societal challenges (van den Bosch et al. 2017). Among the main challenges are climate change, physical inactivity, and mental health problems. Athlete well-being and mental health are similarly under threat according to recent evidence (Moesch et al., 2018). Engagement with nature through green exercise (i.e. physical activity in natural settings) is one possible solution to these broader problems. Among athletes, contact with nature can be used for recovery, restoration and recuperative processes.
METHODS: A concpetual model is proposed which predicts that the combination of exercise, natural settings together with an engagement mindset, the human-nature interaction can be optimised to create synergistic benefits for mental well-being, cognitive function and health. This conceptual model of engagement has particular consequences for athletes during recovery from injury (Kellman et al., 2018). They may be able to use this activity for the purpose of restoration with direct implications for their self-regulation, self-awareness and motivation (Sonnentag et al., 2017). Evidence to support this approach is derived from across the disciplines of environmental, organizational and positive psychology.
CONCLUSION: During times of increased training load this nature based interventions can help ameliorate stress, reduce psychological distress in a way that promotes autonomy and the individuals' capacity for self-regulation. The co-benefits of nature contact in terms of team cohesion, pro-social behaviour and environmental awareness are of significance for athletes, sporting communities and global issues. .

IS-PM01 The effects of acute exercise and long-term exercise training on heart

MYOCARDIAL PERFUSION AND OXYGENATION DURING EXERCISE IN HEALTH AND DISEASE

MERKUS, D.

ERASMUS MC, UNIVERSITY MEDICAL CENTRE ROTTERDAM

Coronary microvascular function and cardiac function are closely related in that proper cardiac function requires adequate oxygen delivery through the coronary microvasculature. Due to the close proximity of cardiomyocytes and coronary microvascular endothelium, cardiomyocytes not only communicate their metabolic needs to the coronary microvasculature, but endothelium-derived factors also directly modulate cardiac function. We propose that the coronary microvasculature plays a key role in the progression of both right and left ventricular dysfunction. Risk factors like (pulmonary) hypertension, diabetes and/or hypercholesterolemia directly affect the coronary microvasculature. Evidence is accumulating that the myocardial oxygen balance is disturbed in the failing heart due to increased extravascular compressive forces and coronary microvascular dysfunction. Importantly, coronary microvascular dysfunction is associated with adverse cardiovascular events. Since alterations in microvascular as well as cardiac function are first revealed during increased physical activity, exercise testing provides a valuable method to interrogate coronary microvascular function. Identification of abnormal microvascular responses, i.e. alterations in neurohumoral influences, endothelial dysfunction and oxidative stress, is an essential step to provide targets for therapeutic interventions to improve microvascular function and thereby delay progression of ventricular dysfunction to overt heart failure.

ECHOCARDIOGRAPHIC ASSESSMENT OF CARDIAC STRUCTURE AND FUNCTION FOLLOWING PROLONGED STRENUOUS EXERCISE

OXBOROUGH, D.

LIVERPOOL JAMES MOORES UNIVERISITY

The human being has evolved over millions of years to become an efficient endurance animal with the primary need to hunt and to survive. Modern day humans however are less physically active than our ancestors and yet it is well established that regular moderate intensity exercise has numerous health benefits. There is however, a growing trend for the human being to push themselves to the limit of endurance with participant numbers at ultra-endurance events increasing annually. This lecture highlights the acute cardiac response to prolonged strenuous exercise as determined by the developing role of cardiac ultrasound (echocardiography) in the assessment of structure and function. Furthermore the question as to whether this 'event' acts as a stimulus for adaptation or something more sinister is discussed and evidence for chronic remodelling of the heart is presented with reference to myocardial fibrosis and exercise induced cardiomyopathy.

ACUTE AND LONG-TERM EFFECTS OF EXERCISE ON MYOCARDIAL FUNCTION, PERFUSION AND METABOLISM

HEINONEN, I.

TURKU PET CENTRE & UNIV. OF TURKU

The last presentation of the session would be given by the chair of the session. It would be a combination of acute exercise and long-term exercise training effects summarizing and advancing the ideas presented by the other two previous speakers, but based on measurements done with different imaging techniques in normal healthy humans and highly trained and performing athletes. Key topics to be dicussed would be myocardial perfusion, oxygen extraction and oxygen consumption in human heart and how they are affected by training. It appears that these variables might actually be key factors limiting endurance exercise performance and this topic will be addressed during this presentation. I wil also show and discuss intervention training results and the effects of high-intensity interval training on hearts circulation and metabolism, and compare those to that observed in skeletal muscles, which should be of interest to many participants in the conference.

Invited symposia

IS-SP02 Multi-disciplinary approach in professional football - Sponsored by GSSI

INTERDISCIPLINARY APPROACH TO RETURN TO PLAY FROM MUSCULASKELETAL INJURIES IN PROFESSIONAL SOCCER

HOLOHAN, D., GOMEZ DIAZ, A.

MANCHESTER CITY FOOTBALL CLUB, FC BARCELONA

Once the severity and timelines of the injury are established by the sports medicine team, a joint program will be agreed with the primary aim of recovering the physical performance of the player as soon as possible. In the acute injury phase activity should be maintained, in a safe way that isolates and protects the injured area, as soon as possible. This can be achieved by targeting only the area of the body unaffected by the injury. Activities such as aerobic exercise without impact (anti-gravity), core-stability, upper and lower body strength training may can be completed but with respect to the injury magnitude and location, as well as its typology. As players engage in functional recovery the objective is to recover the player with reference to the timings indicated by the injury diagnosis. Therefore, principles of adequate progression and periodization of the training exercises are recommended to maximize adaptation, whilst minimizing risk factors for re-injury. This session will share how the training load can be quantified and monitored to inform the "return to play" process, while managing re-injury risk. Key indicators of anticipated recovery timelines include regaining baseline strength measures, completion

of high intensity training comparable to (or even greater than) their anticipated match demands, and demonstration of an appropriate level of football-specific cognitive skills and psychological readiness. Sharing the players progress with the interdisciplinary team, as well as the coaching staff, is critical, with the specific frequency dependent on the timelines of "return to play" initially agreed.

MULTI-/INTERDISCIPLINARY APPROACH TO RETURN TO PLAY FROM MUSCULASKELETAL INJURIES IN PROFESSIONAL SOCCER

CLOSE, G.L.

LIVERPOOL JOHN MOORES UNIVERSITY

Both the acute injury and functional recovery phases offer opportunities for the sport nutritionist to engage with the player. Indeed, nutrition support during an injury often results in players who have been reluctant to engage with nutritionists becoming engaged for the rest of their playing careers, having seen a benefit of sports nutrition support. The aim of this presentation will be to share how a dietary plan may be generated and modified depending on the phase of the return to play, as well as the players preferences. Knowing when to intervene and when to 'back-off' is particularly important during the injury period; this requires a deep understanding of the player and their personality. Thus, a close collaboration between the sport nutritionist and sport psychologist is essential. Whilst subtle differences in the nutrition recommendations during the acute and functional phases of recovery exist, both phases have 3 primary nutritional goals:
1. Understand the change in energy demands
The focus during the acute injury phase should be on ensuring sufficient energy for repair and to maintain lean mass. Energy expenditure could be higher during the acute injury phase as a result of the increased energy expenditure of healing combined with the daily early-phase rehabilitation that will be taking place. It is crucial that the sport nutritionist integrates with the entire support team, speaking with the medical staff about the intensity of the rehabilitation and gaining as much information as possible on training load from the conditioning staff.
2. Prevent muscle atrophy and promote muscle repair
It is well accepted, in laboratory-based studies, that limb immobilisation not only reduces muscle protein synthesis but also induced a degree of anabolic resistance to protein the latter of which could be attenuated through increased ingestion of amino acids. Increasing daily protein intake to 2.3 g/kg body mass may prevent the loss of lean mass during reduced calorie and this therefore may be an appropriate daily target. The protein intake should be equally distributed throughout the day, something many football players fail to achieve. Casein supplementation pre-bed (30-40g) has been shown to improve overnight muscle protein synthesis. The risk is that players reduce total protein intake in response to their gym and field-based training loads being reduced. Recommendations, for other nutrition considerations including fish oil, creatine, vitamin D and collagen will also be discussed.
3. Assess the current body composition of the player to track changes and adapt the dietary strategy.
The assessment of body composition is a valuable tool in the return to play process allowing not only for body fat to be routinely assessed (which will help to evaluate if the player has the correct energy balance), but also to monitor changes of lean muscle mass. Appropriate methods of body composition assessment will be shared. Finally, guidance will be provide

RETURN TO PLAY FROM MUSCULOSKELETAL INJURIES: PSYCHOLOGICAL CONSIDERATIONS

DUDA, J., PODLOG, L.W.

UNIVERSITY OF BIRMINGHAM

In this presentation, research on psychological responses to sport injury and rehabilitation (Heil & Podlog, 2012) will be summarised with specific focus on return to play from musculoskeletal injuries in professional football. During the acute (or immobilization) phase, past work indicates that players need to cope with pain and the often accompanying negative thoughts and emotions. Players also face uncertainties regarding the nature and extent of injury damage, recommended course of treatment, and their implications for a successful return to play. Heuristics have been proposed (e.g., Podlog et al, 2018) that can be used by practitioners and athletes themselves to reduce feelings of apprehension and mitigate pain responses in the acute phase. As players progress from acute to the functional recovery phase, promoting adherence to rehabilitation becomes an important challenge. Past studies have pointed to the relevance of motivational factors to the optimising of the rehabilitation process (Brewer & Redmond, 2017) and quality of post-injury performances (Faltstrom et al, 2016). Injured players not only need to regain physical function and the realisation of performance standards but also restore their confidence in their physical abilities and skills (Magyar & Duda, 2000). Theoretically grounded strategies have been proposed for promoting self-determined motivation for rehabilitation (Podlog & Eklund, 2007) and enhancing self efficacy (Zach et al., 2018) during the functional recovery phase. Finally, a case will be made for why and how psychological factors need to be integrated into an interdisciplinary model of return to play.

Oral presentations

OP-PM04 Metabolic fitness and flexibility

THREE DAYS BED REST APPRECIABLY IMPAIRS WHOLE-BODY GLUCOSE DISPOSAL (WHICH IS FULLY RESTORED BY EXERCISE), BUT IS NOT FURTHER ACCENTUATED AFTER 56 DAYS BED REST

SHUR, N.F., SIMPSON, E.J., CROSSLAND, H., STEPHENS, F.B., MACDONALD, I.A., GREENHAFF, P.L.

THE UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Immobilisation reduces insulin-mediated whole body and muscle glucose disposal (GD) (1). However, the rate and magnitude of change in GD and substrate oxidation (SO) during bed rest (BR) is unresolved, particularly during chronic BR. Furthermore, failure to control for dietary energy intake has resulted in a lack of clarity regarding whether end-point measurements are attributable to BR per se and/or overfeeding. We therefore determined whole-body GD and SO during acute and chronic BR whilst maintaining energy balance, and also the impact of prescribed exercise on restoration of GD and SO following acute BR.
METHODS: Healthy males (n=10, 24±1.25yrs, body mass index (BMI) 22.7±0.60) underwent 3 days of -6o head down tilt (HDT) BR, followed by 3 days of unilateral leg exercise (5x30 one-legged maximal isokinetic knee-extensions, 90 degrees per second). A second cohort of BMI matched healthy males (n=20, 34±1.8 yrs, BMI 23.8±0.41) underwent 56 days of -6o HDT BR. An isoenergetic diet was calculated (2) and maintained throughout both studies (30% fat, 15% protein, 55% carbohydrate). A 3 hr hyperinsulinaemic euglycaemic clamp (60 mU/kg lean mass/min) was performed on day -4 (pre BR in both studies), after 3 days BR (acute BR) and 3 days unilateral leg exercise, and after 56 days BR (chronic BR). Indirect calorimetry was performed before and during the final 30 min of each clamp to calculate whole-body SO. A two-way repeated measures ANOVA was performed to detect differences in means on endpoints. A statistical level of $p< 0.05$ was accepted. All data are expressed as mean ± SEM.
RESULTS: Acute BR resulted in a 30% reduction in insulin-mediated GD (normalised to DXA determined lean body mass) from pre BR (11.0 ± 0.75 vs 7.8 ± 0.55 umol/kg/min respectively, $p<0.001$), which was fully restored by 3 days on non BR and unilateral leg exercise (11.7 ± 0.86 umol/kg/min). The rate of insulin-stimulated carbohydrate oxidation was unchanged from pre BR following acute BR (3.69 ± 0.39 vs 4.34 ± 0.22 mg/kg/min, respectively). Compared to pre BR, chronic BR produced a 22% reduction in GD (10.2 ± 0.42 vs 7.9 ± 0.28 umol/kg/min respectively, $p<0.05$) and a 19% decline in the rate of carbohydrate oxidation (3.34 ± 0.18 vs 2.72 ± 0.13 mg/kg/min respectively, $p <0.05$). The rate of fat oxidation under insulin clamp conditions was reduced by both acute and chronic BR, however the magnitude of suppression was less in chronic BR such that fat oxidation was greater Post BR compared to Pre BR (0.85 ± 0.06 vs 0.60 ± 0.07 mg/kg/min, respectively, $p<0.05$).
CONCLUSION: Impairment of whole-body insulin-mediated GD is significant after 3 days of BR, which was fully restored by 3 days non BR and unilateral leg exercise. Surprisingly, the magnitude of this decline in GD during acute BR is not further accentuated after 56 days BR. However, whole-body SO does differ between acute and chronic BR demonstrating dissociation of the regulation of GD from fuel oxidation from the acute to chronic BR state.

EXERCISE-INDUCED IMPROVEMENTS IN POSTPRANDIAL GLUCOSE RESPONSE ARE BLUNTED BY PRE-EXERCISE HYPERGLYCAEMIA

CARTER, S., SOLOMON, T.P.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Exercise potently improves glycaemic control in individuals with hyperglycaemia-related conditions, such as type 2 diabetes, but the magnitude (and direction) of this effect is variable. Isolating factors contributing to this exercise response heterogeneity is vital to optimise the glucoregulatory effects of exercise, and recent evidence implicates the degree of hyperglycaemia as one possible contributor (1-3). Accordingly, the current study investigated whether pre-exercise hyperglycaemia per se impacts the beneficial effect of a single exercise bout upon glycaemic control.
METHODS: Twelve healthy males (age: 23.6 ± 1.5 years, BMI: 22.7 ± 0.7 kg/m2, HbA1c: 5.4 ± 0.1%, VO2max: 41.5 ± 3.3 mL/kg/min) underwent four experimental trials in a randomised order. Glycaemic control was assessed under strict dietary control but otherwise free-living conditions by continuous glucose monitoring for 24h following no exercise (CON), or following 45 mins cycling exercise (70% HRmax) preceded by 3.5h of normoglycaemia (NG-Ex), steady hyperglycaemia (HG-Ex; constant rate glucose infusion) or fluctuating glycaemia (FG-Ex; repeated glucose bolus infusions, with total glucose load matched to HG-Ex). Data are presented as mean ± SEM and were analysed using one-way repeated measures ANOVA.
RESULTS: Pre- and post-trial physical activity and dietary intake were similar between trials, and exercise intensity, work done and energy expenditure were matched between exercise trials (all $P>0.05$). During the 3.5h ± infusion period, average blood glucose levels were higher in HG-Ex (7.6 ± 0.5 mmol/L) and FG-Ex (7.3 ± 0.1 mmol/L) compared to CON (4.8 ± 0.2 mmol/L) and NG-Ex (5.0 ± 0.2 mmol/L) trials ($P<0.01$), and glycaemic variability was greatest in FG-Ex ($P<0.01$ vs. all other trials). Postprandial glucose response, measured as the sum of post-meal glucose iAUC, was significantly reduced by exercise in NG-Ex compared to CON (321.1 ± 38.6 mmol/L/8h vs. 445.5 ± 49.7 mmol/L/8h, $P<0.05$). However, such benefits were blunted when exercise was preceded by steady hyperglycaemia (425.3 ± 45.7 mmol/L/8h) and fluctuating glycaemia (465.5 ± 39.3 mmol/L/8h) in HG-Ex and FG-Ex, respectively (both $P>0.05$ vs. CON).
CONCLUSION: Pre-exercise hyperglycaemia blunted the glucoregulatory benefits of acute exercise upon postprandial glucose response, confirming that hyperglycaemia directly contributes to exercise response heterogeneity. Clinically, coinciding exercise sessions with periods of improved glucose control (i.e. lower, more stable levels) may be a necessary strategy to optimise the therapeutic effects of exercise in individuals with hyperglycaemia-related conditions, such as type 2 diabetes. Our ongoing in vitro experiments will dissect possible molecular mechanisms mediating this hyperglycaemia-induced heterogeneity.

CHRONIC EFFECTS OF HIGH INTENSITY INTERVAL TRAINING ON POSTPRANDIAL LIPAEMIA IN HEALTHY MALES

WILHELMSEN, A., MALLINSON, J., JONES, R., COOPER, S., TAYLOR, T., TSINTZAS, K.

UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Western diets typically feature substantial fat intake and frequent meal consumption, fuelling sustained postprandial lipaemia (PPL) which exacerbates the deleterious effects of endothelial exposure to lipids, low-density lipoproteins and their fragments. When performed before feeding, high intensity interval training (HIIT) acutely reduces PPL, with relatively little energy expenditure or time-commitment. The aim of this investigation was to determine the chronic effects of HIIT on PPL and metabolic health in healthy human volunteers.
METHODS: Eight untrained young males (Mean ± SD: 22 ± 3years, 1.77 ± 0.07m, 67.7 ± 6.2kg) underwent two mixed-meal tolerance tests, before the first- and ≥72h after the final-session of four weeks of HIIT (16 sessions in total; 10x60s bouts of cycling at 90% maximal oxygen uptake [V̇O2max), interspersed by 60s intervals at 45% V̇O2max). Arterialised and deep venous blood samples across the forearm, brachial artery blood flow measurements, and whole-body indirect calorimetry data were obtained before, and at regular intervals for 6h after, consumption of a mixed-meal comprising 1.2g/kg fat, 1.2g/kg carbohydrate and 0.5g/kg protein. Samples of vastus lateralis muscle tissue were obtained at rest while fasted, to assess changes in the protein content of lipolytic enzymes and lipid transporters.
RESULTS: Sixteen sessions of HIIT significantly increased postprandial circulating free fatty acid (FFA) uptake across the forearm, but did not alter fasting or postprandial triglyceride (TAG) concentrations, nor glycaemic control and insulin sensitivity, when assessed ≥72h post-exercise, despite a 10.2 ± 7.7% improvement in 7V̇O2max. Protein content of adipose triglyceride lipase (ATGL) in the vastus lateralis was reduced by 25 ± 21%.
CONCLUSION: These findings demonstrate a sustained improvement in the postprandial clearance of FFA following HIIT, with a concurrent reduction in muscle ATGL content, which may be indicative of intramyocellular lipid accumulation to enhance local substrate availability during exercise. The data also suggests that previous observations of exercise-induced improvements in postprandial TAG handling is a transient effect of the last exercise bout, highlighting the importance of regular exercise (at least every 48h) for maintaining enhanced lipaemic control.

PEAK FAT OXIDATION RATE AND FATMAX ARE ASSOCIATED WITH LONG-DISTANCE CROSS-COUNTRY SKIING PERFORMANCE

HANSEN, M.T., RØMER, T., FRANDSEN, J., LARSEN, S., DELA, F., HELGE, J.W.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Peak fat oxidation rates (PFO) are commonly determined by graded exercise tests (GE). Recently, PFO (1,2) and the exercise intensity at which it occurs (Fatmax) (2) was found to be associated with prolonged endurance performance in men and women. However, the relation between PFO and endurance performance involving upper body (UB) exercise remains to be elucidated. Vasaloppet is a 90 km cross-country skiing race with high demands to UB aerobic capacity as double poling is the predominant technique. Thus, our aim was to investigate the relationship between performance in Vasaloppet and PFO and Fatmax determined by a graded UB exercise test on a ski-ergometer (GEski) in trained men. We hypothesized that a high PFO and Fatmax would be related to a high performance level in Vasaloppet.
METHODS: 45 trained men (age: 38±2 (18-57) yrs., mean±SEM (range)) with a body fat percentage of 16.2±0.6 (9.0-25.4) % and a double poling VO2peak of 54.1±1.1 (41.6-71.2) ml·min-1·kg-1 completed Vasaloppet 2018. Race time of the last 79 km was used as measure of performance in Vasaloppet, due to queue in the initial part of the race among non-elite skiers. Prior to Vasaloppet the participants underwent one test day in a laboratory in which PFO and Fatmax were determined through the GEski consisting of 3 min steps with 15 W increments on a double poling ski-ergometer. Additionally, a previously validated 10-min self-paced protocol (3) was adapted to the ski-ergometer and applied to determine double poling VO2peak, and a venous blood sample was obtained at rest.
RESULTS: The mean 79 km race time was 5:54:50 (3:47:22-8:58:29) h:min:s. PFO was 0.52±0.02 (0.23-0.84) g·min-1 and Fatmax was 47±1 (31-65) % of VO2peak. Linear regression analyses revealed significant negative associations between race time and PFO (r^2=0.10, p=0.044), Fatmax (r^2=0.26, p<0.001) and VO2peak (r^2=0.32, p<0.001) and a positive association between race time and body fat percentage (r^2=0.16, p=0.009). When all significant associations were entered into a forward stepwise regression model, VO2peak and Fatmax together explained 40% of the variation in race time (adj. R^2=0.40, p<0.05) with VO2peak being the strongest predictor (R^2=0.36).
CONCLUSION: In line with our hypothesis we found that performance in long-distance cross-country skiing is associated with PFO and Fatmax determined by a graded exercise test on a ski-ergometer and with double poling VO2peak. However, only VO2peak and Fatmax were independently associated with long-distance cross-country skiing performance with VO2peak being the strongest individual predictor.

FOREARM IMMOBILIZATION-INDUCED INSULIN RESISTANCE OF GLUCOSE UPTAKE IS NOT EXACERBATED BY HIGH-FAT OVERFEEDING IN HEALTHY, YOUNG MALES

DIRKS, M.L., WALL, B.T., OTTEN, B., CRUZ, A.M., DUNLOP, M.V., BARKER, A.R., STEPHENS, F.B.

UNIVERSITY OF EXETER

INTRODUCTION: The rehabilitation from injury often requires a period of physical inactivity via limb immobilization, which leads to substantial muscle loss. This muscle atrophy is accompanied by an overt impairment insulin-stimulated glucose uptake (i.e. insulin resistance), although the underlying mechanisms are currently unknown. Physical inactivity is often accompanied by a state of positive energy balance, particularly in the immobilized limb, which is also thought to induce insulin resistance by the accumulation of fat and lipid intermediates in muscle tissue. We aimed to delineate the role of high-fat overfeeding in inactivity-induced insulin resistance by applying the arterialized venous-deep venous (AV-V) forearm balance method prior to, and following 2 and 7 days of forearm immobilization to directly measure forearm glucose uptake as a measure of insulin sensitivity.

METHODS: Twenty healthy males underwent seven days of forearm cast immobilization combined with a fully-controlled eucaloric diet (CON, n=10, age 23±2 yr, BMI 23.8±1.0 kg·m-2) or a high-fat diet providing 50% excess energy from fat (HFD, n=10, age 23±2 yr, BMI 22.4±0.8 kg·m-2). Prior to casting, and following 2 and 7 days of immobilization, forearm glucose uptake (FGU) was assessed using the AV-V forearm balance method. For this, brachial artery blood flow (Doppler ultrasound) was multiplied by the AV-V difference in blood glucose. FGU was determined in the fasted state, and every 20 min in the 3 hours following ingestion of a mixed macronutrient drink.
RESULTS: Seven days of HFD led to an increase in body weight of 0.9±0.2 kg ($P<0.05$) and an increase in fasting HDL cholesterol ($P<0.05$), whereas fasting triglycerides or total, LDL, and non-HDL cholesterol were unaffected (all $P>0.05$) and no changes were seen in CON (all $P>0.05$). The HFD affected fasting glucose concentrations (interaction effect $P<0.05$), but not postprandial insulin sensitivity (i.e. postprandial glucose and insulin concentrations, and Matsuda index; all $P>0.05$). Two and seven days of forearm immobilization led to a 40±7% and 52±7% decrease in FGU, respectively ($P<0.05$), with no difference between day 2 and 7 ($P>0.05$) and no effect of diet ($P>0.05$).
CONCLUSION: Forearm immobilization leads to a rapid and substantial decrease in FGU, which is not exacerbated by excess energy from dietary fat. These data suggest that disuse-induced insulin resistance is caused by the removal of muscle contraction, likely as a physiological adaptation to match muscle substrate uptake to the decrease in intramuscular substrate use. Although our data demonstrate that high-fat overfeeding does not worsen the development of insulin resistance during local muscle disuse, further research is warranted to establish the role of lipid in disuse-induced insulin resistance, muscle atrophy, and recovery.

THE ROLE OF FAT-FREE MASS IN METABOLIC HEALTH: AN OPPOSING PERSPECTIVE

LAGACÉ, J.C., PAQUIN, J., MARCOTTE-CHÉNARD, A., TREMBLAY, D., BROCHU, M., DIONNE, I.J.
UNIVERSITY OF SHERBROOKE

INTRODUCTION: The metabolic syndrome (MetS) is an accumulation of metabolic abnormalities which increases the risk of cardiovascular diseases and type 2 diabetes. Since fat-free mass (FFM) is a metabolically active tissue, it is generally recognized that a greater FFM has a protective effect on the risk of developing MetS. This assumption is often based on multiple studies reporting FFM as a percentage of body weight (BW). However, recent work from our group suggests that greater absolute FFM could be deleterious to metabolic health. The first objective of this study was thus to investigate if the conflicting conclusions may be explained by the various expressions of FFM (in absolute terms, relative to BW or relative to height). Secondly, we sought to assess the impact of FFM per se on the relative risk of having the MetS.
METHODS: Overall, 5401 individuals (46.4 ± 16.2 y; 27.5 ± 5.0kg/m2) from the NHANES 1999-2006 dataset were included in the analyses. Absolute FFM (kg), FFM index [FFMi; FFM/height (kg/m2)] and FFM% [FFM/total BW *100] were determined using DXA. Quartiles were determined in a sex and age-specific fashion.
The ATP III definition was used to identify individuals with MetS: 1) waist circumference (WC) > 102 cm for men or >88 cm for women; 2) systolic blood pressure (BP) ≥ 130 mmHg or diastolic BP ≥ 85 mmHg; 3) TG ≥ 1.7 mmol/L; 4) HDL-C < 1.04 mmol/L for men or < 1.30 mmol/L for women; and 5) fasting glucose ≥ 6.1 mmol/L.
The relative risks (RR) for having the MetS were estimated with total FFMi, corrected for FM index (FMi) and physical activity (PA) levels (assessed using a questionnaire - NHANES PAQ). The reference group for RRs was determined as the first quartiles (Q1) of FFMi in each sex and age-specific subgroup.
RESULTS: In total, 1376 individuals (25.5%) had the MetS. The most prevalent risk factor was a high WC (47.4%) followed by high BP (35.1%), low HDL-C (34.0%), high TG (32%) and high fasting glucose (13.6%). The prevalence of MetS was greater with increasing quartiles of absolute FFM or FFMi ($p<0.001$). In contrast, the prevalence decreased with higher quartiles of FFM% ($p<0.001$). Additionally, the RR of having MetS was significantly greater compared to the reference group in all subgroups (all $p<0.05$), except for Q2 and Q3 in young men ($p=0.347$ and 0.095 respectively).
CONCLUSION: These results first suggest that the expression of FFM greatly influences the direction of its association with MetS and, secondly, that the largely purported idea that a large FFM has a protective effect against metabolic abnormalities might stem from flawed conclusions. Indeed, the present study suggests a greater RR of having MetS with increasing FFMi, even when corrected for FMi and PA levels. These results are in line with a growing body of literature as reviewed in Perreault et al. (2016) [1]. It would, therefore, be critical to re-examine our understanding of the contribution of FFM to metabolic health.

INTEGRATED MYOFIBRILLAR PROTEIN SYNTHESIS IN CHRONICALLY TRAINED MASTER ATHLETES COMPARED WITH UNTRAINED OLDER INDIVIDUALS

MCKENDRY, J., SHAD, B.J., WALLIS, G.A., PHILLIPS, S.M., GREIG, C.A., BREEN, L.
UNIVERSITY OF BIRMINGHAM

INTRODUCTION: The rapidly expanding ageing population necessitates strategies to promote the extension of health span. Loss of muscle mass and function with advancing age (termed sarcopenia), may contribute to the development and progression of adverse health conditions in older age. Age-related impairments in the muscle anabolic response to exercise and protein nutrition is thought to be a major driver of sarcopenia. This muscle anabolic resistance is thought to be exacerbated by inactivity in older age. Older individuals still undertaking regular structured exercise training, or Master Athletes (MA), represent an ideal model to study inherent muscle ageing mechanisms, free from the confounding factor of inactivity. Therefore, we aimed to compare basal and resistance exercise-induced integrated muscle protein synthesis (iMPS) rates and anabolic signaling mechanisms in MA and healthy age-matched untrained individuals (OC). We hypothesised that basal iMPS rates would be similar between groups, but that exercise-induced iMPS rates and intramuscular signalling responses would be greater in MA vs. OC, indicative of a greater (or maintained) capacity for muscle remodelling.
METHODS: In a parallel study design, skeletal muscle biopsies and daily saliva samples were collected to determine basal and exercise-induced iMPS over a 48 h period, following a single bout of lower body resistance exercise (RE) in OC (n=8, 73.5 ± 3.3 y) and MA (n=7, 68.9 ± 5.7 y). Intramuscular anabolic signalling was measured 1 h post-exercise. Participants ingested a bolus of deuterium oxide (2H2O)

followed by daily top ups to measure iMPS. Body water enrichment and activity was monitored throughout the study. Dietary intake was controlled during the iMPS measurement period.
RESULTS: Habitual non-structured physical activity, dietary intake and anthropometric characteristics were similar between between OC and MA. Basal rates of iMPS were similar between OC and MA (1.47 ± 0.06 and 1.46 ± 0.08 %·day-1, respectively). Resistance exercise significantly increased iMPS in both OC (1.61 ± 0.08 %·day-1, P<0.01) and MA (1.61 + 0.08 %·day-1 P<0.01), with no difference between the groups. In OC, Akt phosphorylation increased (P<0.05) and p70S6K phosphorylation tended to increase (P=0.06) above rested values at 1 h post-exercise. The phosphorylation of rpS6 increased post-exercise in OC and MA (P<0.05), with no difference between groups.
CONCLUSION: Overall, these data suggest that despite high levels of regular structured exercise training, basal and RE-induced iMPS are indistinguishable between MA and OC. Importantly, this demonstrates that OC retain a capacity for muscle remodelling in response to RE.

NOVEL INSIGHTS INTO HUMAN SKELETAL MUSCLE CREATINE TRANSPORTER EXPRESSION AS A FUNCTION OF AGE

LUO, D., JOANISSE, S., SMEUNINX, B., PHILP, A., BREEN, L.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Intramuscular creatine (Cr) is a fundamental component of cellular energy regulation. The creatine transporter (CreaT) protein plays a key role in intramuscular Cr uptake and metabolism [1], but remains largely unexplored in human skeletal muscle. Muscle protein turnover is an energetically costly process that is integral to muscle proteostasis [2]. Age-related muscle loss (sarcopenia) is driven by impairments in muscle proteostasis [2] that may be explained, in part, by disturbances cellular energetics resulting from reduced physical activity [3]. We firstly aimed to validate and optimize immuno-fluorescent staining and blotting methods to investigate CreaT distribution and expression in human skeletal muscle. Subsequently, we aimed to understand how CreaT expression and distribution is modulated by old age.
METHODS: Antibody validation and negative control tests were applied to confirm that the antibody used in immunoblotting and immunofluorescence microscopy specifically recognized CreaT in human skeletal muscle. Following this, muscle biopsy samples from 6 young (26.8±4.3yrs) and older (68.8±2.0 yrs) were used for immunoblotting and immunofluorescence microscopy analysis to identify fibre-specific CreaT distribution and expression, Creatine kinase (CK) content and high-energy phosphagens. A new method of calculation was developed to identify CreaT protein intensity in specific muscle fibre regions, referred to as ring (sarcolemmal membrane) and centre (non-membrane bound) CreaT intensity.
RESULTS: Peptide blocking and negative controls indicated that the antibodies specifically recognized CreaT in human skeletal muscle. A CreaT positive stain was visualized in skeletal muscle with no clear fibre-type or age-related difference. Additionally, more positive CreaT was observed close to sarcolemma membrane regions (per ring area and centre area CreaT intensity) (0.194±0.036 vs.0.029±0.008, P<0.01), with no fibre-type or age-related difference. Intramuscular CK (Young: 1.33±0.08, Old: 0.98±0.01, P<0.01) and PCr (Young: 69.33±3.05, Old: 61.09±1.81, P<0.05) content were lower in old than young.
CONCLUSION: Overall, the results suggest that aspects of intramuscular creatine metabolism are altered by ageing, whereas CreaT protein content remains relatively unaffected. CreaT protein mainly distributes around cell membranes without any fibre-type difference. In summary, we have developed a validated/optimized experimental approach to study CreaT in human skeletal muscle. These findings provide a platform to investigate whether fibre-specific CreaT expression/activity is a rate-limiting step in the muscle anabolic response to exercise and supplemental creatine interventions that may attenuate sarcopenia.

SHORT-TERM TRAINING AND DETRAINING RESPONSES FOLLOWING DIVERGENT EXERCISE MODALITIES IN MIDDLE-AGED MEN

CALLAHAN, M.J., PARR, E.B., CONCEIÇÃO, M.S., HAWLEY, J.A., CAMERA, D.M.

AUSTRALIAN CATHOLIC UNIVERSITY

INTRODUCTION: The effects of high intensity interval training (HIIT) on metabolic and cardiovascular responses are well documented (1). However, less is known regarding HIIT and changes in body composition. Evidence suggests HIIT can increase lean mass in women (2), although the effects of HIIT in overweight, middle-aged men are unknown. The primary aim of this study was to determine if HIIT and high protein availability can increase lean mass. A secondary aim was to assess training and detraining responses for body composition, peak oxygen uptake and maximal strength between HIIT, resistance exercise (REX) and endurance cycling exercise (END).
METHODS: Untrained men (n=35; 40 ± 2 years; BMI: 29 ± 3 kg/m2 [mean ± SD]) were randomly stratified (by lean mass) to either HIIT (8-15 reps x 30-60 s, 25-30 min, 90-130% VO2peak cycling), REX (3-4 sets x 9-12 repetitions upper/lower body exercise) or END (45-60 min @50-75% VO2peak cycling) for 3 d/wk for 6 wk followed by ~2.5 wks of detraining. All participants consumed ~1.4 g/kg BM/d of protein for the duration of the study. Body composition by dual-energy x-ray absorptiometry (DXA), peak oxygen uptake (VO2peak cycling) and maximal leg press strength (1RM) were measured prior to (PRE), 48 h following the final session (POST) and ~2.5 wks post-detraining (POST-DT).
RESULTS: Training increased lean mass following HIIT (+1.1 kg, p=0.01) and REX (+3.0 kg, p<0.001) but not END (+0.4 kg, p>0.05), and this was maintained after 2.5 wk of detraining. Similarly, leg lean mass (time, p<0.01) only increased following HIIT (+0.8 kg, p=0.04) and REX (+1.0 kg, p<0.01). No changes in fat mass were observed. Training increased VO2peak (L/min) by +14% and +10% for HIIT and END (p<0.001), while detraining was associated with a -5% decline for both groups. Maximal leg press strength increased PRE to POST (time, p<0.01) with no effect of condition.
CONCLUSION: These data suggest HIIT combined with high protein availability can increase lean mass, peak oxygen uptake and lower limb strength in middle-aged sedentary males. These findings promote the use of HIIT and protein for preserving skeletal muscle mass in a population susceptible to muscle loss with aging.

CHANGES IN PLASMA C1Q AND APELIN CONCENTRATIONS FOLLOWING DESCENDING VERSUS ASCENDING STAIR WALKING

NOSAKA, K.

EDITH COWAN UNIVERSITY

Complement component 1q (C1q) is a protein complex involved in the innate immune system, and C1q level in the blood was shown to be related with decreases in muscle mass and strength with ageing [1]. A previous study reported that 12-wk resistance training of the knee flexors and extensors decreased serum C1q level (39%), and increased maximal voluntary isometric contraction strength (MVC: 8-12%) and muscle cross-sectional area (7%) of older adults [2]. It has been known that apelin regulates endothelial NO synthase, promoting NO production, and plasma apelin concentration increased by 117% after 8-wk aerobic exercise training in older adults [3]. We reported that 12-wk of descending stair walking (DSW) increased MVC and decreased systolic blood pressure (SBP) greater than ascending stair walking (ASW) in elderly obese women [4]. The present study compared between DSW and ASW for changes in plasma C1q and apelin concentrations to test the hypothesis the magnitude of changes in plasma C1q and apelin levels from baseline to post-training would be greater for DSW than ASW.

METHODS

Plasma samples of elderly (≥60 y) obese women who performed the 12-wk DSW or ASW training (n=12/group) were analysed. An elevator was used to eliminate ascending stairs for DSW, and descending stairs for ASW [4]. DSW and ASW were performed twice a week by increasing the repetitions over 12 wk. Knee extensor MVC strength, upper thigh circumference (CIR), and blood pressure were measured before and after the intervention. Overnight fasting blood samples were taken 3 days before the first training session and 4 days after the last training session, and analysed for C1q and apelin using ELISA kits (GenAsia).

RESULTS

Greater ($P<0.05$) increases in MVC strength (36% vs 16%) and CIR (3% vs 1%), and decrease in SBP (9% vs 3%) were evident for DSW than ASW [4]. At baseline, no significant differences between DSW and ASW groups were found for plasma C1q (5 ± 2 μg/mL) and apelin (1083 ± 530 ng/mL). After the 12-wk DSW training, plasma C1q decreased by 25% (4 ± 1 μg/mL), and plasma apelin increased by 11% (1094 ± 376 ng/mL). In contrast, C1q increased by 33% and apeline did not change after ASW. The magnitude of the decrease in plasma C1q concentration after DSW was correlated ($P<0.05$) with the magnitude of increase in MVC ($r=-0.78$) and CIR ($r=-0.80$), and the magnitude of the increase in plasma apelin concentration was correlated ($r=-0.71$, $P=0.005$) with the magnitude of decrease in SBP.

CONCLUSION

These results suggest that the greater increases in MVC strength and CIR, and decrease in SBP after DSW than ASW training were associated with decreases in plasma C1q concentration and increases in plasma apelin concentration. It is interesting to investigate further why DSW was more effective than ASW for these changes.

INTRODUCTION: Ageing is associated with changes in body composition, physical fitness and motor skills. Sedentary lifestyle accelerates ageing, reducing functional capacity and decreasing self-efficiency in the elderly. Our aim was to assess the efficiency of long-term supervised aerobic-strength training in increasing physical fitness, walking speed and motoric skills.

METHODS: Results of the supervised long-term (21 months) exercise intervention were evaluated in 18 (M/F 5/13) seniors (69±5yrs, at the time of last evaluation) from the on-going intervention program. Body composition (quadrupedal bioimpedance) and motor performance (10-Meter Walk Test by maximal or preferred speed; 5-Sit-to-Stand Test) were evaluated in the 3-month intervals. Supervised aerobic-strength training was performed (2 x 1h per week) and intensity was maintained at 50-60% of VO2max or 1RM (Rockport Walk Test and dynamometry).

RESULTS: An increase in both maximal and preferred walking speed was detected after just 3-month of aerobic-strength training. Moreover, increase in both, maximal and preferred walking speed peaked after 9 months of training, reaching to more than 11.2% increase from baseline pre-exercise state ($p<0.001$). From then on, maximal walking speed remained steady until completion after 21 months (latest evaluation period) ($p>0.01$). Preferred walking speed slightly fluctuated between (9-21 months) ($p>0.01$) but, it remained well above the baseline values. Similar training effect trajectory was found for the performance in the 5-Sit-to-Stand Test, with a peak performance at 9 months (baseline:11.25s; 9month follow up:7.84s) representing 43.5% improvement in performance ($p<0.001$). This effect was again maintained well above the baseline levels until 21 months of exercise ($p>0.05$). It is important to note, that the aforementioned functional improvements were not associated with any significant changes in body composition during the 21-month exercise training period in the elderly.

CONCLUSION: Supervised aerobic-strength training led to improvement and long-term maintenance of motor functional performance and body composition in the elderly. The data indicate that the regular physical training is an easily accessible and inexpensive tool, which should be used to prevent and improve the age-associated decline in motor functions, enabling thus long-term maintenance of functional independence in the elderly.

PULMONARY AND HEART RATE OFF-TRANSIENT KINETICS IN VERY OLD INDIVIDUALS

FERRI, A., ADAMO, S., LONGARETTI, M., LANFRANCONI, F., MARZORATI, M., GRASSI, B.

VICTORIA UNIVERSITY

INTRODUCTION: After exercise, oxygen uptake (VO2) does not return immediately to resting levels, but follows a curvilinear time course (VO2 off-transient kinetics) that has been linked to the restoration of depleted O2 and local creatine phosphate stores to pre-exercise conditions. During high-intensity exercise, cardiac output recovery kinetics have been shown to be slower than the VO2 off-kinetics in healthy individuals (Yoshida & Whipp 1994), probably to ensure sufficient O2 flux to the muscle to meet the metabolic demands. However, most of this research has been conducted in young individuals and a detailed analysis of the recovery kinetics in elderly is missing from the literature. In this study, the effects of ageing on pulmonary (VO2) and heart rate (HR) off-transient kinetics were evaluated at the end of moderate- and high-intensity exercises in 10 elderly (E) (78.7±1.0 y, mean±SE) and 10 young (Y) (25.8±1.2 y) sedentary individuals.
METHODS: Participants performed an incremental exercise test to voluntary exhaustion on a cycle ergometer to evaluate peak VO2 and the gas exchange threshold (GET). Then, individuals completed three, 6-min constant-load exercises below (GET). VO2 and HR off-transient kinetics were evaluated during 6 min of passive recovery at the end of the constant-load exercises. Pulmonary VO2, VCO2, and ventilation were determined breath-by-breath. HR was measured continuously by 12-lead ECG, and recorded beat-by-beat.
RESULTS: VO2peak in E (17.5±1.2 mL·kg-1·min-1) was ~50% lower ($p<0.001$) than in Y (31.8±1.7 mL·kg-1·min-1). The time constant (τ) of the primary component of VO2 kinetics-off was higher ($p<0.01$) in E than in Y, in both GET (59.0±3.7 vs 44.9±2.0 s). In both E and Y, the VO2 and HR kinetics-off were better fitted by a mono-exponential than a double exponential function. The τ HR-off was also slower in E with respect to Y ($p<0.01$) during GET (53.5±8.4 vs 64.4±9.6 s; $p=0.42$). In E, VO2 and HR kinetics did not differ between moderate and high-intensity exercise, while in Y both values were significantly slower during >GET.
CONCLUSION: The results of this study show that ageing slows the VO2 and HR recovery kinetics after exercise, indicating a reduced muscle oxidative capacity (Paganini et al 1997) and/or a reduced oxygen delivery in elderly.

OP-BN05 Gait I

EFFECT OF HOME-BASED ROBOTIC-ASSISTED GAIT TRAINING ON SPATIOTEMPORAL GAIT PARAMETERS IN PATIENTS WITH CHRONIC STROKE

WRIGHT, A., JOBSON, S., SMITH, G., STONE, K., FRYER, S., FAULKNER, J.

UNIVERSITY OF WINCHESTER

INTRODUCTION: A large majority of stroke survivors rank improving their ability to walk among their top rehabilitation goals (1). As health care delivery shifts away from traditional hospital settings and increasingly into the community (2), there is a growing need and interest in the efficacy of home-based rehabilitation interventions. Traditional gait rehabilitation therapies can be labor intensive, often requiring multiple therapists, however the capacity of robots to deliver training with high intensity and repeatability makes them a valuable tool (3). The evaluation of patients' performance and progress throughout interventions is usually subjective because few adequate objective measures are available (4). This study aims to objectively assess the effectiveness of a home-based robotic-assisted gait training (RAGT) programme in patients with chronic stroke.
METHODS: Forty stroke patients (age: 62.2±14.1y; time since stroke: 29.9±19.1months) were randomised into a RAGT programme or control group (CON) while continuing their regular rehabilitation therapy. Participants receiving RAGT performed 10-weeks of home-based rehabilitation using a lower limb robotic device (Alter G Bionic Leg, USA) and were required to wear the device for a minimum of 30mins per day. Robotic settings were adjusted every 2 weeks to induce progressive overload. Participants in the CON group were advised to engage in a minimum of 30mins of physical activity per day. Before and after the 10 week programme, spatiotemporal gait parameters (G-Walk, USA) were assessed during repeated 10m walks. Data was analysed using Two-way ANOVA (Time [Pre/Post] x Condition [RAGT/Con].
RESULTS: The following results are from a preliminary cohort of participants (n=16). A significant Time*Condition interaction was observed for the stance phase ($P<0.05$; $\eta p2=0.304$), with the RAGT group demonstrating a significant reduction in the duration of the stance phase (pre: 67.6±8.2%; post: 59.3±6.1%), compared to CON (pre: 72.5±5.9%; post: 73.9±5.2%). Although non- significant, similar findings were observed for speed, with increases seen in the RAGT group (pre: 0.61±0.33m/s; post:0.81±0.38m/s), but not for CON (pre: 0.43±0.17m/s; post: 0.47±0.18m/s) ($P=0.07$; $\eta p2=0.212$). No significant interactions were seen for RAGT or CON for cadence or gait cycle duration (both $P>0.05$).
CONCLUSION: A 10-week home-based RAGT programme improved gait outcomes in patients with chronic stroke. Results showed a decrease in time spent in the stance phase, leading to a more typical non-pathological gait (60% stance, 40% swing), and an increase in speed. The present results demonstrate encouraging evidence supporting the use of RAGT in a home-based environment.

PROSTHETIC GAIT OF UNILATERAL TRANSTIBIAL AMPUTEES WITH CURRENT AND NOVEL PROSTHESES

DE PAUW, K., SERRIEN, B., BAEYENS, J.P., CHERELLE, P., DE BOCK, S., GHILLEBERT, J., LEFEBER, D., ROELANDS, B., VANDERBORGHT, B., MEEUSEN, R.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Novel lower-limb prostheses aim to improve the quality of locomotion of individuals with an amputation. The current study evaluates a novel bionic foot, i.e. the Ankle Mimicking Prosthetic foot (AMPfoot) 4.0 in terms of kinetics and kinematics during normal speed walking. Improved gait kinetics and kinematics were hypothesised, especially at the level of the ankle.
METHODS: Able-bodied individuals (5 men, 2 women, age: 26 yr (SD 5), height: 1.75 m (SD 0.10) and weight: 72 kg (SD 12)) and individuals with an amputation below knee (TTA: 6 men, age: 54 yr (SD 14), height: 1.76 m (SD 0.08) and weight: 80 kg (SD 13)) were included. Able-

bodied individuals conducted one experimental trial, whereas TTA conducted a familiarization and two experimental trials; experiment 1 with the current, passive prosthesis and experiment 2 with AMPfoot 4.0. Each trial included a 2-minute normal speed walking task. Biomechanical data was gathered using a force platform embedded in the treadmill and a motion capture system using a 6-camera VICON MX F20 system. Data were analysed using 1D Statistical Parametric Mapping and (non)-parametric tests. Significance level was set at 0.05.
RESULTS: Walking with the current prosthesis at normal speed reduced maximal heel forces ($P<0.001$) and increased ankle angle velocity and trunk sagittal velocity at midstance ($P\leq0.011$), and knee angle ($P\leq0.026$). Walking with AMPfoot on the other hand, did not elicit significant alterations of these parameters, with the exeption that AMPfoot reduced maximal heel force ($P=0.004$). Furthermore, walking with AMPfoot at normal speed significantly reduced stride length ($P=0.01$), and significantly altered trunk sagittal angle and velocity during the swing phase ($P\leq0.047$). These differences did not occur when comparing able-bodied walking and walking with the current prosthesis.
CONCLUSION: As hypothesized, TTA walking with the AMPfoot 4.0 better mimics gait characteristics of able-bodied walking compared to the conventional prosthesis during normal speed walking. Three-dimensional motion capture data of TTA walking with the current prosthesis demonstrates significant alterations compared to able-bodied walking. Walking with the AMPfoot also resulted in altered gait characteristics compared to able-bodied walking. However, these alterations were subtler and less disturbing than during walking with the current prosthesis. Conventional prosthetic feet do not provide the required dorsi- and plantarflexion, which leads to altered gait patterns and locomotion difficulties. This is countered through the mechanics of AMPfoot 4.0. Thus, TTA walking with AMPfoot 4.0 better mimics able-bodied walking.

TIMING OF GROUND REACTION FORCE PROGRESSION IN ELITE KENYAN VERSUS RECREATIONAL DISTANCE RUNNERS

BURNS, G.T., TAM, N., SANTOS-CONCEJERO, J., TUCKER, R., ZERNICKE, R.F.

UNIVERSITY OF MICHIGAN

INTRODUCTION: Quantifying biomechanical determinants of running economy (RE) and performance is challenging given the multifactorial complexity of gait (1), but the elite distance runners of East Africa provide a unique population to explore these factors (2). Shorter ground contact times (CT) have been linked to their superior RE, but additional biomechanical factors remain elusive (3). In novice runners, ground reaction force (GRF) and leg-axis component-alignment have been linked to enhanced RE (4), and the energy-conserving spring-loaded inverted pendulum model of running is characterized by coordinated energy transfer in the vertical and horizontal planes (5). We hypothesized that elite Kenyan runners have better coordination of vertical and horizontal GRF than recreational runners and their enhanced RE is related to GRF coordination.
METHODS: Single-step GRFs were recorded (2000 Hz) during shod and barefoot running in elite Kenyan (K) distance runners (n=15; 10km: 28.7 min) at 12 and 20 km/h and recreational South African (REC) distance runners (n=15; 10km: 42.8 min) at 12 km/h. RE was measured via gas exchange at 12 km/h. The GRF timing difference (GRF TD) was calculated as the difference between time of peak vertical GRF and time of transition from braking to propulsion in horizontal GRF. CTs were recorded, and ratios for vertical loading and unloading times (VLUR) and horizontal braking and propulsion times (BPR) were calculated
RESULTS: GRF TD was significantly lower for K compared to REC at 12 km/h (10±1 ms vs. 14±1ms; $p<0.001$). There was a significant interaction between groups and the barefoot/shod conditions, where REC exhibited an increased GRF TD when shod (16 ms vs. 13 ms), whereas K remained unchanged. In K, there was a significant speed effect, where GRF TD was significantly lower at 20 km/h (0±1 ms). While CTs differed between K and REC (0.21±0.02 vs. 0.24±0.03 s), VLUR and BPR patterns were consistent with GRF TD patterns. VLUR did not differ (0.78±0.11 and 0.78±0.14), while BPR was lower (i.e., closer to VLUR) in K (0.94±0.12 vs. 0.99±0.11). After controlling for group, RE was significantly related to GRF TD, with superior RE being associated with a shorter GRF TD (0.42 mL/kg/min per ms, $p<0.001$).
CONCLUSION: Kenyan distance runners exhibited a more coordinated transfer of energy in their loading/unloading and braking/propulsion patterns. REC runners continued braking for a greater time after they had begun unloading, whereas the K runners had a closer coupling of this transition. Independent of group, better running economy was associated with a better coordination of the vertical and horizontal GRFs. This superior coupling of energy transfer provides further explanation for the greater performance capacity of K runners, and GRF TD may serve as a metric by which coaches and clinicians can monitor an athlete's force-development coordination during running.

EFFECTS OF WALKING WITH UNSTABLE FOOTWEAR ON PELVIS-TRUNK COORDINATION VARIABILITY

BUCHECKER, M., MÜLLER, E., BIRKLBAUER, J., WIESINGER, H.P., STÖGGL, T.

UNIVERSITY OF SALZBURG

INTRODUCTION: Applying an entropy approach to assess the fluctuation patterns of gait, Buchecker et al. (2018) reported a „decomplexification" of centre of mass dynamics while participants were adapting to unstable footwear (UF), especially in the medio-lateral direction. If true, walking with UF should affect upper body function in terms of inter-segmental couplings over time in a similar way. Therefore, this study aimed to evaluate coordination variability (CV) between movements of the pelvis and the trunk when using UF before and after accommodation.
METHODS: Three-dimensional kinematic signals of twelve healthy subjects walking on a motorised treadmill (5 km/h) were recorded at first exposure to UF, and following a ten week familiarisation period. Standardised footwear (SF) served as a control during both laboratory visits. CV was determined for the middle ten stance and swing phases by two classical ("Tepavac" [Tepavac and Field-Fote, 2001] and "Heiderscheit" [Heiderscheit et al., 2002]) and one recently proposed ("Stock" [Stock et al., 2018]) vector coding technique applied to angle-angle plots relating pelvic and trunk motions. Statistics included two-way repeated-measures ANOVAs with Student-t post-hoc-tests.
RESULTS: Most importantly, the only significant shoe-by-visit interaction was detected during stance phase in frontal plane CV utilising the novel method introduced by Stock et al. (2018), $F(1,11) = 8.1$, $P = 0.016$, $f = 0.86$. A detailed investigation of this effect revealed that here, compared to the SF condition, the higher initial variability (33 %, $P = 0.037$) within the pelvis-trunk system in the UF condition decreased (-36 %, $P = 0.012$) to normal (i.e., SF condition) levels with practice. Yet neither the "Tepavac" nor the "Heiderscheit" calculation procedure could confirm any of those findings.

CONCLUSION: Although the results observed concerning CV indices were shown to depend on the specific analysis selected, in particular, the "Stock" outcomes are probably the most representative. This is mainly because of their great robustness – unlike the more traditional algorithms (i.e., "Tepavac" and "Heiderscheit") – in case of short vector lengths, such as are frequently noticed during gait (Stock et al., 2018). Thus, the current experiment generally supports the original data from Buchecker et al. (2018), and also highlights that UF should provide valuable stimuli for motor development. Nevertheless, further research is required to examine the physio-mechanical concept of UF within prevention and rehabilitation settings.

EFFECT OF TRICEPS SURAE MUSCLE-TENDON UNIT BIOMECHANICAL PROPERTIES ON WALKING ECONOMY IN OLDER ADULTS: A COMBINED CROSS-SECTIONAL AND LONGITUDINAL INVESTIGATION

EPRO, G.1, STANGIER, C.2, MIERAU, A.3, KARAMANIDIS, K.1

1 LONDON SOUTH BANK UNIVERSITY; 2 GERMAN SPORT UNIVERSITY COLOGNE; 3 LUNEX INTERNATIONAL UNIVERSITY OF HEALTH, EXERCISE AND SPORTS

INTRODUCTION: Previous studies have reported that triceps surae (TS) muscle-tendon unit (MTU) properties are major determinants for running economy (1,2) in younger adults, with more economical runners demonstrating both higher TS muscle strength and tendon stiffness. The present study aimed to investigate the hypotheses that (i) older adults with different walking economy would also show differences in TS MTU mechanical and morphological properties, and that (ii) an exercise-induced enhancement of these properties would improve walking economy during different task constraints.
METHODS: 26 older females (60-75y) walked on a treadmill under varied conditions: 1.2 and 1.4 m/s level, 1.2 m/s at 9% incline and 0.7 m/s at 14% incline. Gait economy, defined as the rate of oxygen consumption (VO2; ml/kg/min) and metabolic energy cost (J/m/kg) was measured at steady state using a portable spirometer. The mechanical (muscle strength, tendon stiffness) and morphological properties (e.g. fascicle length) of TS MTU were assessed using dynamometry and ultrasonography. The participants were classified into 2 groups for each walking condition based on VO2 using a median split. The participants were then recruited to either an experimental group (14 weeks TS MTU resistance exercise intervention; n=16) or to a control group (no exercise intervention; n=10).
RESULTS: GroupHighEco (n=13) in comparison to GroupLowEco (n=12) showed on average a 23% lower VO2 ($P<0.05$) and 22% lower metabolic energy cost ($P<0.05$) across all walking conditions. However, no differences in TS MTU mechanical (muscle strength, tendon stiffness) or TS morphological properties were detected between the groups. Similarly, no correlations were found between gait economy and TS MTU biomechanical properties. After 14 weeks, experimental group displayed a 23% higher TS muscle strength ($P<0.05$) and a 25% greater tendon stiffness ($P<0.05$) compared to baseline. Despite enhanced TS MTU capacities no changes were found in steady state VO2 or metabolic cost of walking after 14 weeks, irrespective of walking condition.
CONCLUSION: Based on the current cross-sectional investigation within a group of older adults, we were unable to support the hypothesis that the biomechanical properties of the TS MTU are major determinants for walking economy. In accordance with this, our longitudinal investigation revealed that an exercise-related enhancement of the TS MTU capacities does not lead to a measurable reduction in the metabolic energy cost during level or inclined walking at different velocities in older adults. Therefore, our findings might indicate that, in contrast to running, the ankle muscle-tendon system is of less importance for the net metabolic cost in human walking in ageing.

OP-MI01 Training and testing: Talent

IMPROVING THE ACCURACY OF ATHLETE SELECTION IN YOUTH FEMALE SWIMMING: AN APPLICATION OF CORRECTIVE ADJUSTMENT PROCEDURES

ABBOTT, S., MOULDS, K., SALTER, J., ROMANN, M., COBLEY, S.

THE UNIVERSITY OF SYDNEY

INTRODUCTION: Children participating in organised sport are typically grouped according to chronological age. Inadvertently, children born closer to age cut-off dates, and who are relatively older, are commonly overrepresented compared to the relatively younger in the age-group; resulting in Relative Age Effects (RAEs). In swimming, being relatively older is associated with performance and selection advantages due to developmental advantages. Recently, corrective adjustment procedures have been shown as a potential strategy to mitigate against RAEs in male youth front-crawl swimming (Cobley et al., 2018). In this study, we firstly aimed to accurately estimate the longitudinal relationship between decimal age (i.e., chronological and relative) and performance in female Breaststroke swimming. Secondly, we tested whether corrective adjustment procedures could remove RAEs, by controlling for age differences and subsequently improving the accuracy of performance evaluation.
METHODS: To identify longitudinal performance trends, repeated years of swimming performance data were examined. In Part 1, participants were N= 765 100m and N= 428 200m female Breaststroke swimmers (10-18 years) who participated in ≥ five annual events between 1999-2017 (inclusive). This data enabled quantification of longitudinal growth curves between decimal age and swimming performance. The curve generated an equation that permitted corrective adjustment of age differences in both events. In Part 2, participants were N= 3162 100m and N= 1992 200m female Breaststroke swimmers (12-15 years) who swam at state/national events in 2013-2018. Relative age distributions for 'All', 'Top 25%' and '10%' of swimming times were examined based on raw and correctively adjusted swim

times. Chi-square, Cramer's V and Odds Ratios (OR) determined whether relative age (Quartile 1-4) inequalities existed according to age-group, selection level and correctively adjusted swim times.
RESULTS: Based on raw swim times for 'All' swimmers, RAEs were evident from 12-14 years-old for 100m and 200m events. RAE effect sizes increased in magnitude (small-medium effects) with selection level ('All'-'Top 25%') in the 12 and 13 year age-groups for both events. However, when correctively adjusted swim performances were examined, RAEs were primarily absent across all age-groups and selection levels.
CONCLUSION: With accurate longitudinal reference data, corrective adjustment procedures can effectively remove relative age advantages from 100m and 200m female Breaststroke swimming performance. Removing the influence of age-differences might help improve the accuracy of identifying genuinely skilled youth swimmers.

THE RELATIVE AGE EFFECT IN AGE GROUP SWIMMING – GERMANY COMPARED TO AUSTRALIA

STAUB, I.1, MUNDELSEE, L.2, VOGT, T.1,3

1 GERMAN SPORT UNIVERSITY COLOGNE, GERMANY; 2 UNIVERSITY OF ERFURT, GERMANY; 3 WASEDA UNIVERSITY, JAPAN

INTRODUCTION: Relatively older athletes, who were born in the first two quartiles of a year, have an increased probability of being selected and exposed to a higher level of coaching, training and other talent-promoting factors. Therefore, it is considered as one of the errors within the process of talent identification (Wattie, Schorer & Baker, 2015). Research has conceded the prevalence of the relative age effect (RAE) across various sports, e.g. reports on Australian age group swimmers showing consistent RAE for male and female athletes until 15 and 14 years of age (yoa). The effect diminishes at 16 years and turns inverse at 17-18 years of age (Cobley et al., 2017). This investigation determines a magnitude and transient pattern of the RAE according to sex and stroke across German age group swimming.
METHODS: RAE was examined in German top-100 age group rankings (2004-2013) including birth months of three cohorts (born 1995-1993; n=3630) for the age groups 11-18. Chi-Square tests and Cramer's V estimated effect sizes, Odd's ratios (OR) and Confidence Intervals (CI, 95%) calculated relative quartile discrepancies. These steps were applied across age groups and according to sex and stroke.
RESULTS: The RAE is significantly present over all strokes for female swimmers until 17 yoa and for male swimmers until 18 yoa. Effect sizes were medium until 12 yoa for girls and 15 yoa for boys. No inverted effects were visible until 18 yoa.
CONCLUSION: Compared to previous reports on an Australian cohort, the RAE was prevalent over a longer time period. Therefore, the impact of negative outcomes from RAE appears larger with respect to a similar cohort from Australia. These findings will be discussed, ranging from a less permeable talent detection system in Germany to potentially biased decisions in talent selections by different peers (Hancock, Adler & Côté, 2013).

'BIRTHDAY-BANDING' AS A STRATEGY TO MODERATE THE RELATIVE AGE EFFECT: A CASE STUDY INTO THE ENGLAND SQUASH TALENT PATHWAY

JEFFREYS, M., TAYLOR, J., GOUGH, L., KELLY, A.

BIRMINGHAM CITY UNIVERSITY, UNITED KINGDOM; ENGLAND SQUASH, UNITED KINGDOM

INTRODUCTION: The relative age effect (RAE) refers to the bias influence of birthdate distribution, with athletes born later in the selection year being under-represented in youth talent development programmes. Researchers often cite the need for talent development programmes to incorporate strategies to moderate such effect (Wattie et al., 2015). Accordingly, England Squash adopted a 'birthday-banding' (BB) approach to their Talent Pathway, whereby young athletes move up to their next birthdate group on their birthday, with the aim to remove particular selection time-points and specific chronological age groups.
METHODS: To test the BB strategy implemented within the England Squash Talent Pathway, the twelve months of the year were divided into four birth quarters (BQ), conforming to the current strategy applied to distribute chronological age groups. To align with the timing of the English chronological age groups, September was defined as 'month 1', whilst August was defined as 'month 12'. In-line with the England Squash Talent Pathway, three mixed-gender groups were populated; 1) Senior Team and Academy athletes (n=26), 2) Development and Potential athletes (n=53), and 3) ASPIRE athletes (n=270). Chi-square ($\chi 2$) analysis was used to test BQ distributions for each of the sample groups against relevant birth population values.
RESULTS: There was a significantly skewed birthdate distribution for the Senior Team and Academy athletes ($\chi 2=30.0$, $p<0.001$; V=1.0), whereby an overrepresentation was observed in BQ3 (n=10; 38.5%) and BQ4 (n=7, 26.9%) compared to BQ1 (n=5, 19.2%) and BQ2 (n=4, 15.4%). A significantly skewed birthdate distribution was also observed for the Development and Potential athletes ($\chi 2=20.0$, $p<0.003$; V=1.0), whereby BQ1 was underrepresented (n=7, 13.2%) compared to any other BQ (BQ2 n=16, 30.2%; BQ3 n=14, 26.4%; BQ4 n=16, 30.2%). Similarly, within in the ASPIRE athletes, a significantly skewed birthdate distribution was observed ($\chi 2=30.0$, $p<0.001$; V=1.0), whereby BQ1 was again underrepresented (n=53; 19.6%) compared to any other BQ (BQ2 n=77, 28.5%; BQ3 n=78, 28.9%; BQ4 n=62, 23.0%).
CONCLUSION: In contrast to other talent development programmes in youth sport organisations (Cobley et al., 2009), these findings reveal BQ1s are significantly underrepresented throughout the England Squash Talent Pathway compared to their younger BQ peers. It may be suggested this is a result of chronologically younger athletes being more likely to be positively recruited through the BB strategy. Consequently, it appears BB offers an alternative approach to group young athletes to moderate the RAE in youth sport.

THREE IN A ROW? RELATIONSHIP BETWEEN JUNIOR AND ELITE SUCCESS IN ROWING

HOFFMANN, A., ALTMANN, K.

INSTITUTE FOR APPLIED TRAINING SCIENCE

INTRODUCTION: Talent promotion systems are based on the assumption of a progressive trend in performance development with a normative ascent from junior to senior competition levels, often (Vaeyens, Güllich, Warr & Philippaerts, 2009). Previous studies show that the correlation between junior and elite success varies strongly between sports (Hoffmann & Wulff, 2013). The aim of this study is to analyse this relationship in rowing pro- and retrospectively.
METHODS: The study is threefold – First, to identify national promotion strategies for long-term athlete development correlations of medal rankings (mean 2014-2018) at Junior World Championship (JWC), Under 23 World Championships (U23 WC) and World Champion-

ships/Olympic Games (WC/OG) were calculated. Second, participation and success in U23 WC and WC/OG of finalists in 2008 JWC (N=268) were analysed on descriptive level. Third, JWC- and U23 WC-results of finalists in 2016 OG (N=276) were analysed retrospectively.
RESULTS: Medal rankings of JWC, U23 WC and WC/OG correlate moderately ($0.55 < rs < 0.58$). About one third of JWC finalists make the leap to WC/OG, almost all of them via intermediate stage U23 WC. Female JWC medalists have a greater chance of participating in WC/OG than finalists (χ^2 [3, 118] = 13,27; $p < .01$). There is no correlation between the best result in JWC and the best result in WC/OG, but a medium correlation between results in JWC and U23WC ($r=.44$). The probability of participation in WC/OG is greater for small boat JWC-medalists than for big boat medalists ($\chi^2[1,N=138] = 4.85$, $p < .05$, $\phi = 0.19$). From junior to senior level, the change between small boat and big boat is more likely than the change between sweep and scull. 54 % of the OG-A-finalists already rowed in JWC, 80 % in U23 WC. Participants in JWC reach elite level about two years earlier than non-participants ($F[275,3] = 54.87$, $p < .001$, $eta^2 = .38$).
CONCLUSION: The generalized assumption of participation in international junior competitions as a prerequisite for elite success was not confirmed. U23 WC seem to be an important milestone in rowers' career development. Results at JWC, on the other hand, should not be overestimated. Enable discretionary entries when promoting prospect athletes.

THE COGNITIVE AND PHYSICAL CHARACTERISTICS OF YOUNG, TALENTED GYMNASTS

LAUREYS, F., DE WAELLE, S., MOSTAERT, M., DECONINCK, F., LENOIR, M.
GHENT UNIVERSITY

Introduction.
Traditionally, the focus in the majority of studies on talent identification in sports is on physical characteristics. However, the explained variances of these physical characteristics are limited (around 40% of the expertise level at best) and the power of predictive models decreases with increasing time span of the prediction (Vandorpe et al., 2012). Other factors should be included to improve these predictive models, such as cognitive functions. Different studies have shown that adult elite athletes have better cognitive functions than sub-elite athletes or sedentary people (Scharfen & Memmert; 2019). In spite of the importance of the potential predictive value of cognitive functions, virtually no studies were found where these functions are combined with physical characteristics.
Methods.
A total of 67 9-to-14-year old male and female gymnasts, selected for a talent developmental programme, conducted anthropometrical, physical, motor coordination and cognitive tests at different test days organised by the Flemish Gymnastics Federation. For the cognitive tests we used seven tests of the Cognitive Brain Sciences test battery that evaluate visual-spatial working memory, planning, inhibition, shifting and attention. Gymnasts were matched with a control group, based on gender and age. The control group were children from elementary and high schools, who did not practice sports or practiced a team-sport not more than 3 hours per week. These 67 control children performed the multidimensional test battery during their PE-classes.
Results and discussion.
A MANOVA showed that the gymnasts outperformed the control group on all physical and motor coordination tests ($F= 62.2$, $P<0.001$). With the amount of training hours per week, it is unsurprising that the gymnasts have a better physical profile than the control group who did not (or in a low amount) practiced sports. Second, this is one of the first studies to investigate the cognitive profile in athletes at a pre-adolescence age. Interestingly, the gymnasts scored significantly better on two cognitive tests (inhibition control: $F= 3.384$, $P=0.068$; spatial planning: $F= 8.854$, $P=0.003$). These characteristics correspond well to the demands of a closed-skill sport like gymnastics. On the other five cognitive tests, there was no significant difference between the gymnasts and the control group. This outcome supports the hypothesis that gymnasts have better scores on specific cognitive characteristics, even at a pre-adolescence age. These findings might prove valuable in the context of talent identification in artistic gymnastics.

MIND, BODY, AND SHUTTLE: MULTIDIMENSIONAL PROFILES OF BADMINTON YOUTH PLAYERS OF DIFFERENT LEVELS.

ROBERTSON, K.
GHENT UNIVERSITY

INTRODUCTION: The acquisition of sport specific profiles of youth badminton players paves the way for Talent Identification programmes which are essential to identify the better athletes at an early stage and to the optimal development of these individuals (Pion, 2015). In badminton literature, however, there is a lack of morphological, physical, coordinative and maturity characteristics of youth players. The aim of this study was to identify the key differences in anthropometric, physical performance, motor coordination, and psychological characteristics among groups of youth elite, recreational and novice badminton players and participants through the use of a multi-dimensional test battery. This study focused on bringing a more multifaceted approach to its data, as most available research tends to be more unidimensional in nature. Therefore, the mental element was also taken into consideration, as psychological characteristics of a badminton player play an important role (Zivdar et al., 2012).
METHODS: Sixty-one male participants between the ages of 12-18 were divided into three groups: elite (N=10), recreational (N=24), and novice (N=27). Standard test batteries for anthropometry (including measures to estimate biological maturity), physical performance, and non-sport specific motor coordination were applied, as well as a modified PCDEQ2 questionnaire for psychological characteristics of youth athletes (Hill, 2016). For each of these four domains, MANCOVAs with age and biological maturity as covariates were used to investigate differences between expertise levels. A discriminant analysis was used to reveal to what extent individual participants could be correctly assigned to their expertise group.
RESULTS: Significant differences between groups were found in variables related to physical performance (explosivity, flexibility, speed, and endurance), BMI and motor coordination. In the psychological domain, perfectionism was found to be significantly different between groups where elites scored highest. The discriminant analysis reported that 100% of the groups were correctly classified and that 80.0% were also correctly cross validated.
CONCLUSION: This multidimensional battery has proven to be an important asset in talent identification in badminton, in spite of the absence of badminton-specific tests included in it. Such a battery is not only informative on the profile of elite players as is commonly

focused upon in literature, but also enables discrimination between several levels of experience. This research has provided coaches with data that facilitates them with the ability to make more objective decisions as to whether or not an athlete's weaknesses possess some level of "trainability" that can lead to performance improvements. A more diverse and multidimensional battery, ensures that a coach can have a more complete picture or vision of their young athletes and thus develop a strong talent identification model.

FOUR WEEKS OF ISOMETRIC STRENGTH TRAINING DETERMINE DIFFERENTIAL CHANGES IN MUSCLE FIBRE CONDUCTION VELOCITY IN HIGH- AND LOW-THRESHOLD MOTOR UNITS

CASOLO, A.1,2, FARINA, D.2, BAZZUCCHI, I.1, FELICI, F.1, DEL VECCHIO, A.1,2

1 UNIVERSITÀ DEGLI STUDI DI ROMA FORO ITALICO, ROME, ITALY; 2 IMPERIAL COLLEGE, LONDON, UK

INTRODUCTION: Short-term strength training elicits adaptations in the central and peripheral properties of motor units. However, changes in the membrane properties of muscle fibres of individual motor units induced by short-term strength training are unknown. The average velocity of propagation of action potentials along the muscle fibres innervated by individual motor neurons, which we will refer to as motor unit conduction velocity (MUCV), reflects the electrophysiological properties of fibre membrane (1) and is associated to the fibre diameters (2). This study aimed at investigating MUCV adjustments after four weeks of strength training.
METHODS: Twelve participants (INT) performed 4 weeks of strength training characterized by isometric ballistic (x40) and submaximal sustained (x30) contractions, while twelve acted as controls (CON). Measurement sessions involved recordings of maximal (MVF) and submaximal isometric muscle forces of ankle dorsiflexors during linearly increasing ramp contractions (35, 50, 70% MVF) while recording high-density surface EMG signals from the tibialis anterior muscle. EMG signals were decomposed into individual MU discharge timings (3) and the identified MUs were tracked across sessions (4). MUCV was estimated with a multi-channel maximum likelihood algorithm (5). Two-way RM ANOVAs and linear regressions between MUCV and recruitment threshold (RT) were performed.
RESULTS: Maximal voluntary force (PRE: 284.3±64.0, POST: 324.4±61.5 N; P=0.003), normalized MU recruitment threshold (PRE: 32.2±18.1, POST: 27.4±15.7 %MVF; P=0.001), and average MUCV (PRE: 4.52±0.39, POST: 4.66±0.44 m/s; P=0.028) changed significantly in the INT group. MUCV of the tracked MUs was positively correlated with normalized RT in all conditions and groups (R2 =0.71±0.16; P<0.05). However, the slope of the regression line between MUCV and RT increased significantly only in the INT group (PRE: 0.019±0.007, POST: 0.025±0.011 m/s·%MVF; P=0.028), indicating a progressive greater increase in MUCV for higher threshold motor units. On the other hand, the initial value of MUCV did not change significantly. Similarly, average MU discharge rate at recruitment did not change significantly with training. None of the changes observed in the INT group were observed in the CON group.
CONCLUSION: The increase in the rate of change in MUCV as a function of motor unit recruitment, but not the initial value of MUCV, suggests that short-term strength training elicits specific adaptations in the higher threshold motor units. Moreover, the increase in MUCV was not accompanied by changes in discharge rate. Our results provide the first evidence of specific adaptations in the electrophysiological properties of the muscle fibre membrane in high-threshold motor units.

THE EFFECT OF FATIGUE RELATED SUSTAINED GROUP III/IV MUSCLE AFFERENT FIRING ON INTRACORTICAL EXCITATORY AND INHIBITORY BRAIN NETWORKS.

LATELLA, C., VAN DER GROEN, O., RUAS, C.V., TAYLOR, J.L.

EDITH COWAN UNIVERSITY

INTRODUCTION: Feedback from group III/IV muscle afferents reduces drive to the muscle during intense exercise (1). These afferents fire in response to muscle metabolites produced during exercise, evoking sensations of muscle work and pain. If blood flow is occluded post exercise, sustained afferent firing occurs and voluntary activation is impaired (1,2,3). Supraspinal mechanisms are thought to contribute to this impairment (2), but have not been identified. Thus, we aimed to determine whether fatigue-related group III/IV muscle afferent firing acts at the motor cortex to affect intracortical facilitation or inhibition.
METHODS: In two studies, each comprising two sessions, participants undertook a sustained isometric maximal index finger abduction of first dorsal interosseous (FDI) until force decreased by 40%, with post-exercise blood flow occlusion in one session and not in the other (control). Pre- and post-exercise single- and paired-pulse transcranial magnetic stimulation (TMS) elicited motor evoked potentials (MEP), intracortical facilitation (ICF) and short-interval intracortical inhibition at 2 and 3 ms (SICI2, SICI3). Ulnar nerve stimulation evoked maximal M-waves (MMAX). Potentials were recorded from FDI. In study 1 (n=16), TMS intensities were 120% and 70% of resting motor threshold for the MEP and conditioning stimulus, respectively. In study 2 (n=16), the MEP was maintained at 1mV pre- and post-exercise. The conditioning TMS was optimised for each individual pre-exercise. Pain was assessed pre- and post-exercise using a 0-10 scale.
RESULTS: Pain was significantly higher during post-exercise occlusion compared to control in both studies (P<0.001). In study 1, the FDI MEP (normalised to MMAX) was reduced post-exercise (P=0.007) but did not differ between occlusion (-2.1 ± 1.5% MMAX; (Mean ± SD)) and control (-2.6 ± 3.3% MMAX). No differences were observed for SICI or ICF (P>0.05). In study 2, the normalised MEP increased (P=0.027) for both occlusion and control (2.0 ± 1.5% and 1.3 ± 1.8% MMAX, respectively). For SICI2, the conditioned MEP increased (less inhibition) post-exercise from 53.9 ± 28.1% to 62.6 ± 17.2% of the single-pulse MEP (P=0.021) but was not different between conditions. ICF decreased post-exercise for the control condition (-28.0 ± 35.4%, P=0.006) but not with occlusion (-4.2 ± 30.3%, P=0.5867).
CONCLUSION: Consistent with previous findings, the reduction of MEPs after exercise is not influenced by the maintained firing of fatigue-sensitive group III/IV muscle afferents. Similarly, cortical inhibitory networks were modulated by fatigue but not by afferent feedback. By contrast, a fatigue-related reduction in ICF was counteracted by sustained afferent firing. Collectively, the findings do not support the idea that actions of group III/IV muscle afferents on motor cortical networks lead to reduced voluntary activation.

ACUTE EFFECTS OF HEAVY- VS LIGHT-LOAD RESISTANCE TRAINING ON NEUROMUSCULAR AND FUNCTIONAL FATIGUE IN OLDER PEOPLE

RODRIGUEZ-LOPEZ, C., ALCAZAR, J., NAVARRO-CRUZ, R., GARCIA-TERCERO, E., CSAPO, R., ARA, I., ALEGRE, L.M.
UNIVERSITY OF CASTILLA-LA MANCHA

INTRODUCTION: Resistance training is recognized as an effective strategy to promote neuromuscular and functional improvements in older people (1,2). Acutely, resistance training may impair neuromuscular and physical function (3), but the effects of changing loads have scarcely been studied in elderly subjects. This study aimed to assess the acute effect of different resistance training loading schemes on neuromuscular and physical function in older people.
METHODS: Fifteen well-functioning older volunteers (6 women; 73.6±3.8 years; 11.7±0.5 points in the Short Physical Performance Battery) with no previous experience in resistance training were included. Subjects completed two sessions of leg extension exercise using volume × load-matched heavy (HL: 6x6x80% 1-RM) or light loads (LL: 6x12x40% 1-RM), respectively, in a randomized order. Maximal isometric force (MIF) and rate of force development (RFD; 100, 200 and 400 ms) during knee extension and muscle power in the functional sit-to-stand (STS) test were evaluated before and after each training session (4). Volunteers were encouraged to complete all repetitions as fast and hard as possible. Time (PRE-POST) x Load (HL-LL) within-subjects' interactions were evaluated through repeated measures ANOVAs followed by Bonferroni-adjusted paired t-test. Pearson's coefficients were calculated to assess correlations between study variables.
RESULTS: There were significant time × load interactions in RFD at 100, 200 and 400 ms (all $p<0.05$), with decreases being observed only after the HL session (delta HL: RFD 100=−338.2 N/s; RFD 200= −248.4 N/s; RFD400= −120.0 N/s, all $p<0.05$). By contrast, no significant time × load interactions were found for MIF and STS power. MIF decreased only after the HL session ($p<0.05$) while no changes in STS power were found in any group ($p>0.05$). Finally, changes in RFD at 200 and 400 ms were significantly correlated with changes in STS power after the HL session ($r=0.53$ and 0.63, respectively; both $p<0.05$).
CONCLUSION: Despite the well-documented long-term benefits, resistance training impairs rapid force production and reduces functional performance in activities of daily living, with decrements being significantly greater when the training is performed with heavier loads.

A MUSCLE SYNERGY PERSPECTIVE ON MODULAR SHOULDER MUSCLE CONTROL DURING MULTIPLANAR MOVEMENTS

UMEHARA, J., YAGI, M., HIRONO, T., UEDA, Y., ICHIHASHI, N.
KYOTO UNIVERSITY

INTRODUCTION: Due to redundant muscular degrees of freedom a large number of muscle activation patterns can produce identical joint kinematics. This redundancy problem can be simplified and solved with muscle synergies, which are hypothesized control modules grouping muscles with similar function (1). The shoulder is a good model for studying redundancy and muscle synergies because of the shoulder's large kinematic range of motion and its large, relatively superficial and easily measurable muscles. The purpose of this study was to investigate how the shoulder muscles having redundant degrees of freedom are controlled during multiplanar shoulder movements. We hypothesized that a small number of shared muscle synergies in multiplanar movements and/or their combinations could account for redundant activity patterns in shoulder muscles.
METHODS: Thirteen healthy males performed 14 specific multiplanar shoulder movements; to summarize, five movements were associated with elevation and lowering, five were associated with horizontal abduction and adduction, and four were simple rotations at different positions. Muscle activity was measured from 8 muscles (12 portions) using surface electromyography (EMG). Using non-negative matrix factorization, synergies were calculated first for the entire dataset (containing all movements; "global" synergies), and then for each movement separately ("separate" synergies). Then cosine similarity (r) was calculated between the global and separate synergies. Additionally, assuming the separate synergies consist of global synergy combinations (2), r was also computed between separate and merged synergies.
RESULTS: Decomposed EMG data could adequately reconstruct the original data. For each subject, entire muscle activities were accounted for by 6.1±0.5 global synergies extracted from the entire dataset. Muscle activities for each movement were also accounted for by 2.8±0.9 separate synergies extracted from sub dataset. Across all subjects separate synergies were similar to global synergies and/or merged synergies ($r=0.86±0.08$).
CONCLUSION: Categorization of the shoulder muscles into fewer than seven muscle synergies and combination of these synergies simplified numerous patterns of the shoulder muscle activities during multidirectional movements. This finding suggests that, depending on the movement task, the selection and the share of muscle synergies as control modules could overcome the redundancy when shoulder muscles were controlled.

INFLUENCE OF KNEE EXTENSOR AND PLANTAR FLEXOR MUSCLE-TENDON BEHAVIOUR ON THE ENERGY COST OF RUNNING AT DIFFERENT SPEEDS

MONTE, A., MAGANARIS, C., ZAMPARO, P., BALTZOPOULOS, V.

UNIVERSITY OF VERONA; LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: It is postulated that the utilization of series elastics elements (SEE) strain energy is enhanced when running speed increases: tendons contribute proportionally more positive work as running speed increases, thus allowing the muscle fibers to operate more efficiently and this should influence the energy cost of running (Cnet) (Fletcher & MacIntosh, 2017). The aim of this study was to investigate the operating length and velocity of vastus lateralis (VL) and gastrocnemius medialis (GM) during running at different speeds to understand the possible relationships between muscle-tendon behaviour during running and Cnet.
METHODS: Fifteen male endurance athletes (years: 24 2.4 years; body mass: 74 2.8 kg; height: 1.77 0.04 m) participated in the study. The force-length and force-velocity relationships of VL and GM were experimentally assessed by means of maximal isometric and isokinetic contractions of the knee extensors and plantar flexors, respectively; the optimal length (Lo) of VL and GM and the maximal contraction velocity (Vmax) were thus determined. Ultrasound and EMG were utilized to record the fascicle length and the EMG activity of VL and GM during these contractions. Oxygen uptake, kinematics of the body segments, ground reaction forces, EMG activity and fascicle length of VL and GM were recorded synchronously during running at three different speeds: 10, 13 and 16 km h-1.
RESULTS: During running VL was significantly longer and GM shorter in respect to Lo. Muscle fibre contraction velocity significantly decreased for VL and increased for GM as a function of running speed. Both muscles showed lower contraction speeds compared to Vmax: 3.13% (at 10 kmh-1) and -2.83.8% (at 16 kmh-1) of Vmax for VL and 54.8% (at 10 kmh-1) and 127% (at 16 kmh-1) of Vmax for GM. Cnet was unaffected by the running speed (4.040.38 Jkg-1m-1 , on average). The average MTU changes during the stance phase of VL showed a positive correlation with Cnet (N=45; r=0.53; P<0.001), whereas no correlation was observed in the case of GM. A significant negative relationship was observed between Cnet and the maximum fascicle shortening values of VL (N=45; r=0.46; P<0.001) and GM (N=45; r=0.50; P<0.001), as well as between Cnet and the SEE elongation of GM (N=45; r=0.50; P<0.001), whereas, no correlation was found between Cnet and VL SEE elongation.
CONCLUSION: This study confirms the notion that SEE strain is enhanced when running speed increases and demonstrates that muscle-tendon behaviour of VL and GM have indeed an influence on Cnet.

NEUROMUSCULAR ADAPTATIONS INDUCED BY ELECTRICAL STIMULATION TRAINING APPLIED OVER THE NERVE AT LOW INTENSITY

VITRY, F., MARTIN, A., PAPAIORDANIDOU, M.

INSERM U1093 - UNIVERSITÉ DE BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: Electrical stimulation (ES) is used to improve muscle strength. However, the main drawbacks are an excessive discomfort caused by the use of high stimulation intensities and a premature fatigue due to a non-physiological recruitment of motor units (2). To counteract these limitations, protocols using low intensity, high frequency and nerve application have emerged (1). Even if acute effects of these protocols have been studied (3), their impact on the neuromuscular system after a chronic application has never been investigated. The aim of the present study was to examine the effects of an ES training applied over the motor nerve at a low intensity on muscle strength as well as on accompanied neuromuscular adaptations. In order to cope with eventual important torque declines during high-frequency ES due to activity-dependent changes of motor axons excitability (4), two different frequencies, 20 and 100Hz, were tested.
METHODS: Thirty young healthy subjects were randomly assigned into three groups: 20Hz, 100Hz and Control group. The ES training consisted of 15 sessions of 25 stimulation trains (20sec ON – 20sec OFF, pulse duration 1ms, stimulation intensity evoking 10% Maximal Voluntary Contraction (MVC)). Before (pre) and after (post) training, MVC was assessed, while changes in muscle contractile properties were evaluated by analysis of the twitch torque (Pt). Neural adaptations were evaluated by the voluntary activation level (VAL) and the V-wave (normalised to the muscle compound action potential, V/MSUP), while the H-reflex and Motor Evoked Potential (MEP) were studied in order to assess spinal and corticospinal excitabilities during MVC (i.e. HSUP/MSUP and MEPSUP/MSUP).
RESULTS: MVC significantly increased after training ($p<.05$) for the 20Hz and 100Hz groups. A significant increase of VAL ($p<.05$), V/MSUP ($p<0.01$) and Pt ($p<.05$) was also observed for the two training groups at post conditions. HSUP/MSUP and MEPSUP/MSUP showed a significant increase at post conditions only for the 100Hz group ($p<.05$).
CONCLUSION: Results indicate that the ES protocols using low stimulation intensity applied over the motor nerve increased MVC torque. This increase of the subjects' maximal force generating capacity was accompanied by muscle adaptations, highlighted by enhanced muscle contractile properties, while neural adaptations, as evidenced by the increase in VAL and V/MSUP, were also observed. Stimulation frequency differentially affected spinal and cortical excitabilities, indicating that neural adaptations had a supraspinal origin for the 20Hz protocol, whereas spinal and supraspinal mechanisms were implicated in the MVC increase after the 100Hz protocol.

MUSCLE MISMATCH BETWEEN O2 DELIVERY AND O2 UPTAKE DURING LOWER AND UPPER LIMBS EXERCISES DETERMINED BY NEAR-INFRARED SPECTROSCOPY

BALDASSARRE, G., PIROVANO, I., PILOTTO, A., AZZARELLO, F., RE, R., SPINELLI, L., CONTINI, D., TORRICELLI, A., MARZORATI, M., PORCELLI, S.

INSTITUTE OF MOLECULAR BIOIMAGING AND PHYSIOLOGY

INTRODUCTION: It is well established that muscle performance, besides depending on O2 delivery and fractional O2 extraction capacity, is deeply affected by temporal and spatial matching between O2 delivery and O2 uptake at skeletal muscle level. Near-infrared spectroscopy (NIRS) is a well-established non-invasive method that helps to gain insights into skeletal muscle oxidative metabolism in vivo during exercise. At the onset of a constant work rate exercise, a mismatch between O2 delivery and O2 consumption is described as a transient "overshoot" of skeletal muscle fractional O2 extraction (usually determined by analyzing the [deoxy(Hb+Mb)] NIRS-derived variable time-course). Aim of this study was to evaluate by continuous wave NIRS the mismatch between O2 delivery and O2 uptake during exercises involving skeletal muscles with different structural and functional characteristics (lower vs upper limbs).
METHODS: Eleven moderately trained male subjects (age: 29.2±6.7 years) volunteered for the study. Each subject performed: i) an incremental exercise up to voluntary exhaustion (INCR); ii) two repetitions of 8-min heavy-intensity (70% of peak power output [Wpeak]) constant work-rate exercise (CWR). Lower and upper limbs exercises were performed on mechanical flywheel ergometers. During the test, pulmonary ventilation (VE), O2 uptake (VO2) and CO2 output (VCO2) were assessed breath-by-breath using a computerized metabolic cart. A chest band monitored heart rate (HR). Fractional O2 extraction changes (Δ[deoxy(Hb+Mb)]) in vastus lateralis and biceps brachii muscles, normalized from data obtained during transient ischemia, were evaluated by NIRS.
RESULTS: During cycling INCR, Wpeak was 260±33W and VO2peak was 3.02±0.42L*min-1, corresponding to 43.8±6.5ml*kg-1*min-1. During arm-cranking INCR, VO2peak was 29±9% lower than values obtained during cycling. HRpeak was not significantly different between cycling and arm-cranking exercise, reaching 99±2% of maximal age-predicted value. Δ[deoxy(Hb+Mb)]peak was 81.9±8.2% and 68.7±5.0% in cycling and arm-cranking exercise, respectively. During CWR, subjects reached a VO2 value of 2.37±0.41L*min-1 in cycling and 1.50±0.23L*min-1 in arm-cranking, corresponding to about 75% of respective VO2peak value. Δ[deoxy(Hb+Mb)] was 75±3% and 74±3% in cycling and arm-cranking, respectively. VO2 kinetics was slightly slower in arm-cranking (τ: 35±5s) compared to cycling (τ: 28±4s); during arm-cranking a VO2 slow component was observed in all subjects (15±5%). A transient overshoot of the Δ[deoxy(Hb+Mb)] kinetics was significantly more pronounced in arm-cranking (18±3) than in cycling (3±2%).
CONCLUSION: This study shows that in the transition from rest to heavy-intensity exercise a more pronounced mismatch between O2 delivery and O2 uptake is present during upper limbs exercise compared to lower limb exercise in moderately trained healthy subjects.

CYCLES OF ISCHEMIA AND REPERFUSION IMPROVE PERFORMANCE AND DECREASE SUBMAXIMAL HEART RATE ON INCREMENTAL CYCLING TEST

MAROCOLO, M., ARRIEL, R.A., OLIVEIRA. J.D., MEIRELES, A., PATTERSON, S.D.

FEDERAL UNIVERSITY OF JUIZ DE FORA

INTRODUCTION: The repeated ischemia/reperfusion cycles, (ischemic preconditioning; IPC), has been effective in attenuation of lactate accumulation during exercise, submaximal oxygen consumption. The IPC intervention, when applied during rest, results in enhancement of parasympathetic activity and reducing HR. We assessed the effects of IPC on performance and heart rate during and immediately after a maximal incremental cycling test (ICT).
METHODS: Eighteen recreationally trained cyclists (28 ± 4 years) were allocated to one of three groups: a. IPC, b. SHAM, c. Control (CON). After the first visit to familiarization and instructions about the tests, cyclists attended the laboratory on two separate occasions to perform an ICT: in the 1st visit they performed the reference test (pre), and in 2nd the test IPC, SHAM or CON interventions (post intervention). IPC was conducted alternately between legs and consisted by 2 cycles of 5-min occlusion (50 mm Hg above systolic pressure)/ 5-min reperfusion (0 mm Hg). The SHAM intervention was identical to IPC, but with an absolute pressure of 20 mmHg during the pseudo occlusion. The CON intervention was no occlusion. During the maximal ICT, heart rate, power output and perceived scale were measured. Immediately after ICT, the heart rate recovery was measured during 300 seconds.
RESULTS: Only IPC group improved performance of 4.8%, decreased heart rate at submaximal point during ICT, of 170 ± 8 to 166 ± 8 bpm, and presented a faster heart rate recovery, mainly on first minute of 151 ± 9 to 145 ± 8 bpm, compared to baseline. No differences for other parameters were found among groups.
CONCLUSION: The IPC intervention improved performance, decreased submaximal heart rate on the same point of exercise intensity, and accelerated heart rate recovery.

CHANGES IN CARDIORESPIRATORY RESPONSES AND RUNNING ECONOMY DURING 45-MIN GRADED TREADMILL RUNNING EXERCISES

GARNIER, Y.M., LEPERS, R., ASSADI, H., PAIZIS, C.

INSERM U1093 CAPS - UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: Compared to uphill, downhill running is characterized by lower oxygen uptake (V̇O2), heart rate (HR), minute ventilation (VE) and energy cost (EC) (Vernillo et al., 2017). A similar increase in V̇O2 and HR has been reported during prolonged level or downhill exercises performed at the same constant speed, while VE remained stable (Westerlind et al., 1994). However, change in EC during prolonged graded exercise is not well documented. This study aimed to investigate changes in cardiorespiratory responses and EC during 45-min exercises performed at the same heart rate in either level, uphill or downhill mode.
METHODS: Nine healthy male volunteers (age: 28 ± 7 years; mass: 73.1 ± 3.9 kg; height: 183 ± 5 cm; V̇O2MAX 56.4 ± 5.1 ml.min-1.kg-1), were recruited for this study. Participants randomly ran at 75% heart rate reserve during 45-min in a level, uphill or downhill condition. Gas exchanges were collected using a breath-by-breath portable gas analyser (Cosmed K4b², Rome, Italy). V̇O2, V̇E, breath frequency

(Bf), tidal volume (VT) end-tidal carbon dioxide (PetCO2), inspiratory duration (Ti) and total breath duration (Ttot) were recorded continuously and averaged over 5-min at two periods, between 10 and 15 min (T1) and 40 and 45 min (T2).
RESULTS: For a similar heart rate (157 ± 3 bpm), VfO2, VE, VT, and PetCO2 were lower during downhill compared to level and uphill conditions ($p < 0.01$). No difference in Bf and Ti/Ttot occurred between locomotion modes. VfO2, VE, VT decreased to the same extent between conditions from T1 to T2 (all $p < 0.01$), and PetCO2 decreased only during the downhill condition ($p < 0.001$). Uphill exercise was associated to a greater EC compared to level (6.2 ± 0.4 J.kg-1.m-1) and downhill (4.1 ± 0.6 J.kg-1.m-1) exercises. EC decreased only during the uphill condition between T1 (11.3 ± 1.3 J.kg-1.m-1) and T2 (10.6 ± 1.2 J.kg-1.m-1; $p < 0.01$).
CONCLUSION: Downhill running was associated to lower VO2, VE, VT, PetCO2 and EC compared to level or uphill exercises. The reduction in VfO2, VE and VT occurring from T1 to T2 during exercise was not different between the uphill, the level or the downhill condition, suggesting that the mode of locomotion did not modulates these changes. BF and Ti/Ttot being similar between conditions, it suggests that mechanical expiratory flow could not explain the reduced cardiorespiratory responses to downhill condition. The reduction of cardiorespiratory responses would rather mirrored a lower metabolic stress. This hypothesis is further supported by the lack of EC change during the downhill exercise while PetCO2 decreased from T1 to T2. These findings suggest that the overdrive ventilation pattern during downhill running is likely due to a greater stimulation of efferent neural factors.

PERFORMANCE DECEPTION IN HYPEROXIA MAY IMPROVE SUBSEQUENT NORMOXIC CYCLING TIME-TRIAL PERFORMANCE

CLARK, B.1, DAVIES, M.J.1,2, GARVICAN-LEWIS, L.A.1,2,3, WELVAERT, M.1,2, GORE, C.J.2, THOMPSON, K.G.1,4

1: UNIVERSITY OF CANBERRA RESEARCH INSTITUTE FOR SPORT AND EXERCISE, 2: AUSTRALIAN INSTITUTE OF SPORT, 3: AUSTRALIAN CATHOLIC UNIVERSITY, 4: NEW SOUTH WALES INSTITUTE OF SPORT

INTRODUCTION: Negative deceptive feedback has been shown to be an effective means to improve cycling time-trial (TT) performance by encouraging athletes to access a performance reserve (1). Similarly, completing a performance task in a hyperoxic environment also conveys performance benefits primarily by increasing oxygen availability at the working muscles (2). However, it is unknown if the performance reserve still exists in hyperoxia and if negative deception can be used to alter performance in a hyperoxic environment. Therefore, we aimed to investigate whether negative deceptive feedback could be used to alter performance in a hyperoxic TT and if any performance changes would be sustained in a subsequent normoxic TT.
METHODS: Twenty-three trained male cyclists (mean ± SD: age 33.8 ± 8.6 years; body mass 73.3 ± 7.7 kg; peak oxygen uptake 63 ± 7 mL.kg-1.min-1; maximal aerobic power 4.9 ± 0.6 W.kg-1) completed seven, 4,000-m cycling TT's. The first trial served as a familiarisation and the second as a baseline normoxic trial (NORM; fraction inspired oxygen content [FiO2]: 0.21 ± 0.04). In trials three and four cyclists inspired hyperoxic air (FiO2: 0.36 ± 0.03), with trial three self-paced (HYP), whereas in trial four (HYP-PACER), cyclists raced a pacer set at the mean power output from HYP. In trial five, cyclists completed a self-paced TT in normoxia (NORM-POST). For trial six, (HYP-102%), cyclists inspired hyperoxic air and raced against a pacer which was set at a power output 2% greater than their HYP-PACER trial however, cyclists were misinformed the pacer represented their best hyperoxic performance. Finally, the deception was revealed and cyclists raced a pacer at a mean power output 4% above NORM without deception (NORM-104%).
RESULTS: Mean power output significantly improved in HYP-102% (392 W, 95% CI = [374, 410]) compared to HYP-PACER (384 W [366, 402]) and in NORM-104% (367 W [349, 386]) compared to NORM (349 W [331, 367]) and NORM-POST (356 W [337, 374]). Improvement in the HYP-102% condition was associated with a higher VO2 and changes to the aerobic-anaerobic energy contribution. Likewise, VO2, the aerobic energy contribution and rating of perceived exertion were higher in NORM-104% compared with NORM and NORM-POST.
CONCLUSION: Our findings suggest an exercise reserve still exists when cyclists exercise in hyperoxia which can be accessed via provision of deceptive feedback. Furthermore, deceptive feedback during hyperoxic trials may alter performance in subsequent, normoxic trials.

THE EFFECT OF SPEED AND GRADIENT ON RUNNING ECONOMY AND OXYGEN UPTAKE DURING DOWNHILL RUNNING

BJÖRKLUND, G., DANVIND, J., SUNDSTRÖM, D.

MID SWEDEN UNIVERSITY

INTRODUCTION: Downhill running poses challenges were the gradient is of importance for energy cost and oxygen uptake. While demonstrated that downhill running at a slight gradient is most efficient, the energy cost increases with a steeper gradient (1). However, the additional effect of running speed has not been studied for downhill running. Therefore, the aim of the study was to analyse the combined effect of gradient and speed in downhill running on oxygen cost and running economy.
METHODS: Runners (n=6) were recruited for the study and performed 1) VO2max and running economy (J·kg-1·m-1) tests and 2) an experimental running protocol at two speeds,12 km·h-1 and 80% of the speed at VO2max (V80) and three gradients (0, -5° and -10°). V80 was higher than 12 km·h-1 for all participants. All testing was performed on a large treadmill 3x5 m (Rodby, Sweden) that were controlled for speed and gradient. The experimental protocol was performed continuously with 5 min at each workload in a randomized order, 30 min in total. VO2 was measured throughout the experimental protocol using a mixing chamber (Moxus Metabolic Cart, USA).
RESULTS: VO2 expressed as ml·kg-1·min-1 increased because of speed ($F1,5=27.8$, $p=0.003$) and decreased with gradient ($F1,5=87.6$, $p<0.001$). Between -5° and -10°, VO2 decreased less during V80 compared to 12 km·h-1 shown by an interaction ($F2,10=7.9$, $p=0.009$). However, speed did not influence running economy ($F1,5=0.9$, $p=0.38$) while gradient increased running economy ($F1,5=90.1$, $p<0.001$). A non-significant interaction effect suggests a shift in running economy between -5° and -10° depending on speed ($F2,10=3.5$, $p=0.07$). The running economy at V80 was higher compared to 12 km·h-1 at -5° but reversed at -10°. While a relation between running economy at V80 -10°, V80 -5° and 12 km·h-1 -10° ($rs>0.88$, $p<0.019$) was found, no relations between running economy on level terrain and steep downhill running (-10°) were recognised.
CONCLUSION: While we found no effect on running economy from speed alone, we did see a shift in the running economy for different speeds at an increased downhill gradient. This indicates that a high speed (V80) is more efficient at moderate downhill gradients, while a

lower speed (12 km·h-1) is more efficient in steeper downhill gradients. While previous research demonstrate that gradient is of great influence to running economy, the findings of this study suggest that speed also affects the running economy in downhill running.

EFFECTS OF TAPER ON GLYCOGEN CONTENT AFTER AN EXPERIMENTAL "LIVING HIGH TRAINING LOW": A DOUBLE-BLIND PLACEBO-CONTROLLED STUDY

PAPOTI, M.1, KALVA-FILHO, C.A.1, SCARIOT, P.P.M,2, RIBERTO, M.1, CASTIGLIA, M.1, LUCHES, G.P.1, BERTUCCI, D.R.1, DELAVECHIA, C.1, GOBATTO, C.2.A, PAPOTI, M.1

1 UNIVERSITY OF SÃO PAULO ; 2 UNIVERSITY OF CAMPINAS/LIMEIRA, SÃO PAULO – BRAZIL.

INTRODUCTION: Previous studies demonstrate that the "living high training low" (LHTL) can be effective to increase the ability to provide energy through the anaerobic metabolism (1). These results can be related with the improvements on glycolytic enzymes and in buffer capacity (1), or to the increase in energy sources related with the anaerobic pathway, as the glycogen contents (GC). During traditional training periodization, the taper period (i.e., non-linear decrease in the volume accompanied with a maintenance in intensity) frequently is prescribed to induce an exacerbate increase in GC, which was not confirmed after LHTL. Thus, the aim of present study was investigate the effects of 18 sessions of normobaric LHTL plus a 3 session of taper on the glycogen content (GC).
METHODS: Fourteen healthy males (28 ± 6 yrs; 81,6 ± 15,4 kg; 179 ± 5,2 cm) participated in this study. The subjects were trained using the one-legged exercise model, allowing four experimental groups (trained leg in hypoxia, TLHIP, n=9; control leg in hypoxia, CLHIP, n=9; trained leg in normoxia, TLNOR, n=5; control leg in normoxia, CLNOR, n=5). All participants performed 18 sessions of training (80-200% of VO2max, with length between 20 to 45 min) and leaving in a normobaric hypoxia environment (14,5% iFO2; ~3000m) or placebo condition (i.e., leaving in similar tends on ~530 m). A double-blind, placebo-controlled strategy was applied in this phase. After this period, all participants underwent 3 sessions of training (1 week) leaving out of tends. Muscle biopsies of vastus lateralis were taken before and after the taper period. The GC was determinate using a calorimetric method (2). The two-way ANOVA and Tukey's post-hoc procedures were used to investigate the possible effects ($p < 0.05$), which was accompanied by the cohen's d value for effect size (ES) estimation.
RESULTS: Baseline values of GC (TLHIP: 0.4 ± 0.1 mg.100mg-1; CLHIP: 0.3 ± 0.2 mg.100mg-1; TLNOR: 0.3 ± 0.1 mg.100mg-1; CLNOR: 0.4 ± 0.1 mg.100mg-1) were not altered after taper for CLHIP (0.3 ± 0.1 mg.100mg-1) and CLNOR (0.3 ± 0.1 mg.100mg-1) and TLNOR (0.4 ± 0.1 mg.100mg-1) ($p > 0,62$; ES: 0.04 to –0.64 [negligible to moderate]). However, the GC was significant higher after taper period for TLHIP (0.5 ± 0.2 mg.100mg-1) ($p = 0,02$; ES: 1.0 [moderate]). Although after the taper no significant differences were observed between TLHIP and TLNOR, a tendency was evidenced ($p = 0,07$) and a moderate and positive ES values of 1.06, indicate that the LHTL induced higher values of GC.
CONCLUSION: Considering the moderate ES and the no increases observed in TLNOR, our results demonstrate that the LHTL was effective to increase the muscle glycogen content and appears to be superior to the traditional training model.

OP-MI05 Agility

IDENTIFYING KEY PERFORMANCE METRICS ASSOCIATED TO HIGH/LOW POINTERS IN WHEELCHAIR RUGBY FROM AGILITY TEST

TSAI, M.

CANADIAN SPORT INSTITUTE PACIFIC

INTRODUCTION: In wheelchair rugby (WCR), agility tests are often used to evaluate athlete mobility from metrics calculated from linear/rotational acceleration and speed using inertial measurement units [1]. Many metrics can be calculated from the tests and it is difficult to identify the most important and relevant metrics for efficient athlete assessment and feedback. Further, in WCR different player classification (high and low point player classification) levels based on physical ability may require different mobility standards and metrics. Therefore, in this study, we aimed to determine key metrics derived from IMU measurement during an agility test that differentiate high and low point WCR athletes through dimension reduction.
METHODS: 22 male athletes performed an agility protocol involving linear and rotational accelerations twice with 2min rest in between. During the agility protocols a 9DoF IMU was mounted to the chair and sampled movement data at 200Hz. Post-processing of IMU data yielded 55 metrics. Exploratory Factor Analysis (EFA) was used to determine the optimal number of factors and the variables most highly contributing to them. MANOVA was then used on the optimal factors to determine the key metrics that differentiate between athlete class (high/low).
RESULTS: Scree plot analysis suggested 3 to 5 factor solutions are optimal. 3-factor solution was selected for its simple structure (ie single loading per metrics) and the variables were grouped into rotational (radial acceleration, radial speed, turning radius), linear (acceleration, speed) and time (time to cone) domains. MANOVA showed no difference in rotation ($p=0.568$), however there is a significant difference in linear ($p<0.001$) and time domain ($p<0.001$) between classes. Univariate ANOVA further revealed significant difference between classes for 1) linear domain variables of forward brake ($p<0.01$) and reverse brake acceleration ($p=0.024$) peak acceleration from pushes (initial 2, initial 3, second 1) ($p<0.001$ for all) and peak backward speed ($p=0.01$) and 2) time domain variable of time to cones (1, 2, 3, 4, 5) ($p<0.001$ for all) and 2) .
CONCLUSION: The EFA decomposed the WCR agility test metrics into 3 domains and the metrics that were different between classes were identified. The identified metrics demonstrate difference between athlete classes were found within linear and time domains and not rotation. The analyses assist practitioners in focusing on the key metrics important to the mobility skill movements for player classes within WCR. Future investigations will evaluate game data to understand the game demands through determining the key domains and metrics. The insights can assist in designing WCR tests that more accurately.

THE INFLUENCE OF ENTRY AND EXIT TIME CONTRIBUTION ON CHANGE OF DIRECTION PERFORMANCE

CLARKE, R.1, HUGHES, J.D.1, READ, P.J.2, HUMPHRYS, B.1, DE STE CROIX, M.B.A.1

1. UNIVERSITY OF GLOUCESTERSHIRE, 2. ASPETAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL,

INTRODUCTION: Recently, the traditional quantification of change of direction (COD) performance via total time to complete a task has been questioned (1). It was subsequently suggested that exploring entry speed and exit speed may provide more information of an athletes' performance capabilities (1). Research has also suggested that increased ground reaction force and knee valgus loading during the plant step (2), and reduced task success (3) are influenced by increased entry speed. Therefore, understanding an athlete's task completion strategy may help practitioners screen for injury risk as well as profile for performance.
METHODS: Thirty-two youth athletes involved with regular strength and conditioning (age: 15.7±1.1 yrs) performed a 180° COD task (5-0-5 test) with a contact mat (Smart Speed and Smart Jump, Fusion Sport) at the plant step of the turn. Entry time was calculated as the time from the 5m gate to 50% of ground contact during the plant step of the turn (4), while exit time was calculated from 50% of plant step ground contact to returning through the 5m gate. To determine performance strategy, percentage contribution of these phases to 5-0-5 time (Entry + Exit) was calculated via (phase contribution/5-0-5 time) *100. All variables were calculated from the best of three dominant side COD attempts. Participants were ranked based upon total 5-0-5 time and a median split (2.52 seconds) was used to separate fast and slow groups. An independent samples T-tests was used to investigate the difference in COD completion strategy between the two groups. In order to explore the individual variation in task completion strategy; individual completion strategy was analysed and participants whose strategy was greater than the mean ± typical error (TE = 1.77%) were identified.
RESULTS: The fast group showed significantly different (p = 0.00) strategy where entry time had a smaller contribution (44.66 ± 2.16 vs 47.43 ± 2.05%) to total time and subsequently exit time had a greater contribution (55.34 ± 2.16 vs 52.57 ± 2.05%). The fast group showed nine participants (56.25%) with a completion strategy outside than the mean ± TE (six higher and three lower), while the slow group showed eight participants (50%) with a completion strategy outside than the mean ± TE (four higher and four lower).
CONCLUSION: In conclusion it may be that a possible trend exists for faster athletes to have reduced entry time contribution to their total performance time. This may indicate a superior deceleration ability in this group. However, athlete strategy shows significant variation regardless of COD speed, meaning that athletes should be analysed as individuals in order to accurately profile performance and prescribe future training interventions.

MOVEMENT VARIABILITY IN THOSE WITH AND WITHOUT ATHLETIC GROIN PAIN DURING A RUNNING CUT TASK.

GORE, S.1,2,3, FRANKLYN-MILLER, A.1,4, RICHTER, C.1, KING, E.1, FALVEY, E.C.1,4, MORAN, K.2,3

1. SPORTS SURGERY CLINIC 2. DUBLIN CITY UNIVERSITY 3. INSIGHT CENTRE FOR DATA ANALYTICS 4. UNIVERSITY OF MELBOURNE

INTRODUCTION: Athletic groin pain (AGP) is a common injury, typically associated with sports involving repetitive agility tasks. Given the association between repetitive loading and chronic overuse injuries such as AGP, there has been a growing interest in the functional role movement variability may have with respect to injury (1). The aim of this study was to investigate if the magnitude of variability differed between those with and without AGP across the total waveform of the analysed variables.
METHODS: Twenty AGP patients and twenty recreationally active male field sports athletes were recruited to this study. Each participant attended the lab on one occasion and completed 7 trials of a 110° cutting action. Motion and force data were captured using 10 Vicon Bonita cameras and 2 AMTI force plates at a sampling frequency of 200 Hz and 1000 Hz, respectively. Data were filtered at 15 Hz and normalised to 101 data points. A modified vector coding approach was utilised to calculate the co-ordination between joints (2). Variability was calculated for both joint angles and the co-ordination between every joint of the lower limbs, trunk and pelvis using the between-trial standard deviation or the circular equivalent for the coordination data. A statistical curve analysis was performed using one-dimensional statistical non-parametric mapping (3) and rank rank-biserial correlation (RBC) was presented as a standardised measure of effect. Only phases of 3% or longer were considered as true differences (4).
RESULTS: Ankle dorsi/plantar flexion (79-93%, RBC = 0.51), Thorax abd/adduction – Hip flex/extension (88-93%, RBC = 0.65) and Pelvis abd/adduction – Hip flex/extension (88-93%, RBC = 0.57) variability were all significantly less in the AGP group in comparison to the uninjured group ($p < 0.01$). In contrast Pelvis flex/extension variability (36-63%,70-84%, RBC =0.49) was significantly greater in the uninjured group in comparison to the AGP group ($p < 0.01$).
CONCLUSION: The results from this study indicate that AGP patients are characterised by reduced movement variability in comparison to uninjured controls for three out of the four significantly different variables identified. While causality cannot be determined from the current study, it is possible that reduced variability represents a risk factor for AGP due to repetitive loading on the pubic symphysis region. AGP rehabilitation may, therefore, benefit from 'over-loading' variability by emphasising the use of a large number of degrees of freedom to encourage the exploration of new movement strategies by the neuromuscular system. While this rehabilitation should be conducted utilising whole-body movements, future research should investigate which rehabilitation exercises best target the variability at the joints affected by AGP.

ICE HOCKEY SPECIFIC REPEATED SHUTTLE SPRINT TEST PERFORMED ON ICE SHOULD NOT BE REPLACED BY OFF-ICE TESTING

LEGERLOTZ, K., KITTELMANN, J., DIETZEL, M., WOLFARTH, B., BÖHLKE, N.

HUMBOLDT UNIVERSITÄT ZU BERLIN & OLYMPIC TRAINING CENTRE BERLIN

Introduction
Although the importance of sport specific testing has been stated in various studies, the application of standard tests that are little related to the requirements in competition is still widespread in performance diagnostics. Further, the exercise mode in testing itself often deviates from the exercise mode in competition. The aim of this study was therefore to investigate how the performance in an ice hockey mimicking repeated sprint shuttle test (RSS) carried out off-ice differs from the on-ice performance (RISS). In addition we assessed how the RISS and RSS tests correlated with a graded exercise test, used to determine aerobic fitness off-ice.

Methods
Three performance tests were performed by 21 male ice hockey players (17.0 ± 0.9 years) within one week of the ice hockey pre-season: 1) a graded exercise test until exhaustion on a running track, yielding distance run; velocity at the individual anaerobic threshold; velocity at 4 mmol lactate; peak lactate; lactate levels three and five minutes post exhaustion and lactate recovery; 2) a RSS test and 3) a RISS test, both yielding best run time; mean run time; total time; mean start time; mean turn time; mean fly time; shift 1, 2 and 3 time; anaerobic fatigue per shift; mean anaerobic fatigue; aerobic fatigue; and the decrement score.
Results
Anaerobic fatigue was significantly larger in RISS and did not correlate with RSS, while best run, mean run, total run time, turn and fly time as well as total times in all three shifts correlated moderately. While the best and mean run times did not differ, these times were achieved with different strategies depending on the test condition, indicated by significantly different split times. Aerobic fatigue in shift three was the only parameter where the off-ice measurement correlated strongly with the on-ice measurement. The parameters correlating with the graded exercise test differed for the RISS and the RSS test, with all detected correlations being moderate only. In addition, a good performance in the graded exercise test was not necessarily related to a good performance on ice. While players who showed less anaerobic fatigue in the third shift on ice had also lower lactate levels five minutes post exhaustion in the graded exercise test, good skaters, defined as players with faster turn times, were slower at 4 mmol lactate in the graded exercise test.
Discussion
Our study showed that the specific technical and physical requirements of running and skating led to differences in the performance test. Our results imply that the off-ice test does not predict on-ice performance with sufficient precision, strongly advocating performance testing in the exercise mode used in competition.

HEART RATE RESPONSE AND RATING OF PERCEIVED EXERTION DURING SUBMAXIMAL YO-YO IR1 TESTING ON SAND: A PILOT STUDY

SZWAJCA, S., EILS, E.

INSTITUTE OF SPORT AND EXERCISE SCIENCES

INTRODUCTION: The use of non-exhaustive field tests is common in team sports to provide useful information about aerobic capacity, physical performance and training status in athletes whilst minimising the burden of fatigue [1, 2, 4]. Since sand-based team sports like beach handball or soccer gain more popularity and professionalism, equivalent surface-specific testing is lacking. Moreover, no research to date has evaluated physiological responses to submaximal Yo-Yo IR1 on sand surface. Therefore, the aim of this observational study was to investigate the difference and relationship between heart rate response and rating of perceived exertion during submaximal Yo-Yo IR1 testing on rigid and sand surfaces.
METHODS: Nine physically active participants (6 male, 3 female; age 24±3 yrs) completed submaximal Yo-Yo IR1 testing indoor and outdoor on two consecutive weeks. Outdoor testing was performed on sand (grain size: 0-2 mm) using a modified Yo-Yo IR1 (15 m shuttle length), resulting in lower total distance (720 m vs. 540 m) and running speeds (10–14.5 km/h vs. 7.5–10.8 km/h). Exercise HR (HRex, every 60 s), post exercise HR recovery (HRR, after 1 min) and rating of perceived exertion (RPE, 6–20 scale) were assessed. Two-way (time x surface) repeated-measures ANOVAs, Pearson correlations (and non-parametric equivalents) were used to evaluate differences and relationships between parameters ($\alpha \leq 0.05$).
RESULTS: Overall, values of HRex and HRR (absolute and relative to est. HRmax) on sand were higher compared to indoor (md: 4.8 bpm, 95% CI: -1.1–10.8; 2.4%, 95% CI: -0.6–5.3). No sign. differences were found for surface ($F(1,8)=3.445$, $p=.101$, $peta^2=.301$; $F(1,8)=3.471$, $p=.099$, $peta^2=.303$) except for HRex60s (md: 11.7 bpm, 95% CI: 1.1–22.4; 6.1 %, 95% CI: .06–11.7). Significant strong to very strong positive correlations were found for most parameters ($r=.733–.924$, $p<.025$), with the exception of HRex60s and relative HRR1. Conversely, RPE was significantly higher ($p=.015$) for indoor condition, showing no significant correlation to other parameters.
CONCLUSION: Collectively, preliminary results indicate that heart rate response (HRex, HRR) for the modified, submaximal Yo-Yo IR1 is comparable between sand and rigid surfaces and therefore, can potentially be used to monitor training status and physical performance of sand-based team sport athletes. However, these findings are limited by a small sample size, test conditions (outside temperature, sand consistency), and the observational character of the study. Moreover, it is of interest, how individual responses differ in elite, well-trained and/or habituated beach sport athletes [3]. Thus, established field tests can be modified to provide robust reproducibility on sand surface.

OP-SH09 History

THE ROLE OF SÃO PAULO CLUBS FOR THE DEVELOPMENT OF GYMNASTICS DEMONSTRATIONS IN THE EARLY TWENTIETH CENTURY: REFLECTIONS FOR GYMNASTICS FOR ALL IN THE 21ST CENTURY

TOLEDO, E.

UNICAMP

INTRODUCTION
At the beginning of the 20th century, clubs played a fundamental role in the development of gymnastics (TOLEDO, 2017) in the city of São Paulo (the largest Brazilian metropolis). The gymnastics demonstrations (by these partcipants), took place on festive dates and at Gymnastics events in the city and beyond. The objective of this research is to identify the aspects that underpinned the gymnastic practices (and their demonstrations) in the clubs of São Paulo in the early twentieth century, bringing reflections to the structuring of gymnastics for all – GfA (of great demonstrative character) in clubs in the 21st century.
METHODS

This is a historical and documentary research, which had as its source the collection of five centenary clubs of São Paulo: Atlético Ypiranga, Athlético Paulistano, Esperia, Pinheiros and Regatas Tietê. Historical clipping: from 1900 to 1960. The second source was composed of all editions of the Book of Abstracts of the International Forum of Gymnastics for All - FIGPT. Historical clipping: from 2001 to 2018. The first research and the last four editions of FIGPT had the support of FAPESP.
RESULTS AND DISCUSSION
It was identified that the clubs had the premise that the provision of gymnastics was in line with national and international health programs, as well as providing an aesthetic character (especially for women). The proposals were based on the European Methods of Gymnastics, and each club chose the method (French, Swedish, German, English, etc.) that most closely related to the immigrant profile of the associative members. Gymnastics classes had, in most clubs: a classification by age and/or by gender; specific place to practice; specialized coaches; facilities; visibility in the local media and promotion and participation in events (festivals). In the Book of Abstracts of FIGPT, we identify that GfA is little promoted in the clubs, probably due to the great promotion of competitive gymnastics and fitness; the lack of training of coaches; and the little knowledge of managers and members about GfA; its recent history in Brazil (PAOLIELLO, 1997); and its lack of publicity in the media. São Paulo still remains a city and a state of prominence in the promotion of the GfA, and of the gymnastic demonstrations, however, this still seems to be little promoted in the clubs. Many factors encouraging gymnastics (and their demonstrations) in the past, could be resumed.

AESTHETICS OF AFRICAN DIASPORA: RELATIONS BETWEEN LADJA (MARTINIQUE) AND CAPOEIRA (BRAZIL)

PASQUA, L., TOLEDO, E.
UNICAMP

INTRODUCTION: Brazil and Martinique are countries that had slave trade during the colonial period and became places where cultural bodily practices from African diaspora were re-signified (Deschi Obi, 2008; Costa & Silva, 2011). This research aims to establish relations between Capoeira (Brazil) and Ladja (Martinique).
METHODS: This is a documentary analysis whose research source are the video Agya Danmye Ladja Compilation, 1936, from the Katherine Dunham Collection and the video of a Capoeira Master, Samuel Querido de Deus, 1937, in the Folk Congress of Bahia (Brazil). The categories of analysis were characterization of cultural manifestation, musicality, body elements and acrobatic movements.
RESULTS: Ladja is a martial art from Martinique with African roots, which a dispute takes place, beginning with a kind of dance and afterwards there is a struggle between two men, performed in a circle structure with individuals dressed in casual clothes. In Capoeira the contest takes place in the form of a struggle, in which two people establishes a corporal dialogue, performed in a circle structure, dressed in clothes from their capoeira group. The musicality is present in both because of the presence of the drums, however the "berimbau" is only present in Capoeira. There are a singer and some people clapping in both practices. As for the body elements, Ladja presents some movements that look like the capoeira "ginga" (swing), with the same function of basic and central movement of the practice; however, very different from Capoeira "ginga". Ladja has rotated kicks and not so much acrobatics, but a lot of movements of expression (dance movements) while Capoeira has more kicks, rotated kicks, defenses, unbalanced movements, and may or may not appear acrobatic elements, the "flourishes" (Pasqua, 2011). We highlight that we found only few similar acrobatic elements between Ladja and Capoeira.
Conclusions:
In conclusion Ladja presents similar dynamics within Capoeira, such as the fact that it happens in a circle structure, followed by instruments and singing and there is fight. There are more dance movements in the Ladja than in the Capoeira, however they seem to have the same function as the flourishes in Capoeira. Ladja and Capoeira have more similarities than differences, corroborating with to the Aesthetic of the cool (Thompson, 2011) which means that could come from the same African roots.

HERO(INE) BOOMER, THE NATIONALIST CONSTRUCTION OF ELITE ATHLETES IN CHINESE SOCIETY

HU, X.
TSINGHUA UNIVERSITY

The research investigates the relationship between the Chinese nationalist narrative and the local interpretation of modern sport, which was introduced to China by the end of the 19th century, through interrogating the nationalist account in the construction of Chinese athletes in the Olympic Games, particularly those after Beijing was awarded its first Olympic Games in 2001.
Employing Critical Discourse Analysis as its theoretical framework, the research firstly discusses the complicated nature of the construction of a national hero in the Chinese society, in which there 56 officially recognised ethnic groups. The researchers subsequently investigates the portrait of Chinese sporting national heroes in the pre-2008 era through examining the government documents and media coverage after Beijing was awarded the 2008 Olympics. And two cases, Liu Xiang and the Chinese women's volleyball team, are selected as the principal data for the analysis of the construction of Chinese hero(in)es in the post-2008 era, for their importance in Chinese elite sport throughout the period immediately preceding and following the Beijing Games and capabilities of attracting great public attention for more than two Olympiads.
Through analysing the qualitative data, the research examines the two-folded nature of the nationalist account in the media construction of Chinese athletes, which is argued as a consequences of the political connotation of the concept of modern sport in Chinese society. It is demonstrated that there is a strong link between media narrative and the account of elite sport policy documents, emphasising Olym-

pic performance as policy task of the Chinese elite sport system. However, there have been changes and continuities in the discursive construction of the national hero(in)es after the Beijing Games, which are in line with the reform of Chinese elite sport, reconstructing the image and culture of Chinese elite sport, and could be argued as a manifestation of a cultural transformation in the Chinese media after the opening-up of China.

COMPARATIVE STUDY OF CHINESE AND WESTERN LEISURE SPORT CULTURES

LI, J., TIAN, H.

SCHOOL OF INTERNATIONAL SPORT ORGANIZATIONS, BEIJING SPORT UNIVERSITY

Comparative Study of Ancient Chinese and Western Leisure Sport Cultures
LI, Juan, TIAN, Hui
Beijing Sport University
INTRODUCTION: China and the western countries have long-held traditions of leisure cultures, and there is much historical documentation on ancient Chinese and western leisure sport activities. Due to the differences of eastern and western cultures, ancient Chinese and western leisure sport cultures exhibit different characteristics. Yet so far few literature has conducted comprehensive comparison of the two. Therefore, the present study aimed to investigate the differences of ancient Chinese and western leisure sport cultures.
METHODS: Materials from historical archives, literature and previous research were studied for the comparative study. Interpretations were based on solid evidence.
RESULTS: 1) Western ancient leisure sport cultures showed admiration of the human body, as was best demonstrated in ancient Greek leisure sport, while ancient Chinese leisure sport cultures emphasized the training of the spiritual mind, as was shown in ancient Chinese pitch-pot game, swordsmanship and traditional daoyin. 2) Western ancient leisure sport cultures upheld muscle strength and vigorous movements, whereas the latter preferred quiet, slow and restrained leisure sport activities such as qigong, daoyin, walking, etc. 3) Western ancient leisure sport cultures were based on cultivation of humanistic values, while much ancient Chinese leisure sport was utilized as a moral tool for feudal ethical education, such as the sophisticated ritual of archery. 4) Western ancient leisure sport cultures included more elements of entertainment, such as gladiators combat and chariot racing, while the latter had more folk customs in relation to seasons and solar terms, such as dragon boat racing on the Dragon Boat Festival, and ice sport on the Winter Solstice. 5) Western ancient leisure sport cultures showed more rationalization and abstraction, while the latter characteristics were more concrete. Many ancient Chinese leisure sport movements mimicked animals in the nature, such as "white crane spreading its wings" and "swallow dipping water" in Chinese Wushu.
CONCLUSION: Ancient western and Chinese leisure sport cultures have many differences in terms of body or mind, vigorousness or quietness, humanistic touch or feudal ethical education, entertainment or folklore, and abstraction or concreteness. These findings could help to understand the development of Chinese and western leisure sport in history.

A CULTURAL STUDY OF DRAGON AND LION DANCES IN CHINA

XIAOJUN, H.

GUANGZHOU UNIVERSITY

Background:
Dragon and lion dance is a traditional Chinese sport which combines martial arts, dance, painting and music. The dragon and lion dances culture fully embodies a national spirit and represents a symbol of a nation.Therefore , through the study of the dragon and lion dance culture, we can better understand the characteristics of the traditional Chinese sports.
Objective:
Through the cultural research of Chinese dragon and lion dance, this paper compares its historical origin and cultural differences between south and north, finds out the influence of its cultural implication on the dance of dragon and lion, and provides a certain reference from the inheritance and development of Chinese traditional folk cultures.
METHODS: This paper adopts three research methods. The first method is by the literature, to understand the legends and customs of dragon and lion dance ; The second is the field survey method, which makes a deep investigation into the differences in the forms of dragon and lion dance in the south (represented by Guangdong) and in the north (represented by Hebei); The third is the interview method, which interviewed 200 performers of each of the South and North dragon and lion dances to understand the differences between the types of dragons and lions in the South and North, techniques and equipment.
RESULTS: The dragon and lion dances is a totem worshipped by the ancient Chinese people . It is the religious behavior of ancient people seeking rain , offering sacrifices to their ancestors and the Buddhist legend of evading evil spirits . The dragon lion symbolizes peace , happiness , and good fortune , and is now an entertainment to add excitement to the festival or celebration .
Chinese dragon and lion dances are divided into different regions, and the dragons are divided into the South dragon and the North dragon, presenting beautiful and magnificent: south dragon looks round and soft in shape, while north dragon looks fierce in shape and moves just Powerful.The lion dance is divided into south lion and north lion:The performance of the Southern Lion is based on the expression and portrays an exaggerated and romantic image of the Lion ; The performance of the Northern Lion is based on realism, imitating the real feeling of the Lion and showing the brave spirit of the Lion. However, with the development of the times, the dragon and lion dance culture gradually appeared problems such as lack of equipment facilities, reduction of audiences, and a decline in the cultural identity of the people.
CONCLUSION: With the change of times, the culture of dragon and lion dance is losing gradually. Therefore , through the cultural research of Chinese dragon and lion dance, We should let the traditional sports of the Chinese nation return to peoples lives , protect the cultural characteristics of the dragon and lion dance , dragon and lion dance of the spirit of Chinese traditional sports will flourish and inheritance .

INVESTIGATION INTO THE CORRELATES AND DETERMINANTS OF OLYMPIC SUCCESS

SOOS, I.1, KISS, T.2, WHYTE, I.3, HOGG, B.3, HAMAR, P.1, MARTINEZ, J.C.4, SZABO, A.5

UNIVERSITY OF PHYSICAL EDUCATION

Introduction

Olympic success is widely recognised in many countries as having positive impacts on three discrete yet often overlapping areas: image; economy; and, physical activity and health. In the past, economic, demographic, geographic, political and cultural hypotheses were most commmonly used to explain Olympic success. We took the first two into consideration in our study. The aim of the study was to investigate if the relationship between GDP per capita and the population/size of the nation are the strongest predictors of Olympic success (measured by the total number of medals won).
Methods
Olympic medal winning countries from the last four Olympic Games were included for data analysis. Of this sample, sixty-two countries were selected for final analyses; namely those who won at least one medal at each of four Olympic Games (Athens, Beijing, London, Rio). Gross domestic product per capita (GDP per capita) and national population size were obtained from the published World Bank online sources (The World Bank, 2017). The data about Olympic medals won were obtained from the BBC Sport (BBC, 2017).
Pearson correlation, multiple regression and MANOVA analyses were performed using IBM's SPSS v. 24 software package. ANOVA was also conducted using statistical software R (R Development Core Team, 2008) with data visualisation being carried out using Deducer package for the R statistical programming language (Fellows, 2012).
Results and Conclusions
Partial correlations were performed on two sets of data: total Olympic medals won and GDP per capita, controlled by population size; total Olympic medals won and population size, controlled by GDP per capita. They both showed weak and medium correlation ($r=.294$ and $r=.445$ respectively) with strong significance ($p<.001$ in both cases).
Multiple regression demonstrated significant relationships between total Olympic medals won and GDP per capita ($p=.012$), and total Olympic medals won and population size ($p<.001$) with a Durbin-Watson statistics 1.172 that indicates non-autocorrelation. ANOVA showed a good model fit ($F=9.407$, $p<.001$).
Multivariate Analysis of Variances (MANOVA) demonstrated a significant interaction effect for total Olympic medals won by GDP per capita and population size ($F=20.249$, $p<.001$), effect by GDP per capita ($F=12.269$, $p=.001$) and effect by population size ($F=43.389$, $p<.001$). The effect size was in the medium range ES=.31.
In conclusion, the role of the GDP appears to be inflated in previous work that attempted to predict the key factors involved in winning Olympic medals. In our current study, the size of the population of the participating nations accounted for more than twice as much of the variance in the winning of Olympic medals than the GDP-PC, pointing to the fact the success at the Olympic Games is not as much dependent on the national share of wealth as it was presumed. Indeed, the winning of medals at the Olympics may involve several other factors that, to date, were not identified.

PHYSICAL ACTIVITY AND SEDENTARY EXPERIENCES IN HIP AND KNEE OSTEOARTHRITIS: BALANCING BETWEEN BEING CONSTRAINED AND TO KEEP ENJOYING LIFE

KANAVAKI, A.M., HALE, E., RUSHTON, A., KLOCKE, R., DUDA, J.L.
UNIVERSITY OF BIRMINGHAM

Introduction
Promotion of a physically active lifestyle, including sedentary time reduction, should be an integral part of health-care provision for people living with hip and knee osteoarthritis (OA). Living with OA means living with limitations and pain in movement. For promotion of physical activity (PA) to be effective, it is important to understand such behaviours in the context of individuals' daily lives and experience of well-being.
Methods
Twelve individuals with knee or/ and hip OA from secondary care and community settings took part in semi-structured face-to-face interviews. This was a sub-sample from a prospective, observational study with good representation of age, gender, OA duration and severity. Inductive thematic analysis was used for data analysis. Trustworthiness was ensured through several processes (i.e. prolonged engagement, peer debriefing, external audit, thick description, negative case analysis, reflexivity).
Results
There were two overarching themes: PA Negotiations, including the themes valuing mobility, the burden of osteoarthritis, keep going, the feel-good factor and Sedentary Behaviour Negotiations, including the themes the joy of sitting, a lot is too bad, the osteoarthritis constraints. Two more themes, the life context and finding a balance, overlapped between the overarching themes.
Discussion
The findings revealed that PA and sedentary behaviours were multifaceted experiences, related to the burden of OA, the need to keep mobile and keep enjoying life, and life circumstances. There was a dynamic relationship among these facets and a constant negotiation of their relative importance, which was reflected on overt behaviours. PA was impinged by OA, but was also a means of coping with OA and a means of enjoyment and living life to the fullest. Importantly, PA choices were not made solely on the grounds of short term pain relief, but these individuals were consciously aiming at long-term preservation of mobility and living status. Engagement in sedentary activities were viewed as part of a desired way of life: selected activities were enjoyable, although there was a consensus that too much sitting was harmful and signified a degradation of health and well-being. Physical and psychological aspects of PA and sedentary experiences appeared to be interwoven. Well-being was not just a mental state, it was an embodied experience. In line with theoretical frameworks of behaviour change such as Social-Cognitive and Self-Determination Theories, positive PA experiences, beliefs and motivation synergistically laid the foundation for an active lifestyle. Targeting these aspects, with emphasis on mobility and living status preservation, as well as psychological support could hold promise for effective interventions in this population.

THE EFFECTS OF LOW ENERGY AVAILABILITY, ACHIEVED THROUGH DIET OR EXERCISE, ON COGNITIVE FUNCTION IN ORAL CONTRACEPTIVE USERS AND EUMENORRHEIC WOMEN

MARTIN, D.1, PAPAGEORGIOU, M.2, COLGAN, H.3, COOPER, S.B.3, GREEVES, J.P.4, TANG, J.C.Y.5, FRASER, W.D.5, SALE, C.3, ELLIOTT-SALE, K.J.3.1

UNIVERSITY OF LINCOLN

INTRODUCTION: Low energy availability (EA) may impair aspects of cognitive function in athletes (Mountjoy et al., 2018), possibly mediated by oestrogen status (Baskaran et al., 2017). No research has explored the effects of low EA on cognitive performance using dietary and exercise regimens relevant to athletes. Therefore, the aims of this study were: 1) to assess whether short-term low EA affected cognitive function; 2) to explore if the means by which low EA was achieved (e.g, diet or exercise) affected cognitive responses and 3) to examine whether oral contraceptive (OC) use affected responses.
METHODS: Following a DXA assessment of lean body mass (LBM), 20 female participants (10 eumenorrheic, 10 OC users) completed three, 3-day conditions: controlled-balanced EA without exercise (BAL; 45 kcal·kg·LBM-1·day-1), diet-induced low EA without exercise (DIET; 15 kcal·kg·LBM-1·day-1) and exercise-induced low EA (EX; 15 kcal·kg·LBM-1·day-1, including 30 kcal·kg·LBM-1·day-1 treadmill running at 70% VO2max). A cognitive test battery assessing verbal memory (Rey Auditory Verbal Learning Task [RAVLT]), spatial awareness (mental rotation test), executive inhibition (Stroop-colour test), psychomotor function (visual search test) and attention (Rapid Visual Information Processing [RVIP] task) was completed before and after each 3-day condition. Change from pre- to post-condition scores were analysed using two-way (group x condition) (RAVLT, RVIP) or three-way (group x condition x test level) (mental rotation test Stroop test, visual search test) mixed-model ANOVAs followed by Bonferroni adjusted post-hoc tests and Cohen's d effect size. Significance was set at $P \leq 0.05$.
RESULTS: Change from pre-to post-condition was different between conditions for accuracy in the mental rotation test (main effect of condition, $P = 0.045$). Post-hoc tests showed that whilst accuracy improved in the BAL condition, there was a decline in accuracy in the EX condition (BAL, +2.5%; EX, -1.4%; $P = 0.042$, $d = 0.85$). DIET (+1.3%) was not different to BAL or EX ($P > 0.05$). All other measures of cognitive performance were not affected by condition (main effect of condition, $P > 0.05$) and OC use did not affect cognitive responses to BAL, DIET or EX (group x condition interaction effect all $P > 0.05$)
CONCLUSION: Accuracy in the mental rotation test was impaired when low EA was induced through increased exercise energy expenditure, but all other aspects of cognition were unaffected by three days of low EA. OC use did not mediate the effect of low EA on cognition.

UNDERSTANDING BARRIERS AND ENABLERS FOR NUTRITIONAL ADHERENCE IN HIGH-PERFORMANCE SPORT

BENTLEY, M.R.N., PATTERSON, L., MITCHELL, N., BACKHOUSE, S.H.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Poor adherence to nutritional guidance by athletes may compromise their health and performance. Improving athlete nutritional adherence is a growing priority for sport and exercise nutritionists and high-performance sport systems. To advance understanding, we utilised the Capability, Opportunity, Motivation – Behaviour (COM-B) model and the Theoretical Domains Framework (TDF) to qualitatively explore the barriers and enablers of elite athletes' adherence to nutritional guidelines.
METHODS: Seven semi-structured focus groups were conducted with a purposive sample of 39 UK-based funded athletes ($M = 23$ years, $SD = 3.81$), participating in either Olympic and Paralympic sport ($n = 30$) or professional sport ($n = 9$). All participants had access to a trained nutritionist and the focus groups lasted $M = 90$ minutes (range 1 hour – 2 hours). Data were analysed using thematic analysis and the interpretations of the findings were guided by COM-B and the TDF.
RESULTS: Athlete adherence to nutritional guidance was seasonal and included inadequate energy intakes and episodes of binge eating. The behavioural analysis identified capability, motivation, and opportunity as both barriers and enablers to athlete nutritional adherence, exemplifying the complexity of the behavioural system. For the first time, this study illustrates athletes' motivational barriers are mutually reinforced through their social interactions within the high-performance environment (social opportunity). To achieve nutritional adherence, this research has illuminated the need to intervene across all three interacting COM-B components.
CONCLUSION: Using a theory-based approach ensured systematic and comprehensive identification of a wide range of barriers and enablers for nutritional adherence in high performance sport; laying the foundations for the development of targeted and multifaceted behavioural interventions that can help to protect athletes' overall health, well-being and performance. In particular, the person-environment interactions noted are directly relevant to the sport and exercise science community who are architects of the environment within which athletes are situated.

HEALTH-RELATED AND PSYCHOSOCIAL CORRELATES OF SEDENTARY BEHAVIOUR IN PEOPLE LIVING WITH RHEUMATOID ARTHRITIS: A LONGITUDINAL STUDY

OBRIEN, C.M., DUDA, J.L., KITAS, G.D., VELDHUIJZEN VAN ZANTEN, J.J.C.S., METSIOS, G.S., FENTON, S.A.M.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Rheumatoid Arthritis (RA) is an autoimmune disease characterised by high-grade inflammation, leading to joint pain and musculoskeletal deterioration, thereby compromising psychological wellbeing. People with RA engage in high levels of sedentary behaviour (SB), which may exacerbate RA outcomes. Thus, interventions to reduce SB may contribute to improved health in RA.
Prior to intervention, research exploring the role of SB for RA outcomes, as well as modifiable determinants of SB in RA, is required. In such studies, it is critical that measures of SB have been specifically validated for use among people with RA. Therefore, this study validated measures of SB (activPAL and GT3X), and subsequently employed these measures to investigate longitudinal associations between SB with: 1) pertinent RA outcomes, and 2) hypothesised psychosocial determinants of SB (informed by Self-Determination Theory [SDT]).
METHODS: People with RA (n=53) completed questionnaires to assess depression (Hospital Anxiety and Depression Scale), vitality (Subjective Vitality Scale), functional disability (Dartmouth COOP Charts) and autonomous motivation (AM) to reduce SB (Behavioural Regulation in Exercise Questionnaire-2 [adapted for reducing SB]). A fasting blood sample determined participants' Disease Activity Score-28 (DAS28 [Erythrocyte Sedimentation Rate plus swollen-and-tender joint count]) and systemic inflammation (C-Reactive Protein [CRP]). Participants wore an activPAL and GT3X for 7 days to measure SB and physical activity (PA). The protocol was repeated after 6 months.
The activPAL and GT3X were validated against direct observation and indirect calorimetry, respectively. RA-specific GT3X cut-points were developed for analysis: SB, 0-244 counts per minute (cpm); light PA, 245-2500 cpm.

RESULTS: Aim 1: Regression analysis revealed change in activPAL-assessed SB significantly positively predicted change in DAS28 (B=.24), CRP (B=.45), depression (B=.28) and functional disability (B=.41), and significantly negatively predicted change in vitality (B=-.38). Reverse associations were observed between standing with RA outcomes (DAS28, B=-.24; CRP, B=-.40; depression, B=-.24; functional disability, B=-.41; vitality, B=.33). Change in stepping significantly negatively predicted change in CRP (B=-.34) and depression (B=-.25), and significantly positively predicted change in vitality (B=.29). Change in GT3X-assessed SB significantly positively predicted change in CRP (B=.33). Aim 2: Change in AM to reduce SB significantly negatively predicted change in SB assessed by the activPAL (B=-.44) and GT3X (B=-.38), with reverse associations observed for activPAL-assessed standing (B=.40) and stepping (B=.29), and GT3X-assessed light PA (B=.41).
CONCLUSION: Findings suggest SB is adversely linked to RA outcomes. In addition, AM to reduce SB is beneficially associated with levels of SB. Thus, SDT may provide a theoretical basis for SB change interventions in RA, with the potential to improve pertinent RA outcomes.

EFFECTS OF LIFE-SKILLS DEVELOPMENT PROGRAM ON YOUNG ELITE FEMALE ATHLETES

HORINO, H.

WASEDA UNIVERSITY

INTRODUCTION: In recent years, elite athletes must increasingly devote themselves to their competitions in order to survive and win more sever competitions. Simultaneously, Life- skills development of athletes is getting to be more important component of both athlete's high-performance and personal development. Life-skills development program(LSP) is one of essential components for positive youth development framework. Several Olympic committees and sport organizations have implemented LSPs for elite athletes. However, few studies have revealed the effect of long-term intervention on young elite athletes in athletic fields as well as in daily life. The purpose of this study was to investigate the effect of LSP the both fields on young elite athletes.
METHODS: Thirty-five female young footballers of national elite academy in Japan, aged 13 to 15yrs, participated in the LSP for three years. The LSP was age-specific and consisted of several group-work lessons designed to develop psychological skills(goal setting, emotion control, self-recognition, empathy with colleagues, decision making, problem-solving, management for stress, leadership and career planning) . The LSP was delivered to players in the classroom of their dormitory every other month. The daily life skill scale (DLSS) and life skill evaluation scale for athletes(ALSS) were used to assess life-skills of participants.
RESULTS: Wilcoxon signed-rank test were performed for the changes of life-skills scores before and after LSP. The score of three factors in the DLSS significantly increased after LSP(planning; $Z=3.73$, $p<0.01$, knowledge summarization; $Z=2.73$, $p<0.01$, and empathy; $Z=2.51$, $p<0.05$) . LSP also significantly increased the score of five factors in the ALSS(stress management; $Z=2.05$, $p<0.05$,, setting goals; $Z=2.17$, $p<0.01$, thinking carefully; $Z=3.67$, $p<0.01$, communicating; $Z=2.80$, $p<0.01$, taking responsibility for ones own behavior; $Z=3.33$, $p<0.01$) .
CONCLUSION: Our results indicated that continuous intervention of LSP had a positive impact on life-skills development of young elite athletes both in athletic field and in daily life. This finding revealed that the LSP could enhance athletes' life-skills in athletic field. The findings suggest that LSP might improve athletic performances. In order to achieve athletic performance excellence, practitioners of youth development framework must support players through strong relationships with their coaches.

CREATION AND VALIDATION OF THE HUNGARIAN SPORT MOTIVATION SCALE (H-SMS)

PRISZTÓKA, G., PAIC, R., KAJOS, A.

UNIVERSITY OF PÉCS

Introduction
Although the motivation of athletes involved in sport gathered a lot of attention in the last two decades (Pelletier et al., 2013; Vallerand, 2007) and Hungarian researchers also tried to measure athlete motivation, a validated measurement tool in Hungarian using the original SDT framework were non-existent. Thus, the goal of our research was to translate, adapt, and validate the latest version of the Sport Motivation Scale (SMS-2) in Hungarian. In order to achieve this the main aims of the current study were to assess the construct validity of the Hungarian-SMS (H-SMS) by employing exploratory (EFA) and confirmatory factor analysis (CFA).
Methods
As a first step, we translated the original item pool of 61 questions used for creating the SMS-2 by using a translation, back-translation methodology. After this a group of experts – including a pedagogy expert, a sports psychologist, a qualified coach and an expert of consumer behaviour – assessed and accepted the preliminary version of the questionnaire. The content validity of the questionnaire was assessed based on the opinion of this group of experts. Following this, the scale was assessed in classroom environment among students majoring in sport at the University of Pécs, Institute of Sport Science and Physical Education. The validation sample consisted of 500 athletes (319 males and 181 females) whose average age was 21.16 years (SD = 6.45) involved both team and individual sports at an amateur level and trained on average 4.5 times a week (SD = 2.18), with half of the athletes participated in 4 or 5 training sessions a week.
Results and Conclusion
The final version, including six factors and 19 items, was derived after testing two different models, one of which provided the best fit for the data. The results supported the psychometric properties of the scale (CMIN/df=1.77; SRMR=0.042; RMSEA=0.40; PClose=0.983; NFI=0.953; TLI=0.973; CFI=0.979). Additionally, the Hungarian Sport Motivation Scale (H-SMS) kept the factor structure (of the original SMS-2 scale intrinsic, integrated, identified, introjected, extrinsic regulations and amotivation). Furthermore, our analyses confirmed that the intrinsic motivation factor can be further divided into cognitive intrinsic (perceived competence) and effective intrinsic (self-effectiveness) factors.

IS-SH02 The role of perception in sport

FOOTBALL PLAYERS' ACTION CHOICES IN A FREE-KICK TASK: ACTION-SPECIFIC EFFECTS ON PERCEPTION ARE GROUNDED IN AFFORDANCE PERCEPTION

SAVELSBERGH, G.

VRIJE UNIVERSITY

The aim of the study was to investigate how performance accuracy on a soccer free-kick task affects perception of the distance between the ball and goal and the perception of kickability. It was hypothesized that action-specific biases in perception of environmental properties (i.e., distance) would be grounded in affordance perception (i.e., kickability). We used a modified staircase procedure in order to investigate the accuracy with which skilled soccer players were able to perceive whether free-kick situations presented over a wide range of distances from goal were kickable or not. Participants were also required to estimate the distances of the free-kicks from goal using a perceptual-matching task. Results showed that distance perception was correlated with kicking performance, but only at the boundary of the participants' perceived kickability. It was also found that perception of kickability was more strongly related to success in the free-kick task than distance perception per se. Results support the notion derived from Proffitts (2006) account that action-specific effects on the perception of the environment properties are grounded in the perception of affordances.

EMBEDDING VIRTUAL REALITY SYSTEMS IN TRAINING PERCEPTUAL EXPLORATION BEHAVIOURS OF ENGLISH FOOTBALL ACADEMY PLAYERS: AN ECOLOGICAL DYNAMICS RATIONALE.

DAVIDS, K.

SHEFFIELD HALLAM UNIVERSITY

A rapidly developing area of research in sport science concerns use of Virtual Reality (VR) systems to enhance athlete performance in sport. It is assumed that implementing VR technologies could enhance skill acquisition and promote athlete development. However, implementation of VR systems in athlete development and performance preparation needs to be grounded in theory, with practice designs informed by a clear scientific rationale. This communication suggests how using the theoretical conceptualisation of Ecological Dynamics can support application of VR technology to enrich athlete development and performance preparation in team sports. It is argued that VR system technology needs to be efficiently and effectively used by coaches and athletes to save time, energy and other resources in practice and training. An ecological dynamics framework can underpin research and applications of VR in athlete development through: (i) individualised training and assessment programmes, (ii) supporting exploration of variable and creative practice environments, and (iii), ensuring context-dependent perception and decision making, and actions, where technology permits. This communication discusses an applied sport science case study of VR technology implementation in a professional football club academy. In modern football, playing a penetrating pass to a teammate, running behind a cooperating line of defenders, can lead to an assist or an attempt to shoot at goal or cross the ball into a critical scoring space. For this reason, when defending, teams seek to restrict spaces between and behind defensive lines of players (sometimes 4 and 5 defenders in two lines) to prevent attackers from playing a penetrating pass into a critical scoring space or dangerous area of the field for crossing a ball into the goal area. Implementation of VR training systems can be used provide attacking players with the dexterity (Bernstein, 1967) needed to perform successfully in this context, specifically helping them develop the tools and skills to utilise available affordances to play penetrative passes, behind a defensive line, accurately and rapidly. The communication presents data to showcase how VR systems in individualised training programmes for learners was used to enrich practice environments and value add to the work on field of coaches and athletes.

ANTICIPATION AS PERCEPTION OF CONCATENATED AFFORDANCES

ARAUJO, D.

UNIVERSITY OF LISBON

Behaviours can be sustained by simultaneous and successive affordances, and not necessarily by a hierarchical plan or representation capturing a sequence of performance operations. These patterns of behavioural organisation oriented towards future states emerge in situations in which different affordances (opportunities for action) can be utilised to enhance performance in contexts like sport.
One important way to explain how affordances are selected is based on information for the next affordance (Araújo et al., 2017). This is the informational basis for the selection of affordances in multi-scale dynamics. This means that affordances are conditionally-coupled, allowing a dynamic assembly of overall behavioural sequences. We will present examples in varied sports, and particularly in tennis where prospective behaviours, expressed as successive strokes in a rally, were shown to be based on conditionally-coupled affordances.
Anticipation is a process that is developed though successive actions, where nested affordances are dynamically assembled and imply perceptual attunement of skilled players to information for the next affordance.

IMPLEMENTATION OF EXERCISE AND CANCER GUIDELINES IN EUROPE

SCHMITZ, K., WISKEMANN, J.

PENNSYLVANIA STATE UNIVERSITY

The implementation of exercise and cancer guidelines varies largely between countries. Some countries do have rehabilitation systems in place where every patient has covered access to. Others, have limited access and/or only partly coverage by the health care system. Further, existing programs are sometimes evidence-based and following guidelines, others not. For example, in the Netherlands, large randomized controlled clinical trials have been conducted to evaluate the effectiveness and cost-effectiveness of exercise programs that meet the Dutch cancer rehabilitation guidelines in various patient groups (Alpe d'HuZes Cancer Rehabilitation). In the UK Macmillan Cancer Support's "Move More" campaign aims at encouraging more people living with cancer to adopt a healthier lifestyle by being more active both during and after cancer treatment. Therefore, a structured qualification program (CanRehab) was developed and evaluated as well as recently recognized by the health care system. In Germany, a guideline-orientated inpatient rehabilitation system is in place regarding exercise sessions as a central measure of care. However, this system is not evaluated but further concepts of early outpatient rehabilitation were recently developed and are currently under evaluation (Oncological Training Therapy/OnkoAktiv). There are also comprehensive exercise-based rehabilitation systems in Scandinavian countries and a trend to more structured rehabilitation in Northern America.

RELATIONSHIP OF EMPOWERING ENVIRONMENTS CREATED BY THE COACH AND PSYCHOLOGICAL NEEDS SATISFACTION TO MEXICAN ADOLESCENT-AGE ATHLETES' INTENTIONS TO CONTINUE PARTICIPATION

RAMÍREZ-MEJÍA, J.J., LÓPEZ-WALLE, J., TOMÁS, I., RÓDENAS, L., DUDA, J.L., BALAGUER, I.

AUTONOMOUS UNIVERSITY OF NUEVO LEON , UNIVERSITY OF BIRMINGHAM , UNIVERSITY OF VALENCIA

Introduction
Recently Duda and collaborators (Duda & Appleton, 2016; Duda, Appleton, Stebbings & Balaguer, 2018) have proposed an integrated conceptualization of the motivational climate and its consequences drawing from both achievement goal theory and self-determination theory. This conceptualization postulates that the motivational climate is multidimensional and can be more or less empowering or disempowering. The model also assumes that empowering climates (which are task involving, autonomy supportive, and socially supportive) and the satisfaction of basic psychological needs are positively related to optimal functioning. Such hypothesized relationships have been tested at the individual level, however, few studies have examined such associations from a multilevel perspective. The latter approach is appropriate as past work has found athletes' views of the motivational climate within teams to be interdependent. The aims of this study therefore are to test a multilevel model by analyzing the following hypotheses: 1) the satisfaction of basic psychological needs

(individual level) positively predicts young athletes' intention to continue (individual level); and 2) young athletes' perceptions of the degree to which their coach is empowering climate (team-level) positively predicts the intention to continue.
Methods
Participants were 326 adolescent athletes from Mexico (63% boys and 37% girls) with an age range of 11 to 16 years (M = 13.22, SD = 1.28) who were members of one of 27 teams (representing different sports disciplines at the College in which they studied). During a training session, they were administered a questionnaire pack containing validated scales assessing the variables of interest.
Results and discussion
Results revealed that, at the individual level, the satisfaction of the basic psychological needs positively related to the intention to continue (B = .42, 21% of variance, p < .001). At the team level, perceptions of the empowering climate were a positive predictor of the teams' mean value of intention to continue (B = .58, p < .001) and accounted for 72% of the variance in the teams mean value intention to continue. A mixed-level analytic approach is warranted to test whether basic psychological needs mediate the relationship with shared views of an empowering team climate and such indicators of optimal functioning.

DIFFERENCES IN PERCEIVED SOCIAL SUPPORT IN BOYS ENGAGING OR NOT ORGANIZED SPORT

SILVA, G., AIRES, L., BAPTISTA, H., SÁ, C., LAGOA, M.J.

UNIVERSITY INSTITUTE OF MAIA

INTRODUCTION
This study aimed to analyse differences in physical activity behaviours and perceived social support in boys engaging or not organized sport.
METHODS
Participants were 172 boys, aged 10 to 14 years old (12.0±1.1y), from secondary schools and from a football club from the North of Portugal. Boys that take part in organized sport (ORG) were 30.2%, while boys that do not engage organized sport (NORG) were 69.8%. Physical activity (PA) levels and behaviours were measured by a questionnaire [Mota & Esculas (2002)] and a PA index was calculated based on the sum of answers (4-5 points scale) to 5 question regarding participation in 5 PA contexts. Perceived social support was assessed by a questionnaire [Ommundsen et al. (2008)] with 11 questions (answers expressed in a 4 points scale) organized in 4 domains: perceived parental support, perceived parental encouragement; perceived peer support and perceived teacher support. A General Linear Model (Analysis of Covariance, ANCOVA), with age as covariate, was carried out to analyse differences between ORG and NORG in PA levels and perceived social support. All analyses were completed in SPSS 21, with significance level set at 5%.
RESULTS
ORG group presented a significantly greater PA index in comparison with NORG [16.36 (0.38) vs. 11.80 (0.24); F=99.436; P<0.001; Partial η2=0.370]. Perceived parental support [3.35 (0.11) vs. 2.48 (0.07); F=40.141; P<0.001; Partial η2=0.192], perceived parental encouragement [4.16 (0.16) vs. 3.52 (0.10); F=11.407; P=0.001; Partial η2=0.063] and perceived peer support [3.62 (0.14) vs. 2.77 (0.09); F=26.446; P<0.001; Partial η2=0.135] were also greater in ORG in comparison with NORG. No differences were found between ORG and NORG for perceived teacher support [2.57 (0.12) vs. 2.69 (0.08); F=0.622; P=0.431; Partial η2=0.004].
CONCLUSIONS
Boys engaging organized sport (football) showed higher levels of physical activity, greater perceived parental support, perceived parental encouragement and perceived peer support. This work was supported by national funding through the Portuguese Foundation for Science and Technology, I.P., under project UID/DTP/04045/2019. Corresponding author: gsilva@ismai.pt

INVESTIGATING CONFIDENCE AND SELF-EFFICACY RATINGS IN ATHLETIC TRAINING STUDENTS IN JAPAN: A LONGITUDINAL STUDY FROM JUNIOR THROUGH SENIOR YEAR.

IDE, Y.1, OKAWA, M.2, FURUSHO, A.1, HIRASAKI, K.1

KYUSYU UNIVESITY OF NURSING AND SOCIAL WELFARE

INTRODUCTION: The role of the athletic trainer is to conduct athletes health management, sports related injury prevention, emergency response, athletic rehabilitation and training, and conditioning in close cooperation with sports doctors and coaches. The purpose of this study was to conduct investigation of the relationship between athletic training students' confidence and self-efficacy and compare annual change to identify the learning process of undergraduate athletic training students.
METHODS: Subjects were ten students currently enrolled in medical university, which has the JASA-AT accredited program. The Athletic Training Student Confidence Scale (ATSCS) questionnaire consisted of 30 items. Subjects scored each item on a 5-point Likert scale to rate their confidence in completing athletic training program. The General Self-Efficacy Scale (GSES; Sakano&Tohjoh, 1986; Bandura, 1977) consisted of 16 items were rated on a 2-point scale and the total score relating to high self-efficacy was used in the analysis (range: 0-16). Three factors were able to measure in the GSES. Subjects were required to take ATSCS and GSES end of each fall semester (by the junior and senior years). All statistical analyses were calculated with a confidence level of p<.05.
RESULTS: The GSES score for the senior year were 8.1±2.1 and the junior year were 7.8±2.2. There was no significant difference between the senior year and the junior year at the GSES [t (18) =.36, p=.73, d=.11]. However, confidence in the evaluation of injury [t (18) =2.32, p=.045, d=.74], confidence in emergency care [t (18) =2.18, p=.057, d=.67], and understanding of risk management [t (18) =3.21, p=.01, d=1.01] showed statistically difference.

CONCLUSION: There are two type of self-efficacy; General self-efficacy (GSE) and Task-specific self-efficacy (SSE). Typically, GSE does not depend on specific situations or individual tasks, however, it would be influenced by individual behavior, which generalized over long time. On the other hands, SSE examine individual's perception of his or her ability to perform the actions specific to a situation (Bandura, 1977). Additionally, GSE is influenced by SSE, because it is based on the idea of generalization of SSE. This is because SSE is obtained by executing a certain task or area, which generalized beyond the task and area, leads to increase GSE (Sakano & Maeda, 2002). Hence, to understand learning process of athletic training students, it is necessary to develop SSE for athletic trainer to identify the integration of knowledge, skills, and self-efficacy as an athletic trainer.

GENDER DIFFERENCES IN THE GAME OF GO: PARENTS' EXPECTANCY AND VALUE BELIEFS ON YOUNG PARTICIPANTS

CHAO, Y.C., LIAO, C.M.

NATIONAL TAIWAN SPORT UNIVERSITY

Gender Differences in the Game of Go: Parents' Expectancy and Value Beliefs on Young Participants
Chao, Y-C. & Liao, C-M.
National Taiwan Sport University
Introduction
According to expectancy-value theory (Eccles et al., 1983), boys and girls may choose to strive for achievement in different domains due to parents' expectancy-value beliefs of their children in certain domain influenced by gender stereotypes and perceived gender appropriateness. The game of go is a popular activity in Asia and an official event in 2010 Asian Game. However, there are relatively very few young females than males participating in the game. It is possible that parents may have different beliefs in boys and girls in the game of go and stop girls from participating. The purpose of this study was to examine differences between boys' and girls' parents in expectancy and values beliefs regarding their children's participation in the game of go and to test if parents' expectancy and values beliefs could predict parents' willingness to have their children pursuing a career as professional Go players.
Methods
Participants were 190 parents (Age M=39.2, SD=0.52; Father N=71, mother N=119) who accompanied their children attending two national Go tournaments in Taiwan. A modified Chinese version of Expectancy-value Beliefs Scale was administered. Children in question consisted of 30 girls and 119 boys, age ranged from 6 to 18 (M=11.10, SD=2.50).
Results and discussion
MANOVA showed a significant difference in expectancy and values beliefs between boys' and girls' parents (Wilk'sλ= .93, F (1,188) = 2.22, p = .044, partial η2 = .07). Follow-up univariate analysis found that girls' parents experienced negative emotion more often than boys' parents, regarding their children's involving in Go (F (1,188) = 5.20, p = .024, partial η2 = .03). In terms of parents' willingness to have their children become professional Go players, multiple regression analysis found a significant prediction (F (6,183)=5.51, p < .001). Specifically, parents who believed that their children have higher abilities in Go (t = 3.52, p = .001, sr2 = .24), were more worried about their children' performance in Go (t = 2.38, p = .019, sr2 = .16), and believed that other people(teachers, relatives) expected their children to participate more in Go (t = 2.83, p = .005, sr2= .19), tend to be more willing to have their children become professional Go players. These findings support Eccles' expectancy-value theory, parents' beliefs of their children's participation in an activity may be influenced by gender stereotypes and perceived gender appropriateness. These findings may also help to shed some light on the cause of gender-imbalance in the game of go.

THE EFFECT OF NATIONALITY, GENDER, AND GRADE UPON MOTIVATION FOR PHYSICAL EDUCATION AMONG ELEMENTARY SCHOOL CHILDREN IN JAPAN AND SOUTH KOREA

IKEDA, T.1, AOYAGI, O.2, HAN, N.3, CHOI, T.3, KOO, K.4, SEO, Y.5, IKEDA, T.O.6

1 FUKUOKA PREFECTURAL UNIVERSITY, 2 FUKUOKA UNIVERSITY, 3 JEJU NATIONAL UNIVERSITY, 4 CHANGWON NATIONAL UNIVERSITY, 5 CHOSUN UNIVERSITY, 6 NISHI-KYUSHU UNIVERSITY

Introduction
Japan (JPN) and South Korea (KOR) are currently facing similar problems relating to physical activity among children. Physical fitness among Japanese children has been declining since the 1980s (Ministry of Education, 2001), and body mass index levels have increased among many of their South Korean counterparts (Tomkinson et al., 2007). Physical education (PE) in school is therefore an important opportunity to offset these trends and spur healthy growth and physical development. The aim of this study was to investigate the effect of nationality, gender, and grade upon Motivation for Physical Education (MPE) among children in JPN and KOR.
Methods
The participants were 2,008 children (JPN: 834, KOR: 1174; Boys: 1015, Girls: 993; 4th grade: 1020, 6th grade: 988). All of the participants completed a questionnaire relating to MPE and consisting of 21 items based on Nishida (1989). The questionnaire elicited the number of days registering physical per week (PAD) and time spent per activity (PAT) relative to three physical-activity intensity levels ("mild," "moderate" and "intense"). Theory of quantification type I (TQ-I) was applied in order to investigate the effect of nationality, gender, and grade upon MPE without affecting the PAD- and PAT-intensity levels.
Results and discussion
The factor analysis extracted the following three factors constituting MPE: 1) positive attitude towards PE, 2) anxiety (concerning the possibility of failure), and 3) physical competence (contribution rate = .42). Data derived from the TQ-I was as follows: "positive attitude towards PE" was affected by nationality (Partial Correlation Coefficient: PCC = .098, p < .001, JPN > KOR) and grade (PCC = .123, p < .001, 4th > 6th) but not by gender (PCC = .027, p = .335). "Anxiety" was also affected by nationality (PCC = .144, p < .001, JPN > KOR) and grade (PCC = .168, p < .001, 4th < 6th) but not by gender (PCC = .004, p = .883). "Physical competence," however, was strongly affected by nationality (PCC = .175, p < .001, JPN < KOR), gender (PCC = .085, p < .01, boy > girl) and grade (PCC = .110, p < .001, 4th > 6th). These findings indicate that all of the factors constituting MPE are affected by aging, social background, and the educational and cultural differences between the two countries. Furthermore, and when excluding the physical-activity intensity level, no gender differences are apparent in terms of "positive attitude towards PE" and "anxiety," though boys register higher "physical competence" levels than girls.

DOES AGE MATTER? A QUALITATIVE COMPARISON OF MOTIVES AND ASPECTS OF RISKS IN ADOLESCENT AND ADULT FREERIDERS

FRÜHAUF, A., ZENZMAIER, J., KOPP, M.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Recent research has shown multiple motives for high-risk sport participation behind the one-dimensional view of sensation seeking (Barlow, Woodman, & Hardy, 2013). Those motives were derived from research on high-risk sport participants older than 26 years because young people (16-25 years) tend to seek risk-taking opportunities in diverse activities (Brymer & Gray, 2010) . The aim of the study was to provide insights into motives and risk-related aspects in adolescent high-risk sport participants and to compare those findings with adults of the same activity.
METHODS: Semi-structured interviews were conducted with 24 adolescent (14 to 20 years) freeriders (skiers/snowboarders who ski outside the protected areas of a ski resort) and 24 adult freeriders (26 to 41 years). Analyses were done using MAXQDA software following a code theme approach.
RESULTS: Both cohorts reported the motives Challenge (adolescents: 92%, adults: 88%), Freedom/Pleasure (adolescents: 88%, adults: 75%), Friends (adolescents: 88%, adults: 79%) and Balance (adolescents: 63%, adults: 63%). However, the description of the motive Friends differed between adults and adolescents. Whereas adolescents referred to a community and shared interests, adults described the importance of trust and the development of deep friendships through the activity. Nature was a major motive in adults (83 %) but not in adolescents (29%). Most of the adults have already experienced a major accident or close call (n=19; 79%), contrary to adolescents (n=7; 29%). All freeriders acknowledged the risks of the activity and reported risk-management behaviours. Adolescents learned about the risks in freeriding primarily through their families (n=10) and the ski club (n=9). Adults reported to have realized the risk in freeriding after starting with the activity. "Ten years ago a friend of me died just next to the slope in an avalanche [..] That was a wakening call; I realized you don't just ride next to the slope without safety equipment and experience." (adult4-32yrs)
CONCLUSION: Both cohorts were largely motivated by the same motives. Contrary to adults and prior research on motives in high-risk sports (Brymer & Gray, 2010), experiencing the nature was not a motive in adolescents. Early education about risk-taking behaviour might help to minimize negative outcomes in freeriders.

TEAM UNITY AS A PREDICTOR OF ATHLETE COMPETITIVE MOTIVATION

KAI, Y.

HOSEI UNIVERSITY

Introduction
Majority of athletes spend their competitive careers as sports team members and share time with other teammates. It is advantages for sport coaches to take team status and team relationships, as well as interactions between athletes into consideration. Team unity is one index for assessing these conditions. According to Yukelson (1997), unity is a core component in building team success, the effectiveness and success of coaching also reside within the unit relationship between team members (Jowett, 2017). Enhancing team unity is suggested as a method of improving team performance and bolstering the motivation of individual members for team building (e.g., Carron et al., 2002). Therefore, it was hypothesized that the relationship between team members would facilitate individual and team performance, as well as the optimal competitive performance of athletes. Team unity was investigated as a predictor of the competitive motivation of athletes, which is a major component of psychological performance.
Methods
Data were collected in a questionnaire survey conducted from July 2016 to December 2018 with athletes in three university teams. Incomplete or defective responses were excluded from the study. A total of 957 athletes (727 males and 230 females: Mean age 19.65 ± 0.95 years) in 49 different sports participated in this study. The survey questionnaire inquired participants' demographic characteristics including gender, age, and their sport and included four scales assessing psychological variables related to athletic performance: (1) The Unity Scale for Sports Teams (USST: Yamada et al., 2013), (2) the Psychological Performance Collective Efficacy Scale (PPCES: Arai, 2011), (3) the Sport Commitment Scale (SCS: Hagiwara and Isogai, 2014), and (4) the Competitive Motivation Scale (CMS: Tokunaga and Hashimoto, 2000) included in the Diagnostic Inventory of Psychological-Competitive Ability for Athletes.
Results
There were significant positive correlation between scores of all scales ($r = .28–.60$, $p < .001$). Additionally, covariance structure analysis supported a conceptual model in which the USST score indirectly predicted the CMS score ($\beta = .36$, $p < .001$), mediated via the PPCES and SCS scores (GFI = .99, AGFI = .97, CFI = .99, RMSEA = .05).
Conclusion
These results indicated that team unity was positively related to competitive motivation. Furthermore, although enhancing team unity did not directly improve athletes' competitive motivation, team unity indirectly improved competitive motivation. Collective efficacy and sports commitment within the team were particularly helpful in facilitating the competitive motivation of athletes and team unity. It is suggested that both coaches and athletes should attend to relationships between team members, including their unity, and develop solid and interactive relationships within the team for improving sports performance.

WHY DO FANS FOLLOW THE ATHLETES SOCIAL MEDIA (BRAND) PAGES?

KAJOS, A.

CORVINUS UNIVERSITY OF BUDAPEST

Introduction
The concept of the athlete as a human brand (Thomson, 2006) plays an evenly growing role in the sports management literature (Arai et al., 2014; Carlson & Donavan, 2013; Walsh & Williams, 2017). Furthermore, the internet and social media particularly plays an increasingly growing role in building the athlete's human brand. However, using social media as a brand communication tool requires the utmost understanding of the consumer. In our case the behaviour and motivations of the athlete's (brand) page followers. Therefore, the goal of this study is to develop and validate a scale available to identify and measure the motivations linked to the consumption of athlete's social media (brand) pages by using the Uses and Gratification Theory.
Methods
After a widespread literature review and a preliminary study – using free thought-listing survey – among 88 sports management students, a total of 236 different reasons were collected. These reasons were categorized into broad concepts that were assumed to be components of the motivational background. As a result, a preliminary scale with 38 questions and 12 factors was developed. With a convenience online sample of social media fans of Hungarian athletes (n=693), a final version of the scale containing 8 factors (role model, love towards the sport, sport performance, team love, athlete's physical appearance, information seeking, athlete's fame and personal life) and 28 items were created.
Results and discussion
The Motivation Scale for Athlete Social Media Consumption (MSAMC) had high internal consistency and good reliability (Cα=0,708-0,892; CR=0,708-0,897; AVE=0,524-0,745; AVE>MSV) and psychometric (CMIN/df = 2,804; RMSEA=0,051; SRMR=0,059; TLI=0,918; CFI=0,929) properties. Our results indicate that the most important motives for following an athlete's social media page are information seeking; the emotions towards the athlete's team; the athlete's private life and his or her role model function. The established scale explains 56-69% of social media site followers behaviour. The use of the MSASMC scale gives the athlete and its management the opportunity to create social media content most adequate to their own fans needs thus generating a higher impact and reactions.

IMPLICIT AND EXPLICIT ACHIEVEMENT MOTIVES OF YOUNG ATHLETES

KNISEL, E., OHLBRECHT, H., SCHRÖDER, S.

OTTO-VON-GUERICKE UNIVERSITY OF MAGDEBURG; FACULTY OF HUMANITIES

Introduction
The purpose of study was to analyze the associations between explicit and implicit achievement motives in terms of an early drop-out of young athletes. Additionally, demographic variables (gender) were examined. Research has provided evidence for the existence of two different motivational systems. The explicit achievement motives refer to cognitive beliefs, subjective goals, and self-attributed choices. Implicit achievement motives, in contrast, are affect-based needs and associations built over a longer period of time (McClelland, Koestner & Weinberger, 1989).
Method
53 female athletes and 52 male athletes of the Olympic Centre in Berlin aged 14-18 years (Mage=15.97, SD=1.1) participated in the longitudinal study over two years with two observations (t1; t2). After the second observation the athletes were divided into two groups: athletes withdrawn from competitive sport (dropout group; n=37) and athletes continuing training and engaged in competition (active group; n=68). Participants´ implicit achievement motives were assessed using the sport-specific Thematic Apperception Test (TAT; Gabler, 1972). Explicit achievement motives were measured with the sport-specific German version of the Achievement Motives Scale (AMS-S; Elbe, Wenhold & Müller, 2005).
Results
The results demonstrate a significant relationship between the implicit and the explicit achievement motives in the active group (r=.256; p<.05) at t1. No significant association was found in the dropout group (r=.034). Results show a strong correlation between the two motives with the female athletes in the active group (n=31; r=.630; p<.01) contrary to the male athletes (n=37; r=-.087). The data show that both the implicit and explicit achievement motives at t1 were higher in the active group than in the dropout group especially with the female athletes.
Discussion
Our results suggest that a relationship between implicit and explicit achievement motives of young athletes seems to be important to maintain a career in performance sport. The extent of relationship between two motive systems is associated with gender. McClelland et al. (1989) assume that both types of motives are acquired and shaped at different times during ontogeny. Future research identifying these age periods when the degree of concordance between implicit and explicit achievement motives is important in terms of a long-term engagement in performance sport is required.

A LONGITUDINAL COMPARISON OF ANAEROBIC PERFORMANCE IN ELITE CZECH JUNIOR ICE HOCKEY PLAYERS IN THE PERIOD 2001 TO 2018

HELLER, J., VODICKA, P.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY,

INTRODUCTION: Longitudinal studies in professional ice hockey players revealed substantial changes in anthropometric and physiological variables comparing recent data with those found in elite players in eighties and nineties. For example, body height, body mass and anaerobic performance indices showed a gradual increase over the last decades in professional ice hockey players (1). The aim of the present study was to compare anthropometric and anaerobic performance data in elite Czech junior ice hockey players over a period 2001 to 2018 to reveal the possible tendencies in elite junior players, members of the top ice hockey league of juniors.
METHODS: Altogether 6282 junior ice hockey players (at about 200 to 400 junior players every year) aged 18 years participated in the study. The testing took place always in the pre-season period and included anthropometry and a 30s anaerobic Wingate test on a cycle ergometer Monark E824 using a breaking force of 6 W.kg-1 that equals 0.106 kg.kg-1. The main results were 5s peak power [PP, W, W.kg-1], total work or anaerobic capacity [AnC, kJ, J.kg-1], and fatigue index (FI). The development trend of the indices over the period 2001-2018 was calculated using a linear regression.
RESULTS: The mean body mass, body height and fat-free mass of the elite junior ice hockey players increased over the 18-year-lasting period from 79.0 to 80.1 kg (i.e. + 1.3 %; R2= .63, p< .01), 180.2 to 181.1 cm (i.e. + .5 %; R2= .53, p< .01) and 70.2 to 71.7 kg (+ 2.1 %; R2= .25, p< .01), respectively. Body fat, however, did not change and corresponded to 9.8 % on the average. Absolute values of PP increased from 1119.7 to 1143.1 W (i.e. + 2.1 %; R2= .24, p< .05) whereas relative values of PP did not change (14.3 W.kg-1; R2= .02, n.s.). Absolute values of AnC (26.9 kJ) did not change (R2= .18, n.s.) but relative values of anaerobic capacity significantly decreased during the 18-year-lasting period, from 344.0 to 339.1 J.kg-1 (- 1.5 %; R2= .56, p< .01). Mean values of fatigue index slightly increased from 39.1 to 40.9 % (i.e. + 4.6 %; R2= .32, p< .05).
CONCLUSION: The results of the study indicate that body mass, body height, fat-free mass and absolute values of PP and FI slightly increased during the period 2001 to 2018, similarly to the findings found in adult professional ice hockey players (1). PP values relative to body mass and body fat did not substantially change and anaerobic capacity values relative to body mass even slightly decreased in elite Czech junior ice hockey players during the 18-year-lastig followed up. The results indicate some discrepancy between body and functional development among young hockey players.

THE ESTABLISHMENT OF PHYSICAL FITNESS AND TECHNICAL SKILLS EVALUATION INDEX FOR CHINESE PROFESSIONAL MEN'S BASKETBALL ATHLETES

WANG, Z.

SHANGHAI RESEARCH INSTITUTION OF SPORT SCIENCE

INTRODUCTION: In order to strengthen the training of basketball athletes' physical and technical abilities, understand the overall performance of the athletes' physical fitness and technical skills; allowing coaches and athletes to train and competes with scientific evidence in the future, took the physical fitness index and commonly used technical skills data established by the Chinese Basketball Association as the base of the evaluation index, on top of that, we will establish the physical fitness and technical skills evaluation index for Chinese professional Men's basketball Athletes.
METHODS: A total number of 281 Chinese basketball players in the Chinese mens Basketball Association (CBA) playoff teams in the seasons of 2014-2015 and 2015-2016 were selected for the research. By measuring the athletes' physical fitness data before the season starts, and by video observing nearly hundreds games during the season, and collecting data on each players technical skills, regression analysis was used to help established the training evaluation model for the elite Chinese Men's basketball players.
RESULTS: (1) Efficiency as an important embodiment for a highly competitive basketball athletes. The change in efficiency will have a great impact on the game's progression and final results. Use the efficiency value as the dependent variable, based on that the regression equation was established. After the analysis of the CBA player's physical fitness and technical skills, the contribution degree of each index to the efficiency value was investigated. And according to the principle of the regression, if VIF is greater than 10 then the dependent variable will be selected to remove, and after removed the collinearity variables, then the variables are being regressed.
The established regression function:
Y=0.143*X1+0.081*X2+0.067*X3+0.049*X4+-0.038*X5+0.189*X6+0.318*X7 +0.292*X8+0.153*X9+0.154*X10+0.136*X11+0.097*X12
(Y:Efficiency,X1:Height,X2:Weight,X3:Strength,X4:Special,X5:Deep Squat,X6:Score3,X7:Penalty,X8: Assisting,X9:Intercept,X10:Slam Dunk,X11:Block Shot,X12:Foul)
(2) CBA requires their athletes meet different physical fitness and the technical skills based on their different positions, according to that the regression evaluation model was established as follow:
1.Forward:Y=50.787+0.21*X1+0.057*X2+4.758*X3+0.01*X4+0.023*X5 +0.074*X6+5.789*X7+2.145*X8+3.522*X9 ;
2.Center:Y=3.776+0.018*X1+0.002*X2+4.122*X3+0.005*X4+0.055*X5+0.145 *X6+3.11*X7+3.835*X8+1.575*X9 ;
3.Backfielder:Y=-41.399+0.131*X1+0.11*X2+6.009*X3+0.025*X4+0.117*X5+0.309*X6+3.006*X7+3.562*X8+1.506*X9 ;
（Y:Efficiency,X1:Height,X2:Weight,X3:Strength,X4:DeepSquat,X5 : Bench, X6 : Special, X7:Score2,X8:Score3,X9:Penalty）
(3) The establishment of the evaluation grade, the evaluation criteria is determined by the percentage method. Based on the total score above 85 is superior; between 66-85 is medium; and below 66 is inferior, as a comprehensive evaluation for the elite basketball athletes.
CONCLUSION: (1) The physical fitness and technical skills evaluation for the Chinese professional men's basketball athlete is center on the efficiency value, and build the regression function based on existing physical fitness and technical skills index. (2) Based on the physical fitness and technical skills model for the elite basketball athletes; successfully build a comprehensive system to evaluate the index for the elite basketball athletes' physical fitness and technical skill.

ATHLETE MONITORING DURING WOMEN'S COLLEGIATE BASKETBALL PRE-SEASON

JONES, M.T., BROWN, F., FIELDS, J.B., BAKER, R.E., WHITE, J.B.

GEORGE MASON UNIVERSITY

INTRODUCTION: National Collegiate Athletic Association Division I (NCAA-DI) women's basketball (WBB) pre-season training is intended to prepare for the rigor of the season. Monitoring internal (IL) and external (EL) load markers in training is beneficial to planning and prescribing sport-specific training (1,2) and tracking athlete recovery. In NCAA-DI men's basketball, IL and EL markers were related in preseason training (1). Since information on WBB is limited, the purpose was to monitor athlete load via IL and EL markers during pre-season training.
METHODS: NCAA-DI WBB athletes (n=6; mean+/-SD age: 19.8+0.8 yr; body mass: 74.1+12.8 kg.; height: 173.3+7.8 cm; body fat: 24.5+5.0%; VO2max: 59.85+7.5mL·kg-1·min-1) participated. IL and EL were monitored in preseason practices (n=25), one scrimmage, and the 1st game of the season (GAME 1). EL markers (Catapult S5) of total jumps (TJ), volume [player load (PL)], and intensity [Player load per minute (PL/min), high inertial movement analysis (IMA, >3.5m/s/s)] as well as IL markers [training impulse (TRIMP), %anaerobic (%AN) (First Beat heart rate monitor)] were collected. Practices were classified as HARD, MODERATE, or LIGHT based upon TRIMP values. Relationships between IL and EL markers were examined with Pearson correlations. Differences in IL and EL markers between practice types, scrimmage, and GAME 1 were identified via one-way ANOVA (p= 0.05).
RESULTS: Average values (mean+/-SD) are presented in order for practices, scrimmage, and GAME 1 for EL markers [PL/min: 4.2+0.96, 5.9+1.25, 5.7+0.37; IMA: 33.3+14.5, 47.0+23.6, 42.4+10.0; PL: 599.7+233, 653.4+133.5, 625.4+47.6; TJ: 79.1+44.3, 59.6+15.6, 59+13.0] and IL markers [TRIMP: 152.6+42.2, 230.6+73.0, 228+40.9; %AN: 49.0+8.4, 50.4+17.3, 56.2+4.6]. No relationships were found between IL and EL markers in practices. IL and EL markers of TRIMP and PL (r=0.967; p=0.007), and TRIMP and PL/min (r=0.977; p=0.004) were correlated within the scrimmage, while TRIMP and PL approached significance (p=0.051) in GAME 1. The scrimmage (p=0.044) and GAME 1 (p=0.018) were different from MODERATE practice for PL/min. TRIMP values for scrimmage (p=0.004), HARD (p<0.001), and MODERATE (p=0.026) were different from LIGHT practices. GAME 1 (p=0.014) and HARD (p=0.011) differed from LIGHT for %AN.
CONCLUSION: IL and EL monitoring may identify how practice compares to game activity. When PL/min for practices was compared to GAME 1, 12% (3/25) were within one SD of GAME 1. No practice had greater PL/min than that of GAME 1. When PL for practices was compared to GAME 1, 16% (4/25) were within one SD of GAME 1, while 28% (7/25) were two or more SDs above GAME 1. Further, scrimmage and GAME 1 were different from MODERATE practices for PL/min. These findings indicate a greater emphasis is placed upon volume (PL) in preseason training than practice intensity (PL/min).

READINESS TO RE-PERFORM DURING A COMPETITIVE WEEKLY CYCLE IN U14 AND U16 MALE SOCCER PLAYERS

LEHNERT, M., MAIXNEROVA, E., ZAATAR, A., SVOBODA, Z., BOTEK, M., DE STE CROIX, M., VAREKOVA, R.

PALACKY UNIVERSITY, FACULTY OF PHYSICAL CULTURE

INTRODUCTION: The main goal of the competitive microcycle (MC) is to prepare players for competitive match play. However, excessive training and/or competitive load may lead to neuromuscular fatigue-induced changes, leading to reduced performance and an increased risk of injury. The aim of this study was to explore the effects of competitive match play and subsequent training on muscular, neuromuscular, and biochemical measures, and to determine the readiness to re-perform at the end of the MC in male youth soccer players.
METHODS: Twenty eight youth soccer players (13-16y) from chronological competition age groups U14 (13.6 ± 0.3) and U16 (15.6 ± 0.2) were recruited. Finally, the data from 13 players from the U14 age group and 9 players from the U16 age group were analysed. Relative leg stiffness (RLS), reactive strength index (RSI), muscle activation via electromyography (EMD), creatine kinase (CK), and perceived muscle soreness (PMS) were determined five times over the MC: the 1st and 2nd measurements were performed prior to and immediately post the first competitive match, the 3rd and 4th measurements at 48h and 96h post the 1st competitive match, and the 5th measurement prior to the 2nd competitive match for the U16 and prior to the 3rd competitive match for the U14 age group (168h post the 1st match for U14 and 145h post the 1st match for U16).
RESULTS: In the U14 group, a significant time effect was reported for RSI ($P < 0.001$, $\eta2 = 0.354$), EMD ($P < 0.001$; $\eta2 = 0.390$), CK ($P < 0.001$; $\eta2 = 0.641$), PMS ($P < 0.001$; $\eta2 = 0.463$). For the U16 group, a significant time effect of time was found for RSI ($P < 0.001$, $\eta2 = 0.506$), CK ($P = 0.002$; $\eta2 = 0.440$), PMS ($P < 0.001$; $\eta2 = 0.756$). A post hoc tests found a number of significant differences between the measurements in both groups. Especially, changes between the measurements after the 1st match (in both groups), and also before the 2nd match in the midst of the observed MC (in U14 group) and other performed measurements were observed in RSI, CK, and VAS. In the case of RLS, only non-significant trends were observed.
CONCLUSION: In both age groups the measurement before the competitive match at the end of the MC did not indicate any significant deterioration in the observed muscular, neuromuscular, and biochemical indicators of ACL injury and thus the players' ability to re-perform was not compromised. However, in the U14 group, where the MC was physically more demanding, the results point to negative changes which may reduce performance and increase injury risk, in particular towards the end of the 1st match and during training sessions and the competitive match in the midst of the MC. To reduce potential risk of injury during a two-match competitive MC, it is recommended to decrease the training load, especially in the first half of the competitive MC.

RELATIONSHIP BETWEEN CONDITIONING AND GPS PARAMETERS IN RUGBY PLAYERS TRAINING IN A SUMMER CAMP

ONISHI, T.

TEIKYO UNIVERSITY

INTRODUCTION: Summer camp athletic training is arduous and physical condition must be monitored in terms of both exercise duration and intensity. A Global Positioning System (GPS) can be used to record many types of data, but its relevance in terms of conditioning remains unclear.
METHODS: We enrolled 39 university rugby players (forwards: n=20, backs: n=19) training over 17 days. The conditioning items evaluated were appetite, subjective training intensity on the previous day, and subjective fatigue. The GPS parameters assessed were training time;

total distance covered; speed (m/min); duration of high-speed running and sprinting; acceleration and deceleration; player load and total number of contacts.
RESULTS: Forwards tended to have larger appetites than backs over the 17 days. Appetite did not change on days after games. We found no significant correlation between rugby-specific parameters and conditioning items. In forwards, subjective training intensity and subjective fatigue affected by total contact number and speed. In backs, subjective training intensity affected by speed.
CONCLUSION: In forwards, when subjective training intensity and subjective fatigue showed high values, it was suggested that adjusting speed and total number of contacts could lead to prevention of conditioning deterioration.The principal GPS parameter associated with conditioning of rugby players was speed. In forwards, the total number of contacts may also be significant.

SMALL-SIDED GAMES LEAD TO LOWER STIMULUS AND GREATER INTER-INDIVIDUAL VARIABILITY IN THE HEART RATE RESPONSE COMPARED TO INTERMITTENT RUNNING IN PREPUBERTAL SOCCER PLAYERS

MASSAMBA, A.1,2, DUFOUR, S.P.1, FAVRET, F.1, HUREAU, T.J.1

1. UNIVERSITY OF STRASBOURG, 2. RACING CLUB STRASBOURG ALSACE

INTRODUCTION: Small-sided games (SSGs) are very popular in soccer and thought to be a time efficient approach to develop concomitantly technical and physical capacities (1). However, most studies were performed on adult players and did not report the time spent above 90% of maximal heart rate (HRmax), which has been identified as a key intensity zone for aerobic adaptations (2). The purpose of this study was to investigate the aerobic contribution of SSGs with various field sizes compared to high-intensity interval training (HIIT) in prepubertal soccer players. We also quantified technical actions to investigate the influence of size of the playing field on technical parameters.
METHODS: Ten young soccer players (13.0±0.3 yrs) from a French academy took part in this study. First, they performed a 30-15 intermittent fitness test (3) in order to determine their maximal aerobic speed (MAS) and HRmax. Then, they performed a HIIT and 3 SSGs of various field sizes (small, 30x20m; medium, 42x38m; large, 51x34m). Each SSG was performed with 5 players per team, using stop-ball zones (i.e. no goalkeeper), during 4x4min interspaced with 1 min of passive recovery in between. HIIT also followed a 4x4min protocol and alternated 30s of running at 100% of MAS with 30s of passive recovery. HR was continuously monitored during experimental sessions. For each exercise modality, time spent above 90% of HRmax (T90%HRmax) was calculated, and technical actions (i.e. number of passes, number of possessions, and number of ball touches per possession) were quantified during SSGs by video analysis.
RESULTS: MAS was 19.5±0.8 km/h and HRmax was 202±4 bpm. T90%HRmax was similar between the 3 SSGs (small, 613±244 s; medium, 628±278 s; large, 519±307 s; P>0.2) but 24-37% lower than during HIIT (826±140 s, P<0.05). Moreover, coefficients of variations in T90%HRmax were 2.3 to 3.5 times larger in SSGs compared to HIIT. For technical actions, number of passes (~13±7), number of possessions (~14±4), and number of ball touches per possession (~2,9±0,6) were similar between the medium and large SSGs. However, greater number of passes (19±6) and number of possessions (21±6), and lower number of ball touches per possession (2,4±0,6) were found in small SSG compared to medium and large SSGs (P<0.05).
CONCLUSION: All three SSGs led to lower acute aerobic stimulus, suggesting a lower potential for chronic aerobic adaptations, compared to HIIT. Moreover, inter-individual variability was substantially greater in SSGs compared to HIIT, suggesting increased heterogeneity among individual responses within a team getting the same training protocol. Based on these results, we suggest prescribing HIIT more than SSGs in prepubertal soccer players if the primary outcome is to improve aerobic capacity. If the technical component is important, the small SSG was the most challenging and should be preferred.

SPRINT THRESHOLDS AND LIMITS OF AGREEMENT IN TESTING MAXIMAL VELOCITY IN U16 FEMALE SOCCER PLAYERS

HODUN, M., DE STE CROIX, M.B.A., HUGHES, J.D.

UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Increases in maximal velocity seen with chronological age begin to plateau by 16y in female soccer players (Vescovi et al., 2011). However, there is a scarcity of data on absolute maximal velocity (MV) for U16 female players or consensus on MV thresholds for use in motion analysis of youth female soccer players. MV is normally reached over longer distances of 25-40m but in soccer matches sprints are usually 5-20m (Bradley & Vescovi, 2015). Therefore, the aim was to compare two different sprint test distances measuring MV using a global positioning system (GPS) and to determine if current sprint speed thresholds in the literature are appropriate for U16 female soccer players.
METHODS: Sixty-four U16 female (58.0±7.9 kg, 163.6±5.5 cm) soccer players completed two MV sprint tests. The test sessions consisted of a 20m sprint test with a 10m deceleration zone and a 92m flying sprint test in which players were asked to reach MV, measured via GPS. For each participant, the best of three trials for each test was used. The limits of agreement (LOA) between tests were examined using the Bland-Altman method . Thirty-four players completed two sessions of both sprint tests one week apart. Consecutive pairwise reliability and Pearson's correlation coefficient were calculated to compare sessions and tests.
RESULTS: MV (mean ± SD) for 20m sprint test and 92m flying sprint were 7.04 ± 0.4 and 7.37 ± 0.4 m·s-1 respectively. The difference between upper and lower levels of agreement from the Bland-Altman method was 0.61. Pearson's correlation was large between tests (r = 0.71) and between sessions (mean r = 0.68).
CONCLUSION: The current study compares a flying sprint with >40m distance with a shorter, soccer-specific sprint of 20m using GPS. MV is normally reached over longer distances of 25-40m but in soccer matches sprints are usually 5-20m (Bradley & Vescovi, 2015). Results from the current study indicate MV from the 20m sprint test and 92m sprint test are positively correlated and LOA from the Bland-Altman plot indicate that results can be compared between the two test methods. The results suggest MV can be assessed using the shorter, match-specific distance for U16 female soccer players.
Methods currently used in analysing female soccer recommend a sprint threshold of 5.6 m·s-1 (Dwyer & Gabbett, 2012). Bradley and Vescovi (2015) suggest using 80 – 85% of maximal velocity from sprint tests. The 80-85% of maximal velocity for the current group using the 20m sprint test is 5.63 – 5.98 m·s-1 suggesting current sprint speed threshold recommendations may be used in U16 female soccer.

TEMPORARY FATIGUE DURING FUTSAL GAMES

OHMURO, T.

RIKKYO UNIVERSITY

INTRODUCTION: Futsal is an intermittent sport that demands high physical, technical and tactical abilities from the players (Barbero et al., 2008). Previous studies show that the distances covered per minute during in-play time together with the whole game conditions decrease in the second compared to the first half (Murilo et al., 2014). Further, temporary fatigue during football games has been observed (Mohr et al., 2005), but futsal games were not investigated yet. Therefore, the aim of this study was to examine the temporary fatigue during futsal games.
METHODS: The subjects were 9 top-level Japanese players (age: 28.4 ± 4.6 yrs, height: 173.2 ± 5.2cm, body weight: 67.6±5.0kg) and the total distance covered was assessed by active profiles of competitive matches using the automatic tracking system (Iseyama et al., 2016). Temporary fatigue of the players in a futsal game was defined by dividing one participating time into three parts (first, middle, final third). All values are presented as means ± SD. Differences in the total distance covered in the first and second half each were compared using a Student's t-test, whereas differences in the three thirds were determined by the one-way ANOVA for repeated measures. In case of significant difference between the three parts, a Bonferroni`s post hoc test was used to identify the point of difference. Statistical significance was set at $p < 0.05$.
RESULTS: The average of the total distance covered during the first half (158 ± 6 m · min-1) was significantly higher than those of the second half (148 ± 12 m · min-1; $p < 0.05$).In addition, the average of total distance covered during the final third (142 ± 9 m · min-1) was significantly lower than that of the first third (155 ± 10 m · min-1; $p < 0.05$).
CONCLUSION: This is the first study indicating that the average of total distance covered during futsal games decreased in the final third. This finding indicates that physical performance decreases with time of participation, and it appears that the players experience temporary fatigue during the game. These results may be a help for player substitution, training design and for physical coaches of futsal players but further it is necessary to investigate fatigue at the end of games, the relationship with physical fitness and recovery time.

CHANGE OF DIRECTION PERFORMANCE OF RUGBY PLAYERS: INFLUENCES OF PHYSICAL AND TECHNICAL ASPECTS

FREITAS, T.T., LOTURCO, I., MCGUIGAN, M., CALLEJA-GONZÁLEZ, J., GUERRIERO, A., ARRUDA, A., REIS, V., PEREIRA, L., ALCARAZ, P.E.

CATHOLIC UNIVERSITY OF MURCIA ; NAR - NUCLEUS OF HIGH PERFORMANCE IN SPORT, SAO PAULO; BRAZILIAN RUGBY CONFEDERATION

INTRODUCTION: Change-of-direction (COD) is a multifaceted skill, underpinned by different physical and technical qualities (1). Recently, the "COD deficit" (additional time required to perform a COD when compared to the time needed to cover the same distance in a linear sprint) has been proposed as a more suitable way to evaluate this quality in team-sports (2). Curiously, faster and more powerful players have been found to present greater COD deficits (3). However, it remains unclear whether more complex mechanical variables (e.g., sprint momentum) and technical parameters can be used to discriminate athletes who are more or less efficient at changing direction.
METHODS: Eleven National Team rugby union players completed the following physical assessments: COD tests (Pro-agility, 45° cutting (CUT) and "L" (L-Drill)); 40-m linear sprint. COD velocities and deficits and sprint velocity and momentum were calculated. Lower-body kinematic parameters were assessed in all COD tests using inertial sensors and a capture and motion analysis system. Pearson's product-moment correlations were performed to determine the relationships between COD velocities, COD deficits, sprint velocity and momentum. The differences between players with higher and lower COD deficits were examined using magnitude-based inferences.
RESULTS: Greater sprint momentum was associated with higher COD deficits, particularly in drills with sharper angles and multiple directional changes (L-drill: $r = 0.85$; $p < 0.05$ and Pro-agility: $r = 0.79$; $p < 0.05$). Sprint velocities were more related to COD velocities (but not deficit) in less aggressive maneuvers (CUT: $r = 0.89$; $p < 0.05$). In addition, faster athletes were less efficient at changing direction and presented greater trunk and knee flexion angles in all COD maneuvers (ES ranging from 0.34 to 1.42).
CONCLUSION: Faster rugby union players appear to be less efficient at changing direction, relative to their maximum sprint velocity. Interventions aimed at increasing linear speed may differently affect COD efficiency, depending on the angle of directional change. For example, in smoother cutting maneuvers (e.g., 45º), velocity maintenance and a greater sprint momentum may be beneficial. In contrast, for directional changes of more than 90º, sprint momentum might lead to increased lower-body loading and trunk and knee flexion angles during COD tasks, which could hamper sport-specific performance (e.g., faster and sharper directional changes, directly associated with greater inertia). Therefore, practitioners are advised to quantitatively (i.e., by the COD deficit calculation) and qualitatively (i.e., using movement pattern analysis) evaluate rugby union players to better understand and monitor their technical and physical performance during different COD maneuvers.

MODELLING THE OVERALL TECHNICAL PERFORMANCE IN YOUNG PORTUGUESE SOCCER PLAYERS. THE INEX PROJECT

ABARGHOUEINEJAD, M.1, BARREIRA, D.1, RIBEIRO, J.1, BAGATIN, R.1, FERNANDES, T.1, GUIMARÃES, E.1, BAXTER-JONES, A.D.G.2, MAIA, J.1

1CIFI2D, FACULTY OF SPORT, UNIVERSITY OF PORTO;2COLLEGE OF KINESIOLOGY, UNIVERSITY OF SASKATCHEWAN

INTRODUCTION: Performance in young soccer players is dependent on a complex interaction of factors. Physiological, technical and tactical skills are known to impact their game performance. Additionally, training years, as well as biological maturation may play important roles [1]. The main purpose of this study was to model the overall technical performance of young male Portuguese soccer players.

METHODS: The sample (n=155 aged 11-15 years) was divided into 4 chronological age groups (U12-U15); players were recruited from the In search of excellence in sport – a mixed-longitudinal study in young athletes (INEX) project. Data were collected at project baseline. Players were recruited from six clubs of the Oporto Soccer Association (north of Portugal). Technical performance data were obtained using the University of Queensland Football Skill Assessment Protocol [2] comprising the following specific skills tests: 20m pass, 20m shot, 35m Lofted Pass, Juggles, Dribble, Rebound 90˚, Rebound 135˚, Wall-pass. An overall measure of technical performance (OMTP) was derived based on individual z-scores. Further, lean body mass and biological maturation were assessed. Also, years of training and hours of soccer-specific training were collected along with a 5m running-speed and agility test, ANOVA and backward stepwise regression were used and alpha= 5%.
RESULTS: Overall, there was a significant increase in means with increasing age (from U12 to U15) in almost all variables ($p<0.05$) except 20m pass, 20m shot and years of training at the $p<0.05$ level. However, not all differences had the same effect sizes (eta square (e2)), and they ranged from e2=0.623 in biological maturation to e2 = 0.066 in agility. From the set of the six predictors to explain OMTP, the final regression model was significant [$F(6, 137)=3.42$, $p=0.004$)], and $R^2= 0.09$, i.e., 9% of the total variation in OMTP was explained by the additive effects of biological maturation and hours of soccer-specific training. Years of training, lean body mass, 5m running-speed and agility did not enter the final equation ($p>0.05$).
CONCLUSION: Overall technical performance appeared to be best explained by contextual (hours of specific training) and biological (maturation) factors. This calls for coaches´ caution when designing training plans, mainly specific skills, because players´ response may favour those advanced in their biological maturation and limit those of late matures. Further, it is possible that relying mostly upon quantity of training hours of technical skills rather than training quality may not be the most appropriate approach. Additionally, practising drills should be contextualised within the game specificities of each age group competition level.

SELF-SELECTED MUSIC REDUCES PERCEIVED EXERTION DURING HIGH-INTENSITY INTERVAL EXERCISE WITHOUT AFFECTING EXERCISE-INDUCED IMPROVEMENTS IN INHIBITORY CONTROL

SUGIMOTO, T.

RITSUMEIKAN UNIVERSITY

INTRODUCTION: High-intensity interval exercise (HIIE) is an effective exercise protocol for improving inhibitory control (IC) (1, 2). However, HIIE induces a higher increase in perceived exertion (3), which can be considered a barrier to exercise participation for some individuals. In a recent study, we demonstrated that listening to self-selected music can mitigate the increase in rate of perceived exertion (RPE) during aerobic moderate-intensity continuous exercise without decreasing the positive effect of exercise on IC (4). Thus, we hypothesized that such effects would be useful in reducing RPE during HIIE without affecting IC response. To test this hypothesis, we examined the effects of self-selected music on RPE and IC in response to HIIE.
METHODS: Fifteen healthy young men (age: 21.7 ± 0.5 years) performed HIIE using cycle ergometer with self-selected music or non-music condition. The HIIE was performed ten 1-min bouts at 90% of VO2 peak with 1-min active recovery at 30% of VO2 peak. Both RPE for respiration and RPE for lower limb discomfort during HIIE were assessed by Borg 6-20 and CR10 scales, respectively. Both RPEs were measured five times every 4 min (i.e., at the end of 2nd, 4th, 6th, 8th, and 10th high-intensity exercise). The self-selected music condition was performed while listening to music through headphones, and only songs under 120 bpm were provided. To evaluate IC, the Stroop test was administered before exercise, immediately after exercise, and every 10 min during the 30-min post-exercise recovery period.
RESULTS: Both RPE for respiration (14.7 ± 0.4 vs. 15.4 ± 0.4, $p<0.01$) and RPE for lower limb discomfort (5.4 ± 0.4 vs. 5.8 ± 0.4, $p<0.01$) during HIIE were significantly lower in music condition than in non-music condition. Compared to before HIIE, the IC was improved immediately after HIIE ($p<0.05$), whereas there was no significant difference between both conditions.
CONCLUSION: These findings suggest that listening to self-selected music is a beneficial strategy in reducing perceived exertion during HIIE without affecting its positive effect on IC.

THE USE OF RESTING HEART RATE AND HEART RATE VARIABILITY TO MONITOR STRESS AND PREDICT PERFORMANCE FOLLOWING HYPOXIC REPEATED SPRINT TRAINING IN RUGBY PLAYERS

HAMLIN, M.J.1, LIZAMORE, C.A.1,2, OLSEN, P.D.2, MARSHALL, H.C.2, GIESEG, S.P.3,4

1: LINCOLN UNIVERSITY, 2: ARA INSTITUTE OF CANTERBURY, 3: UNIVERSITY OF CANTERBURY, 4: UNIVERSITY OF OTAGO

INTRODUCTION: Heart rate variability (HRV) is a non-invasive, low-cost measure of autonomic nervous system balance that is associated with training stress. While HRV has been used previously to monitor training stress in endurance athletes during live high altitude training protocols, little research exists on the use of HRV to monitor stress in team sport players during repetitive sprint training in normobaric hypoxic conditions. The aim of this research was to investigate whether heart measures such as HRV and resting heart rate could detect changes in training stress due to hypoxia. A secondary aim was to then investigate whether such measures could predict performance change post-training.
METHODS: Nineteen amateur club rugby players participated in 3 weeks of repeated sprint training in either hypoxic (RSH, n = 9; age: 20.3 ± 2.1 years; weight: 77.1 ± 10.2 kg; height: 173.9 ± 4.9 cm) or normoxic (RSN, n = 10; age: 22.0 ± 4.1 years, weight: 88.3 ± 14.1 kg; height: 177.9 ± 5.4 cm) conditions. Training included two repeated sprint (cycling) sessions per week in either hypoxic (FIO2: 14.5%) or normoxic conditions (FIO2: 20.9%). Resting heart rate (RHR) and heart rate variability were monitored at rest prior to repeated sprint train-

ing. Repeated sprint ability (RSA, running), and the Yo-Yo Intermittent Recovery Level 1 test (YYIR1) were used to assess performance change over the course of the study.
RESULTS: As a result of training, athletes in the RSH group had possibly lower HRV (natural log of the root mean square of successive difference (LnRMSSD) -8.5, ± 19.1, percent change, ± 90% CL, p = 0.39), but possibly higher resting heart rate (3.2 ± 4.7% p = 0.25) compared to the RSN athletes. For the RSH group, measures with the strongest correlation with post-intervention performance change were resting heart rate (YYIR: r = -0.82; RSA: r = 0.73), LF/HF ratio (YYIR: r = -0.85; RSA: r = 0.77) and RMSSD (YYIR: r = 0.58; RSA: r = -0.53). The correlation between heart measures and post-intervention performance were weaker in the RSN group (correlations ranged from 0.56 between resting heart rate and RSA and -0.11 between LF/HF ratio and YYIR1).
CONCLUSION: Resting heart rate and heart rate variability in the third week of training was improved in the group performing their repeated sprints in normoxia, but remained relatively unchanged in the group performing their repeated sprints in hypoxia, possibly due to the higher exercise stress encountered by training in a hypoxic environment. Strong correlations between resting heart measures of autonomic function and post-training performance suggest these markers may be valuable tools for monitoring training-induced stress during repeated sprint training, particularly when training in hypoxia.

BODY & BOAT: SIGNIFICANCE OF MORPHOLOGY ON ELITE ROWING PERFORMANCE

DELAROCHELAMBERT, Q.

IRMES

INTRODUCTION: Morphology in elite sport whether it be for identification or training can be useful as well as deceitful. The purpose of this study was to determine and weigh the anthropometric indicators statistically associated with pacing performances for each Olympic rowing category.
METHODS: : 2,120 athletes' morphological traits were collected (1,228 men and 892 women) during finals of all World Championships between 2010 and 2015 in each heavyweight Olympic event. Time, speed, and cadence were collected every 50 meters for all boats in each competition. Morphological groupings based on crew biometrical parameters were used to retrace race speeds and pacings. We used a magnitude-based inferential approach to measure the effect of morphological factor on rower's / crew's performance.
RESULTS: This article can directly tell which morphological factors are significant and their effect on each male and female rowing category through speed. Men's single sculls is the category the most significantly affected by height: over each 50m segment, the tallest quartile (199,3 ± 1.5 cm) rows 0.199 m.s-1 faster than the second quartile (196.1 ± 1.9 cm) leading to a 4.22% faster during the entire 2000m race.
CONCLUSION: Morphological factors specifically impact pacing among rowers categories. For some, like height in men's single sculls relationship is obvious: the taller, the better. For other Olympic categories the relationship between speed and morphological factors are more ambiguous. Coupling biometry and race pacing may help to improve training and performance follow-up.

MONITORING THE TRAINING RESPONSE IN A PROFESSIONAL FEMALE LONG-DISTANCE TRIATHLETE USING SUBMAXIMAL EXERCISE TESTS - A PRACTICAL SINGLE-CASE APPROACH

SCHNEIDER, C., VON DER GOLTZ, H., FERRAUTI, A., HANAKAM, F.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: Training monitoring with non-exhaustive exercise tests became popular in training research and practice [1]. In endurance sports, individualizing test protocols based on race performance data may represent a pragmatic alternative to standardized tests. Therefore, the purpose of this observational single-case study was to determine training adaptations during a macrocycle aimed to increase performance at lactate threshold using an individualized submaximal cycling test (SCT).
METHODS: A professional female long-distance triathlete (180cm, 68kg) performed weekly SCTs throughout a 13-week Ironman (IM) preparation. Tests were conducted on Tuesdays after a day of reduced training load. Training responses were monitored by blood lactate (LA), heart rate and rating of perceived exertion (RPE, 6-20 scale) during five 6-min exercise bouts: warm-up (160W) and two stages each at 15W below and above mean cycling power output during IM (200W, 230W) and Olympic-distance (OD, 245W, 275W) races, respectively. Prior SCT, body weight and composition using bioimpedance analysis and perceived recovery and stress were assessed. Tracking devices and a training diary were used to derive training volume (number, duration, distance) and intensity distribution (3-zone model) using the session goal method [2]. Long-term responses were determined by linear regression [3].
RESULTS: A total of 150 triathlon workouts (incl. 3 races) were performed with 55h swimming (187km), 158h cycling (3611km), 57h running (686km) and 15h strength training. Intensity distribution (endurance sessions) in zones 1, 2 and 3 was 57-19-25% for number of sessions and 68-17-15% for training duration. SCT was sensitive to training adaptations, reflected by negative trends in LA (overall effect, range -0.1 to -1.6 mmol/l, -8% to -26%) and slightly reduced RPE compared to week 1. Further, body weight (-2kg) and %-body fat (-2.7%) decreased.
CONCLUSION: Our observations suggest that weekly submaximal tests allow continuous monitoring of training responses and are well tolerated. Long-term LA reductions indicated favorable adaptations which can be related to the emphasis on interval- and threshold-based workouts. This was particularly noticeable by marked LA changes at intensities around OD power output. In combination with decreased body weight and body fat, the results reflect substantial improvements in relative performance at lactate threshold, which may contribute to race performance. However, acute LA changes after middle-distance and OD races have partially exceeded the magnitude of long-term trends, highlighting the importance of the training context in assessing and interpreting physiological markers during exercise. Overall, we conclude that individualized protocols can be a practical and pragmatic alternative to standardized tests and provide valuable information for training adjustments.

SOLDIERING TASKS' PHYSIOLOGICAL DEMANDS BY HEART RATE ZONE SCORES

CANINO, M., FOULIS, S., COHEN, B., WALKER, L., TAYLOR, K., REDMOND, J., SHARP, M.

U.S. ARMY RESEARCH INSTITUTE OF ENVIRONMENTAL MEDICINE

INTRODUCTION: Monitoring heart rate is a prevalent method used in athletics to gauge physical training intensity and recovery in order to produce optimal adaptations. To quantify heart rate training load, summated heart rate zone (SumHR) scores have been utilized by

calculating the duration spent in 5 heart rate zones during an activity (1). Advanced physiological measurements (e.g., metabolics, biomarkers) have been previously used in military populations to quantify the physiological demands required to perform high physically demanding military tasks; however, calculating SumHR scores have not been extensively investigated in military populations performing physically demanding occupational tasks. To determine the relationship between total absolute oxygen consumption (AbsVO2) and SumHR scores in Soldiering tasks.
METHODS: Ten Soldiers (8 males, 2 females) performed 4 Soldiering tasks: foot march (FM), sandbag fill (SBF), sandbag carry (SBC), and ammunition can carry (AMMO). FM required Soldiers to walk for 20 min on a treadmill (2.0-2.5 mph at 0% grade), while wearing 102 lb of equipment. SBF entailed shoveling loose sand into a bucket (30-40 lb) within 52 minutes for 26 fills, while wearing 71 lb of equipment. SBC consisted of lifting and carrying 26 sandbags (40 lb each) a distance of 10 m to construct a fighting position within 26 min, while wearing 71 lb of equipment. AMMO required lifting and carrying 30 ammunition cans (45 lb each) a distance of 15 m and placing them on a vehicle's tailgate as fast as possible, while wearing 71 lb of equipment. Metabolic measurements and heart rate were monitored and recorded. Age-predicted maximal heart rate was calculated (220-age). SumHR were calculated by multiplying the duration (min) spent in each of the 5 heart rate zones by a multiplier factor for each zone (50-59%=1, 60-69%=2, 70-79%=3, 80-89%=4, ≥90%=5). Pearson and Spearman correlations were performed to examine the relationship between AbsVO2 and SumHR.
RESULTS: For SBF and SBC, significant positive correlations exist between AbsVO2 and SumHR ($r \geq 0.75$, $p \leq 0.01$; $rho \geq 0.82$, $p < 0.01$). AMMO had a significant positive $r = 0.82$ ($p < 0.01$) but nonsignificant rho ($p = 0.07$). No significant correlations were revealed for FM ($p \geq 0.27$).
CONCLUSION: A linear relationship exists between the total absolute oxygen consumption and SumHR scores, indicating individuals with higher AbsVO2 values tended to have higher SumHR scores. Calculating SumHR scores may be an acceptable and feasible alternative to metabolic measurements when attempting to assess the physiological demands during Soldiering tasks; however, caution should be used for constrained tasks (e.g., treadmill FM) due to the potential inability to detect significant performance differences.

THE PARKINSON CRITICAL HEART RATE TEST: USING THE CRITICAL POWER MODEL FOR PARKINSON DISEASE

BARBIERI, R.A.1,2, SIMIELI, L.3, VIEIRA, L.H.P.3, SILVA, F.A.3, SILVEIRA, A.P.B.3, IMAIZUMI, L.F.I.3, MORETTO, G.F.3, BARBIERI, F.A.3

1. CENTRO UNIVERSITÁRIO ESTÁCIO RIBEIRÃO PRETO; 2. UNIVERSITY OF SÃO PAULO-EEFERP,3. SAO PAULO STATE UNIVERSITY-UNESP

INTRODUCTION: Parkinsons disease (PD) is characterized by the death of dopaminergic neurons in substantia nigra pars compacta of the basal ganglia causing a variety of symptoms that reduce mobility and quality of life of people with PD. It has been demonstrated that an aerobic exercise program seems to attenuate PD symptoms and improve the quality of life (1). However, few studies have attempted to determine the ideal intensity of aerobic exercise. Critical power model is a cheap and non-invasive method to estimate the exercise intensity demarcates fatiguing from non-fatiguing work. Therefore, the objective of the present study was to propose a protocol (Parkinson critical heart rate test) to determine critical heart rate (CHR) (2) and verify its reproducibility.
METHODS: Fifteen patients with idiopathic PD who are able to practice exercises were recruited to participated in the study (9 men and 6 women 71.1±6.6 years).To the Parkinson critical heart rate test, three, randomly ordered in constant distance (400, 800 and 1200m) (1) where they were instructed to travel the distance in the shortest possible time in a rectangular circuit 10 by 10 meters. The tests in each distance were performed on separate days. This range of distances was selected, so that each subject could complete 3–20 minutes of exercise before exhaustion. Participants were instructed not to run during the test in order to prevent falls. Heart rate values were continuously monitored and recorded as 5-second averages. For each distance, the total number of heart beats (HBlim) was calculated as the product of the average 5-second HR (b.min-1) and time to exhaustion (Tlim). For each velocity, the HBlim was plotted as a function of the Tlim. The CHR was defined as the slope coefficient of the regression line between HBlim and Tlim. To test the reproducibility, the test was repeated 4 weeks after.
The dependent student's t-test for paired samples was performed to compare the results between test and re-test and the coefficients of variation (CV) and typical error (TE) and intraclass correlation (ICC) were also calculated.
RESULTS: The time to travel the distances was not different between test and re-test ($p > 0.05$). Furthermore, the CHR was not significantly different between test and re-test (109.4±22.3 and 107.7±16.9 BPM; $p = 0.69$) and present low typical error (11.87BPB) and coefficient of variation (15.5%). In addition, the data presented significantly ICC for the CHR (0.78; $p < 0.04$).
CONCLUSION: According our results, the Parkinson critical heart rate test is a cheap and non-invasive method reliable and reproducible to estimate the exercise intensity demarcates fatiguing from non-fatiguing work thought the Critical heart rate model.

INCREASED OXIDATION OF LIPID ENERGY SOURCES OCCURS INDEPENDENT OF CHANGES IN RUNNING ECONOMY AFTER AN EXERCISE INDUCED FATIGUE PROTOCOL

KELLY, L.P., BLAIR, J., ADEBAYO, A., SAAD, M., BYRNE, J.M., BASSET, F.A.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Expressing running economy (RE) in terms of the caloric unit cost is reported to be more sensitive to change than expressing it in terms of oxygen cost by accounting for differences in substrate utilization[1]. The purpose of the current study was to evaluate changes in RE at 3 submaximal running speeds due to exercise-induced fatigue (EIF) expressed as both the oxygen cost (ml / (kg·km)) and the energy required to cover a given distance (kcal/(kg·km)). It was hypothesized that RE would be reduced after the EIF protocol and that expressing it in terms of the caloric unit cost would be more sensitive to changes.
METHODS: Nine male distance runners [maximal oxygen uptake 61.6±7.3 ml / (kg·min), body mass 71.0±4.8 kg, height 176.3±6.5 cm, age 29.0±7.5 yrs.] ran on a motorized treadmill for 8-min at three different speeds (10, 12, and 14 km / hr), which were performed in randomized order and with a 2-min rest between bouts; both before and after the EIF protocol. The EIF protocol involved 7 bouts of 1000 m performed on a 200 m track at 94-97 % of maximal aerobic speed with 3-min recovery between running intervals. Oxygen uptake and carbon dioxide production were recorded via an open circuit indirect calorimetry system to evaluate changes in RE at the three speeds before and after the EIF protocol.

RESULTS: Average oxygen cost was 213±18, 202±10, and 193±19 ml / (kg·km) before the EIF protocol and 214±9, 238±13, and 204±11 ml / (kg·km) after the protocol at 10, 12, and 14 km/hr, respectively. Accordingly, a significant increase in oxygen cost was only observed at 12 km/hr (P<0.0001) after EIF. The contribution of lipid energy sources significantly increased across all 3 running speeds (0.18±0.05, P=0.0016; 0.12±0.04, P=0.0053; and 0.10±0.05 kcal/(kg·km), P=0.046), with corresponding decreases in carbohydrate oxidation such that the caloric unit cost did not significantly change after the EIF protocol across the 3 running speeds (+0.002±0.032, p=0.96; +0.016±0.0096, p=0.13; and -0.0032±0.015 kcal/(kg·km), p=0.83).
CONCLUSION: Different effects of EIF on RE were reported when expressed as the oxygen cost of running compared to the caloric unit cost. The current data are inline with previous reports indicating that the expression of RE in terms of the caloric unit cost is a more valuable measure as it takes into account differences in substrate partitioning.
1. Fletcher, J.R., S.P. Esau, and B.R. Macintosh, Economy of running: beyond the measurement of oxygen uptake. J Appl Physiol (1985), 2009. 107(6): p. 1918-22.

COMPLETE WIRELESS EMG PROTOTYPE (WELLFIT EMG) RELIABILITY VERIFICATION: COMPARING AMPLITUDE WITH TELEMYO DTS (NORAXON)

KIM, S., JI, C.

KOREA UNIVERSITY

INTRODUCTION: Standardization of measurement accuracy and measurement method, price competitiveness, expansion of versatility, improvement of design, improvement of portability, expansion of the use of EMG, an increase of user convenience and awareness. Based on bio-signals generated in the muscles, real-time biofeedback and exercise information can be provided to the public at the same time, and the range of applications such as training method, posture correction, injury prevention, and sports field and medical diagnosis field can be diversified.
It can be expected that positive effects such as improvement of exercise effect and injury prevention of an unspecified number of sports and athletes can be expected. For this purpose, the reliability of the newly developed product (WellFit EMG) is compared with that of the existing product to complete the prototype of the newly developed product.
METHODS: Noraxons Telemyo DTS was chosen as the reference device. As the muscle site the Biceps Brachii was selected. The protocol consisted in keeping hand weights at 90 deg elbow angle for about 10 seconds. The first test was an MVC test which was also recorded for 10 seconds. The weights used were 80% 1RM (Repetition Maximum). Three movements such as a barbell curl, a bench press, and a chest press were applied to the same muscle. For the 3M™ Red Dot™ were used with typical electrode distance of 20mm.
A reference electrode was attached to a nearby bony part (acromion or epicondyle). With Noraxon Dual electrode sensor was used. The DTS sampling rate was set to 1500 Hz and the Mpower sampling rate was set to 500 Hz (defaults for the devices). Eight volunteers (2F + 6M) participated in the tests (26.8yr, 76.25kg, 172.7cm). Data with large distortion was excluded.
RESULTS: The vertical value(uV) indicate the subsections corresponding to 80% 1RM of arbell curl, a bench press, and a chest press and the MVC sub-trials. These subsections
of the duration of 10 seconds each were used for further analysis such as calculating the RMS values.There is an apparently good correlation between the EMG envelopes. We can compare the mean amplitudes of Noraxon and Well-fit EMG for the sub-trials by computing the means of the EMG-envelope subsections and presenting the result as a peak voltage. The result for all sub-trials and all participants is presented in the following. The peak values of MVIC were 2089uV (Noraxon) and 3085uV (WellFit), and the barbell curl values were 3786uV (Noraxon) and 3331uV (WellFit). Bench press measurements were 763uV (Noraxon) and 742uV (WellFit). Chest press measurements were 679uV (Noraxon) and 674uV (WellFit).
CONCLUSION: The Telemyo DTS and WellFit EMG devices show similar amplitude outputs. There is a
good correlation between EMG envelopes. The amplitude relation may though vary with
participant characteristics and test conditions. The difference in electrode types probably
contributes to this variation.

LOCATION OPTIMISATION FOR IMUS IN THE DESIGN OF MOTION TRACKING SOCCER TIGHTS BASED ON SOFT TISSUE ARTEFACT ANALYSIS

AHSMANN, L.L., STEYLEN, A., WILMES, E., JANSEN, K.M.B., HUYSMANS, T.

DELFT UNIVERSITY OF TECHNOLOGY

INTRODUCTION: It has been known that effects of Soft Tissue Artefact (STA) cause inaccuracy of motion tracking when using skin-attached markers for kinematic studies (1) (2). However no study has been found to compare the displacement of different marker locations for the implementation of IMUs in soccer clothing. In this study, the displacements of seven marker locations were compared to segments of a Plugin Gait system (3) during acceleration and deceleration trials. The seven marker locations were determined by a preliminary study on comfort and risk of different marker locations during soccer-specific movements, resulting in a ranking of the marker locations.
METHODS: Four able bodied subjects (2M 2F) performed five repetitions of both acceleration (ACC; 0% - 100%) and deceleration movements (DEC; 100% - 0%). Optoelectronic measurements were done in an indoor space surrounded by eight optoelectronic VICON cameras (100 FPS). Sixteen markers placed on bony landmarks were used to model joint centre coordinates of the hip, knee and ankle to simulate bone segments of the thigh and shank to serve as a reference frame. C3D data of markers was processed in Matlab® to calculate displacement both perpendicular and parallel to the reference frame. Parallel displacement is measured relatively and measured from the knee joint centre due to non-constant segment length caused by the modelled hip joint centre.
RESULTS: The total number of data points after eliminating outliers is 963 (488 perp. and 475 para.). Each data point represents the maximum shift for each marker per trial for both legs as the range of distances between the marker and the reference frame. The markers with significant lowest mean displacement according to an ANOVA parametric test (with Post Hoc Scheffe, p = 0.05) are the ones located on the lateral side of the shank and thigh (both 2/3 distal). Significant higher displacement occurs on the Semimembranosus, Vastus Lateralis and Gastrocnemius. Markers located on the lower hamstring (7 cm proximal to knee joint centre, posterior) and Popliteus are neither in the significantly lowest or highest subset of markers.
CONCLUSION: Optoelectronic markers on the lateral side of the thigh and shank cause lower amount of perpendicular and parallel errors in kinematic measurements compared to five other marker locations. As the lateral shank was also recommended in the preliminary study, it would be a good marker location to both minimize comfort issues and measurement errors caused by STA. Lateral thigh locations, however, were perceived to cause discomfort. The designer should consider using the marker location on the Popliteus to balance

between lowest displacement and comfort. It should be noted that displacement highly depends on type of movement and its vector, of which parallel displacement values could be affected by systematic errors of the Plugin Gait model.

CP-SH06 Psychological responses to exercise I

EFFECTS OF PHYSICAL ACTIVITIES AND SLEEPING HOURS LEVEL ON STRESS REACTIONS

TAKANASHI, M.1, SHIMIZU, Y.1, MICHAEL, A.1

1: INTERNATIONAL CHRISTIAN UNIVERSITY

Introduction
Lifestyle factors are associated with university students' mental health. Recently, university students' exercise levels and sleeping hours are decreasing significantly potentially due to the pervasiveness of new technologies (smartphones and SNS for example) in Japan. Mental health issues potentially increase as a consequence of such lifestyle disturbances. This study examines the relationship between undergraduate university students' lifestyle, including physical activity level and sleeping hours, and self-reported stress level.
Methods
Research participants included 488 undergraduate university students (male: 139, female: 349, Mean age: 18.6, SD: 1.7) who answered a questionnaire concerning socio-demographic information, physical activity levels (Frequency, Intensity and Time Index for Japanese), sleeping time (total minutes), and responses to a stress reaction scale. To analyze the potential relationship between study variables, independent samples t-tests, Pearson correlations, one-way ANOVA and multiple regression analyses were performed.
Results
The results of inferential analyses showed that there are significant differences in the average values of physical activity levels between the sexes, with male students showing significantly higher activity. Furthermore, higher physical activity level was negatively associated with two stress reaction factors (Depression and Chronic pain) out of seven. Longer sleeping hours were negatively associated with four out of seven stress reaction factors (Lack of concentration, Physical fatigue, Depression and Chronic pain).
Conclusion
The results of this study indicated that proper exercise load (eg, 150 minutes per week that is WHO recommended) and sufficient sleep hours (eg, 6-8-hour recommendation from the Japanese ministry of Health, Labour and Welfare) effectively reduce the stress reactions of university students. In order to enhance students' mental health, physical education courses that include physical activity practice and lectures (mandatory undergraduate courses within the Japanese university system) need to offer the learning opportunities concerning the interrelationships between activity, sleep and stress.

PHYSICAL ACTIVITY OF NURSERY SCHOOL TEACHERS AND THEIR PSYCHOLOGICAL STRESS.

TAKEDA, N., KIMURA, T.

NAGOYA MANAGEMENT JUNIOR COLLEGE

Introduction
Japanese children's motor skill is decreasing. The reasons for the decline in motor ability include the importance of Active Play is neglected in the consciousness of people involved with children. Takeda et al. (2017) pointed out that the frequency of Active Play recognized by parents is closely related to the results of many motor ability test items, rather than the development status such as height, weight, and month old. Similarly, nursery teachers will influence the development of childrens motor ability.
In nursery schools in Japan, nursery teacher often work with children and seems to be one of the most active occupations today. Also, due to the difference in height with an infant, it is thought that there are many repeats of standing position and sitting position, which is a type of occupation with many fatigue on the back and fatigue of the lower limbs. Until now, there are few reports on the amount of nursery teachers activity at nursery schools, and it is not clear what kind of scene is actually emphasized physically and psychologically. The development of children from 0 to 6 years old is remarkable, and the work of nursery teacher changes greatly if 1 year old changes. Therefore, it is considered that the burden of nursery teacher changes greatly depending on the age of the child in charge. Nursery teacher is said to have high physical fatigue, chronic fatigue syndrome and turnover rate.
Therefore, in this study, the purpose was to investigate and analyze the activity amount and the estimated stress value in nurseries childcare service.
Methods
Target: 10 nursery teachers (1 male, 9 female) engaged in nursing at the public "A" nursery school were targeted.
Measurement method: The subject wears hitoe® made by Docomo Co., which measures biological information about four times a month, and will be engaged in nursery care work. hitoe® is a functional material for collecting biological information (heart rate, acceleration, electrocardiographic waveform) in an unconsciously close state. By accumulating and analyzing biological signals, it is possible to utilize not only efficient exercise, but also information not normally conscious, such as physical condition change and degree of tension, in a visible form. In addition, stress estimate can be measured by measuring Low Frequency / High Frequency (LF / HF). Measurement of biological information was set taking into consideration the influence of time and burden of the nursery teachers at the time of collecting information.

PHYSICAL ACTIVITY, STRESS, AND SEDENTARY BEHAVIOR IN GRADUATE STUDENTS: THE PASS STUDY

DUNSTON, E., TAYLOR, K.

EASTERN WASHINGTON UNIVERSITY

INTRODUCTION: Engaging in physical activity has benefits for both physical and mental health, yet more than half of university students do not currently meet physical activity guidelines. Although beneficial relationships between physical activity and stress have been shown in undergraduate students, little has been studied in graduate cohorts. Graduate students have shown to exhibit high levels of stress during their education with few coping strategies offered. Therefore, the purpose of the study was to determine if stress differs across levels of physical activity and sedentary behavior in graduate students. Further, we aimed to understand the associations among physical activity, sedentary behavior and stress in this population.
METHODS: An online survey was distributed to graduate students (n=67; age 27.5±7.8 yrs) at a regional university. The survey included the International Physical Activity Questionnaire, Sedentary Behavior Questionnaire, Cohen's Perceived Stress Scale and demographic questions. One-way ANOVAs were used to determine differences in stress across tertiles of physical activity and sedentary behavior. Pearson's correlations and multiple linear regressions were used to determine independent associations among variables.
RESULTS: There were no significant differences in stress across tertiles of sedentary behavior (p=0.67) or walking (p=0.69). However, there were significant differences in stress across tertiles of moderate-to-vigorous physical activity (p=0.006). Individuals in tertile 1 (<150 min/week of moderate-to-vigorous physical activity) had significantly higher stress scores (20.32±5.97; p=0.002) than those in tertile 2 (150 to 300 min/week; 13.87±5.26; p=0.003) and 3 (>300 min/week; 15.63±7.44; p=0.02). Further, time spent in vigorous physical activity was negatively associated with stress independent of age, sex, and hours worked per week (β=-0.365, p=0.006). Time spent in sedentary behavior (p=0.559), walking (p=0.902), and moderate physical activity (p=0.074) were not significantly associated with stress in this group.
CONCLUSION: Graduate students meeting or exceeding physical activity guidelines (i.e., ≥150 min/week of moderate-to-vigorous physical activity) had significantly lower stress levels than those who were physically inactive. Additionally, vigorous physical activity was negatively associated with perceived stress independent of age, sex and hours worked per week. This suggests that physical activity may have a positive effect on stress levels; however, the intensity of activity may be important. Moreover, there were no differences or associations between sedentary behavior and stress. Our research suggests that physical activity, particularly vigorous intensity, may be a potential coping strategy for stress in graduate students. Future research should use objective measures of physical activity in a longitudinal study to determine whether changes in physical activity and sedentary behavior influence stress levels in graduate students.

DANCE ON: CAN A COMMUNITY BASED DANCE PROGRAMME IMPROVE THE PHYSICAL AND PSYCHOLOGICAL WELL-BEING OF SOCIO-ECONOMICALLY DISADVANTAGED OLDER ADULTS?

DINGLEY, E., DEAN, E., BRITTEN, L.

UNIVERSITY OF LEEDS

Background: Physical inactivity and sedentary behaviour are prevalent issues in community dwelling older adults aged over 55 and living independently. Subsequently, there is an impact on the physical and psychological health and well-being of these individuals. The Dance On Programme is a multidisciplinary team project, involving One Dance UK, Yorkshire Dance, Doncaster Community Arts and University of Leeds, seeking to engage inactive, socio-economically disadvantaged older adults in 60 minute weekly dance sessions across 3 different areas of Yorkshire – Leeds, Bradford and Doncaster.
Methods: The research element of the programme involves investigating the changes in physical and biopsychological well-being of the older adults at regular time intervals (baseline, 3 months, 6 months and 12 months) throughout the Dance On programme. These include measurements of physical activity levels (Accelerometers and the Short Active Lives Questionnaire), balance and mobility (Timed Up and Go and Falls Efficacy Scale), psychological well-being (EQ-5D-3L and Subjective Well-Being Questionnaire) and cost effectiveness of the programme (Health Economics Questionnaire). Weekly attendance is also monitored, with qualitative work conducted with participants in focus groups.
Results: Up to date (data collection is ongoing), eight participants have been recruited (mean age = 73.2 ± 10.2 yrs., 8 females). From baseline to 3 months, significant increases in physical activity levels have been noted, as well as improvements in balance and mobility and psychological well-being ($p<0.05$). Themes from the focus groups include health benefits, mention of dance-related barriers and use of facilitators to continue engagement with the programme.
Conclusions: Data collection is ongoing, therefore more data will build upon current results. The Dance On Programme also aims to be rolled out nationally, by evidencing the success of community based dance programmes and providing a toolkit for implementation.

ASSOCIATION BETWEEN PHYSICAL ACTIVITY AND ANXIETY AMONG CHINESE COLLEGE STUDENTS: A CROSS-SECTIONAL STUDY

YE, M., ZHAI, X.Y., GU, Q., HUANG, T., FAN, X.

SHANGHAI JIAO TONG UNIVERSITY

INTRODUCTION: Anxiety is a significant contributor to the global burden of mental health (Haller et al., 2014), greatly affecting an individual's quality of life and well-being (Mendlowicz and Stein, 2000; Olatunji et al., 2007). Despite the established benefits of physical activity (PA) for anxiety, little is known about the association of moderate-to-vigorous physical activity (MVPA) with anxiety among Chinese college students. This study aims to: 1) describe the prevalence of PA and anxiety; 2) explore the association between anxiety and PA.
METHODS: Cross-sectional, a large sample of 5,267 participants aged 16-23 years (boy: 63%; girl: 37%) was analyzed. The questionnaire included items assessing PA (International Physical Activity Questionnaire-short form) and anxiety (Self-Rating Anxiety Scale). Binary logistic regression was used to examine the association between anxiety and PA.
RESULTS: Average MVPA time was 40.0±30.5min/day, with boys having more MVPA (42.9±31.8min/day) than girls (35.3±27.5min/day). About 23% of participants met MVPA recommendations, with a higher percentage of boys (27%) than girls (18%). The overall prevalence of anxiety was 9.7% (girls: 11.4%; boys: 8.7%). The prevalence of meeting MVPA recommendations in those with and without anxiety was 18.5% vs. 24.0% (p=0.004). With adjustment for socio-demographics, lifestyle, and academic stress in pooled model, boys who didn't meet MVPA recommendations had 1.42 (95% CI=1.0-2.0) times higher odds for anxiety than those meeting MVPA recommendations. However, no significant association between MVPA and anxiety in girls was found.

CONCLUSION: Meeting MVPA recommendations is associated with decreased prevalence of anxiety in Chinese male college students. There is a need for longitudinal research to establish the directionality of the relationships observed.

RISK AND PROTECTIVE FACTORS: THE ROLE OF PHYSICAL ACTIVITY AT WORK OR DURING LEISURE TIME ON STRESS IN A HIGHLY STRESSED OCCUPATIONAL GROUP

BISCHOFF, L.L., WOLLESEN, B.

INSTITUTE OF HUMAN MOVEMENT SCIENCE

Introduction
Shortages in the labour market and demographic changes result in work intensification and high stress levels among the nursing personnel in stationary nursing homes. Nübling et al. have identified low ratings of 'influence at work' as a stressor and high ratings of 'meaning of work' as a resource in geriatric nurses [1]. Physical activity (PA) is assumed to be associated with better psychological health outcomes [2]. However, little is known about the role PA - whether at work or during leisure time - might play in predicting high stress levels in nursing home personnel in a regression model that includes other associated potential influences like 'influence of work' or 'meaning of work'. The aim of this study was to identify the role of different types of PA as potential protective factors for stress in the highly stressed occupational group in nursing homes.
Methods
An extensive questionnaire was answered by N=138 employees in stationary nursing homes (80% female) located in northern Germany. The survey included the Copenhagen Psychosocial Questionnaire (COPSOQ), Screening Scale of the Trier Inventory for the Assessment of Chronic Stress (TICS-SSCS) and the WHO Global Physical Activity Questionnaire. To identify risk factors for chronic stress, a multiple regression analysis was conducted including 'influence at work', 'meaning of work', 'intensive PA at work', 'moderate PA at work', 'walking or cycling', 'intensive PA leisure time', 'moderate PA leisure time' alongside 'age and 'raising children'. Significance was set to $p<0.05$.
Results
The included variables in the multiple regression significantly predicted stress (SSCS) in employees of stationary nursing homes, $F(9, 114) = 5.331$, $p < .0005$, $R2 = .296$. Neither PA at work nor during leisure time had a significant influence on stress. Non-'walking or cycling' was the main predictor of stress. Considering non PA variables, both 'influence on work' and 'meaning of work' had a smaller but significant influence, whereas having to care for children or the age of employees had no significant influence on stress.
Conclusion
This cross-sectional study suggests that walking and cycling is a protective factor for stress in the highly stressed nursing home staff, whereas other types of PA surprisingly had no significant influence when included in a regression model with other stressors or resources. This highlights the need for a clear differentiation between types of PA in order to identify potential stress reducing effects. Nevertheless, in this study we could not appropriately assess duration or intensity of PA. It might therefore well be possible that leisure time PA did not reach the dose necessary in order to show stress reducing effects.

ASSOCIATION BETWEEN PHYSICAL FITNESS AND ACADEMIC PERFORMANCE AMONG CHINESE COLLEGE STUDENTS

XIANG, F., XIANG, Y.Z., MEI, Y., TAO, H.

SHANGHAI JIAO TONG UNIVERSITY

INTRODUCTION: Physical fitness (PF) is an important health marker both in the early years and later in life. PF was related brain health and academic performance (AP) among children and adolescents. Meanwhile, previous researches suggesting that lifestyle behavior such as physical activity may affect academic performance. Therefore, the present study is aimed to determine the correlation between PF and AP in Chinese college students adjusted for roles of demographic factors and lifestyle behaviors.
METHODS: In 2018, 2324 college students (male: 60.1%; female: 39.9%) aged 17-24 years were randomly sampled from Shanghai Jiao Tong University, China. PF was measured using Chinese National Student Physical Fitness Standard (CNSPFS). AP (GPA) and lifestyle behaviors were collected via a questionnaire. GPA was standardized by z-score. And low (poor academic performance), moderate and high GPA was defined according to the lowest 25%, the middle 50% and the upper 25%, respectively. Overall PF score (OPFS, z-score) was defined as low (the lowest 25%), moderate (the middle 50%) and high level (the highest 25%) according to the quartile of OPFS.
RESULTS: A significant positive trend for the mean±SD of several PF indicators across incremental GPA categories (Male: 50-m sprint, $P<0.01$; standing long jump, $P<0.01$; pull-ups, $P<0.01$; 1000-m run, $P<0.01$. Female: 50-m sprint, $P<0.05$; timed sit-ups, $P<0.01$; 800-m run, $P<0.01$;) were observed. In a multivariate model, the OPFS was positively associated with GPA (male: $P<0.01$; female: $P<0.01$) after adjustment for lifestyle behaviors. The OR for poor AP (the lowest 25% of GPA) in the low OPFS level compared with the high OPFS level was 0.40 (95%CI=0.30-0.56) among male students. Female students in the high level of OPFS had 59% decreased odds of poor academic performance (OR=0.41; 95%CI=0.25-0.67), compared with those PF were in the lowest level.
CONCLUSION: Poor AP were related to higher level of OPFS. And Intervention strategies for college students should target to improve PF, which may be beneficial for AP.

INVESTIGATION OF THE EFFECT OF AEROBIC EXERCISE TO THE UNIVERSITY STUDENTS CREATIVE LEVELS

TEKIN, M.1, GÜN, H.2

1KARAMANOGLU MEHMETBEY UNIVERSITY SCHOOL OF PHYSICAL EDUCATION AND SPORTS 22KARAMANOĞLU MEHMETBEY UNIVERSITY SOCIAL SCIENCES INSTITUTE, PHYSICAL EDUCATION AND SPORTS DEPARTMENT

Introduction and aim
The relationship between exercise and the physical processes of the human body is relatively well understood. The benefits of physical exercise and the subsequent enhancement of physical task performance is a familiar concept. What remains less clear, however, is the existence of a relationship between aerobic exercise and aspects of cognitive functioning,more specifically,creativity.The positive impact of aerobic exercise on physiological functions,particularly cardiopulmonary processes and structures,has been extensively studied and validated(Blanchette and et al 2005).The purpose of this study is to investigate of the effect of aerobic exercise to the university students Creative levels.

Method
The research group;consists of 25Female And25 Male(Age=20,5607+1,6782),50 inTotal, Studying At The Physical Education And Sports School Of Karamanoglu Mehmetbey University."Personal Information Form"developed by the researchers,Creativity Scale developed by Torrance(1966) adapted to Turkish by Aslan(2001)were used in order to reach the aim of the study. During 15weeks,students did aerobic exercise and Experimental design was used in the study,with pre-test and post-test control group.
In the analysis and assessment of the data,Shapiror Wilk Test,Wilcoxon signed rank test was used and significance was taken as P<0.05
Results and Discussion
Within this study;there was a significant difference between the results of the experimental and control groups;and there was significant difference between post-test results of the experimental and control groups.
Also, According to research results; there was a significant difference between total scores mean for fluency, originality, abstractness of titles,enrichment,resistance to early close,creativity forces list of in favor of post- test,in university students that participated Experimental study.When the obtained results were examined for the lower dimensions of TTCT Verbal Form B there was a significant difference between total scores mean for fluency,flexibility and originality,scores of in favor of post test.
As a result of this study;reveals that the aerobic exercise applied to university students positively influences the level of students creativity. These findings us;The most important purpose of aerobic exercise is;The no positive impact of aerobic exercise on physiological functions, particularly on cardiopulmonary processes and structures, but also on there is impact cognitive processes.These results;shows that aerobic exercise has an important structure under the broad and semantic framework of cognitive function

ARE SEDENTARY TIME AND PA ASSOCIATED WITH PERIMENOPAUSE RELATED DEPRESSIVE SYMPTOMS? THE FLAMENCO PROJECT.

MARÍN-JIMÉNEZ, N.1,2, BORGES-CÓSIC, M.1,2, ACOSTA-MANZANO, P.1,2, RUIZ-MONTERO, P.J.3, DE LA FLOR-ALEMANY, M.4, COLL-RISC, I.1,4, BAENA-GARCÍA, L.5, ARANDA, P.1,4, APARICIO, V.A.1,4

1SPORT AND HEALTH RESEARCH CENTRE, UNIVERSITY OF GRANADA, SPAIN; 2DEPARTMENT OF PHYSICAL EDUCATION AND SPORTS, FACULTY OF SPORTS SCIENCE, UNIVERSITY OF GRANADA, SPAIN; 3DEPARTMENT OF PHYSICAL EDUCATIO

INTRODUCTION: The physiological changes characteristic of perimenopause as well as life-style (like sedentary habits) may predispose middle-age women to higher risk of depression. In this regard, increasing physical activity (PA) or decreasing sedentary time may enhance depressive symptoms during this stage. Hence, the aim of the current study was to explore the association of objectively measured sedentary time and PA with depressive symptoms in perimenopausal women.
METHODS: This cross-sectional study included 198 perimenopausal women (age range 45-60 years, mean age 52.2±4.4 years) recruited for the FLAMENCO project. Objectively-measured sedentary time and PA levels were assessed with a tri-axial accelerometer worn in their waist for nine consecutive days. Participant's depressive symptoms were measured with the Beck Depression Inventory (BDI), which contains 21 items measuring depressive symptoms such as sadness, pessimism, suicidal thoughts, tiredness or fatigue, loss of energy, and loss of pleasure, among others.
RESULTS: Partial correlation analyses were adjusted for potential confounders (age, menopause status, study levels and marital status). Pearson correlations showed that Light PA was inversely associated with suicidal thoughts or wishes (r=-0.217, p<0.001), past failure (r=-0.184, p<0.05), punishment feelings (r=-0.168, p<0.05), self-dislike (r=-0.168, p<0.05), crying (r=-0.149, p<0.05), agitation (r=-0.151, p<0.05), loss of interest (r=-0.167, p<0.05), loss of energy (r=-0.165, p<0.05), irritability (r=-0.163, p<0.05) and BDI-total score (r=-0.194, p<0.001). Moderate-vigorous PA (min/week, in bouts ≥10 min) was inversely associated with Indecisiveness (r=-0.165, p<0.05) and worthlessness (r=-0.166, p<0.05). Total PA was inversely associated with suicidal thoughts or wishes (r=-0.203, p<0.001), past failure (r=-0.186, p<0.05), loss of pleasure (r=-0.167, p<0.05), punishment feelings (r=-0.148, p<0.05), self-dislike (r=-0.162, p<0.05), crying (r=-0.157, p<0.05), agitation (r=-0.173, p<0.05), loss of interest (r=-0.171, p<0.05), indecisiveness (r=-0.165, p<0.05), worthlessness (r=-0.162, p<0.05), loss of energy (r=-0.179, p<0.05), irritability (r=-0.174, p<0.05), loss of interest in sex (r=-0.169, p<0.05) and BDI-total score (r=-0.207, p<0.001). Finally, sedentary time was not associated with any studied variable.
CONCLUSION: Greater PA levels (especially, light PA, MVPA, and total PA) were associated with reduced depressive symptomatology during perimenopause.

EFFECTS OF SITTING AND STANDING POSTURES ON PSYCHOLOGICAL AND PHYSIOLOGICAL STATES

AYA, T., HIROSHI, S.

HIROSHIMA UNIVERSITY

INTRODUCTION: Effects of postures on psychological and physiological states have been examined in terms of expansive and contractive postures (e.g., Carney et al., 2010). High arousal and positive (HAP) postures were compared with low arousal and negative (LAN) postures, based on the two-dimensional theory (Russell, 1980), which proposes the arousal-valence dimensions. However, no studies so far have examined high arousal and negative (HAN) postures and low arousal and positive (LAP) postures. This study aimed to investigate the effects of various sitting and standing postures on psychological and physiological states.
METHODS: Twenty-five participants (Mage= 20.32±1.95 years) were given verbal instructions by the experimenter to perform 6 sitting and 6 standing postures over the course of two days. They held each posture for 1 minute followed by a 2-minute rest. Psychological states were measured using the Two-Dimensional Mood Scale (TDMS; Sakairi et al., 2009). Emotions were categorized as HAP, HAN, LAP, or LAN. Heart rate (HR) was measured as an index of physiological arousal.

RESULTS: A dimension (2) x posture (12) ANOVA for TDMS scores revealed significant interaction ($F(5.43,130.28)=17.02$, $p<.001$). Postures predicted to have high arousal had significantly higher psychological arousal than many postures predicted to have low arousal ($ps<.05$). Postures predicted to have positive emotions had significantly higher psychological valence than postures predicted to have negative emotions ($ps<.05$). A one-way ANOVA for HR revealed a significant main effect of posture ($F(6.13,146.94)=13.30$, $p<.001$). Standing postures had significantly higher HR than sitting postures ($ps<.05$). The results of a cluster analysis showed a four-cluster solution; 'HAP posture', 'HAN posture', 'LAP posture', and 'LAN posture'. The high arousal postures resulted in significantly higher HR than the low arousal postures, and positive postures resulted in significantly higher positive emotions than negative postures ($ps<.05$). 'HAP posture' had significantly higher HR than 'LAP posture' and 'LAN posture' ($ps<.05$), and 'HAN posture' had significantly higher HR than 'LAN posture' ($ps<.05$).
DISCUSSION:
This study demonstrated that expansive postures result in HAP states, and contractive postures result in LAN states, as was found in previous research. In addition, it is considered that LAP states were produced by instructions such as "lean on the backrest" and "relax your shoulders" which lowered arousal, and instructions such as "look straight ahead" which increased positive emotions. Furthermore, HAN states were produced by instructions such as "straighten your spine" and "expand your chest" which elevated arousal, and instructions such as "sit forward in a chair", "raise your shoulders" and "tilt your head to the right" which increased negative emotions. It is concluded that all of HAP, HAN, LAP and LAN states can be produced by manipulating postures.

THE RATING OF FATIGUE SCALE: CONSTRUCT VALIDITY AND RESPONSIVENESS TO A TRAINING INTERVENTION

DEKERLE, J., MARLE, M., MCLEAN, M., GAGE, C., BUTTERWORTH, J.

UNIVERSITY OF BRIGHTON

INTRODUCTION: The Rating of Fatigue scale (RoF) has been proposed to measure the construct of subjective fatigue (1). The aims of the present study were to assess both validity of RoF against the fatigue construct of the well-established Profile of Mood States (POMS-F (2) and the responsiveness of both to a training intervention (3).
METHODS: Twenty-six physically active participants gave written informed consent prior to the study. All completed 65-item POMS questionnaire and rated their fatigue intensity (RoF) before (PRE) and after (POST) a 4-week period, as well as 7 and 14 days after POST. Fifteen participants (12 males, 3 females; mean ± SD, age: 21.0 ± 2.1 years, Peak Power Output (PPO): 258 ± 49 W, VO2peak: 3.1 ± 0.7 L.min-1) trained (TRAIN) on a cycle ergometer (Monark 874E, Sweden) for four weeks (14 training sessions consisting of 2 x 15 min blocks at 70% of PPO. Eleven participants (6 males, 5 females; age: 20.8 ± 1.5 years; PPO: 255 ± 58; VO2peak: 3.1 ± 0.8 L.min-1) acted as control (CON). PPO and VO2peak were not significantly different between the two groups at PRE ($P>0.05$). Following check for normality (Shapiro-Wilk), sphericity of each dataset (Mauchly's test), and homogeneity of variance between groups (Levene's test), a Pearson moment correlation (POMS-F vs RoF) and a two-way mixed ANOVA (TRAIN vs CON; PRE vs POST; Bonferroni post-hoc test) were carried out for RoF and POMS-F, respectively. Significance of F-ratios was adjusted according to the Greenhouse–Geisser procedure. Critical value for statistical significance was set at $p < 0.05$. Data is reported as means ± standard deviation (SD).
RESULTS: When pooled together (n=108), the relationship between RoF (2.69 ± 1.63) and POMS-F (8.30 ± 4.95) was significant but moderate ($r=0.47$, $P<0.01$).
POMS-F was not different PRE to POST (TRAINPRE 8.40 ± 3.83, TRAINPOST 10.87 ± 5.30, CONPRE 6.55 ± 5.18, CONPOST 7.64 ± 3.83; $F=0.76$, $P=0.20$, $\eta2=0.07$) despite a tendency for greater values in TRAIN ($F=4.21$, $P=0.05$, $\eta2=0.15$). No time x group interaction was found ($F=0.26$, $P=0.61$, $\eta2=0.01$).
RoF was greater POST compared to PRE ($F=6.93$, $P=0.01$, $\eta2=0.20$) but with no significant group difference ($F=1.39$, $P=0.25$, $\eta2=0.05$) or time x group interaction ($F=0.77$, $P=0.39$, $\eta2=0.03$). Post-hoc analysis revealed a significant increase in TRAIN (PRE: 2.47 ± 1.25, POST: 3.47 ± 1.19; $t=2.51$, $P=0.03$, $dav=0.82$) but not CON (PRE: 2.14 ± 1.79, POST: 2.64 ± 1.78; $t=1.25$, $P=0.24$, $dav=0.28$).
CONCLUSION: The construct validity of RoF against POMS-F is weak with surprisingly a stronger responsiveness of RoF to a 4-week training period.

PSYCHOLOGICAL RESPONSES TO FOUR HIGH-INTENSITY INTERVAL EXERCISE PROTOCOLS

MARQUES, M., ALVES, E., HENRIQUE, N., FRANCHINI, E.

UNIVERSITY OF SÃO PAULO

INTRODUCTION: High-intensity interval exercise (HIIE) is an efficient method to improve health-related physical fitness1. However, considering the strenuous characteristics of this type of exercise, there is an inconsistency in the literature concerning the acute psychological responses to different HIIE protocols2. Moreover, no previous study evaluated the psychological responses to different HIIE protocols using the same subjects. Therefore, the current study aimed to investigate perceived exertion, feeling and enjoyment responses during HIIE protocols1.
METHODS: Twenty-three subjects, 11 males and 12 females (mean ± SD; age = 25.3 ± 4.0 years, body mass = 62.6 ± 11.7 kg, height = 165 ± 9 cm) were recruited to this study. After screening, a maximal aerobic velocity (MAV) test was conduct to quantify protocol intensity. Next, they completed four HIIE protocols in different days: (HIIEL - 10 x 60 s efforts at 100% of MAV by 60 s pause; HIIES - 2 sets of 10 x 30 s efforts at 120% of MAV by 30 s pause, 120 s pause between sets; RST - 19 x 6 s "all out" efforts by 40 s pause; and SIT - 4 x 30 s "all out" efforts by 240 s pause. Then, a final behavioural choice follow-up session. Rating of perceived exertion (RPE) and feeling scale (FS) values were collected pre (baseline), post each bout and post exercise. Enjoyment (PACES) was registered immediately after each protocol. To equalize the comparisons between protocols, quarter cut-points (25%, 50%, 75% and 100% of total number of exercise bouts) were established.
RESULTS: RPE significantly increased across all HIIE protocols ($F3,252 = 372.91$, $P < 0.001$,$\eta2 = 0.774$), with larger values in each subsequent quarter (25%: 12±3 a.u.; 50%: 14±3 a.u.; 75%:16±3 a.u.; 100%: 17±3 a.u.; $p < 0.001$ for all comparisons). A time and protocol interaction was also observed ($F9,252 = 5.12$, $P < 0.001$,$\eta2 = 0.123$), with higher values ($p = 0.033$) in the first quarter during SIT (14±3 a.u.) compared to HIIEL (11±3 a.u.). For FS, only an effect of time was observed ($F5,420 = 37.53$, $P < 0.001$,$\eta2 = 0.309$), with higher values pre-exercise (3±2 a.u.) and at the first quarter (2±2 a.u. compared to all other time points (50%: 1±3 a.u.; 75%: 0±3 a.u.; 100%: 0±3 a.u.; 20-min post: 1±2 a.u., $p < 0.001$ for all comparisons), higher values at mid-point compared to the last two quarters ($p < 0.001$), and higher values 20-min after exercise compared to the last two quarters ($p < 0.001$).

CONCLUSION: RPE increased while FS decreased across the different HIIE protocols, with no difference between male and female participants. Enjoyment did not return to baseline even after 20-min post exercise. The only major difference between protocols occurred in the first quarter, when SIT resulted in a higher RPE compared to HHIEL. Moreover, PACES and preference for the protocols did not vary between sexes and HIIE protocols.

ENDURANCE PERFORMANCE AND PSYCHO-PHYSIOLOGICAL RESPONSES TO SELF-PACED RUNNING EXERCISE FOLLOWING PARTIAL SLEEP DEPRIVATION

SOUISSI, W., HAMMOUDA, O., AYACHI, M., KHCHAREM, A., SOUISSI, M., DRISS, T.

PARIS NANTERRE UNIVERSITY

INTRODUCTION: Sleep is considered as an essential factor in daily life affecting physical, physiological and cognitive functions. It has restorative effects including immunity, endocrine function and cognitive performance. However, athletes are often exposed to sleep loss in response to psychological and physical stresses of heavy training and competition (1). Previous studies have shown a decrease in anaerobic performance following short-term exercise (2). However, few studies investigated the effects of partial sleep deprivation on aerobic performance, and have shown controversial findings (2). The present study aimed to investigate the effects of partial sleep deprivation at the beginning and the end of night on pacing, physical, psychological and physiological responses following self-paced running test.
METHODS: Fourteen runners (22±1 years, 73±6 kg, 177±4 cm) performed in a counterbalanced design 12-minute self-paced running exercise following two conditions: a control sleep night (CON) and a one night of partial sleep deprivation (PSD) separated by three days. Core temperature was measured before exercise. Speed, covered distance (CD), rating of perceived exertion (RPE) and cardio-respiratory parameters [Heart rate (HR), oxygen uptake (VO2), ventilation (VE), and respiratory exchange ratio (RER)] were assessed through exercise. Mood, vigilance and reaction time [simple reaction time (SRT) and choice reaction time (CRT)] were recorded before and after running test. Blood lactate concentration [La] was measured at the end of exercise.
RESULTS: Main significant interaction were observed for CD ($p<0.05$), speed ($p<0.05$), SRT ($p<0.05$), CRT ($p<0.05$), mood ($p<0.001$), RPE ($p<0.05$) core temperature ($p<0.01$) and VE ($p<0.001$).
Cognitive performance decreased following PSD compared to the CON condition ($p<0.001$) and VE was higher in PSD ($p<0.001$) However, most of cardiorespiratory parameters (HR, VO2, RER) and [La] were not affected by sleep deprivation ($p>0.05$). There was only a significant main effect of time in HR, VO2 and RER ($p<0.05$).
CONCLUSION: Pacing endurance performance, perceptual responses and ventilation seem to be impaired following PSD in the present study according to Fullagar et al. (2). However, most of cardiorespiratory parameters were unaffected. The increase of RPE following PSD in our study could explain the reduction of the total covered distance. Effective strategy should be introduced to overcome the deteriorations of physical performance and mood during self-paced exercise due to PSD.

EXERCISE DURING ISOLATION – DAILY VS. EVERY SECOND DAY EXERCISE PROTOCOLS AND THEIR (NEURO)PSYCHOPHYSIOLOGICAL EFFECTS

ABELN, V.1, KLEIN, T.1, WEBER, J.1, KRIEGER, S.2, CRUCIAN, B.3, SCHNEIDER, S.1,4

1INSTIT OF MOVEMENT/NEUROSCIENCES, GERMAN SPORT UNI COLOGNE 2 NASA JOHNSON SPACE CENTER, HOUSTON, TX, USA,3 SCHOOL OF HEALTH AND SPORT SCIENCE, UNI OF THE SUNSHINE COAST, MAROOCHYDORE, AUSTRALIA

INTRODUCTION: Not only astronauts in space, but also our population on Earth is faced with physical and social isolation to an increasing degree. Isolation has been shown to trigger divers psychological and physiological impairments (e.g. mood/affect, cognitive performance (1,2)) potentially resulting in decreased productivity, health and life quality and increasing health and economical costs. The present study aimed to compare exercising daily versus every second day in order to examine the effect and amount of exercise needed to counteract isolation-triggered impairments.
METHODS: Two groups of sixteen participants each were included in isolation campaign 3 (group C3: 30-day isolation, N=16, aged 36.3 years) and 4 (group C4: 45-day isolation. N=16, aged 39.4 years) of the National Aeronautics and Space Administration (NASA) within the Human Exploration Research Analog (HERA) at Johnsons Space Centre in Houston, Texas. Participants were asked to exercise on a daily basis during C3 and every second day during C4 alternating between bicycle ergometer and stretching and toning exercise. Tests included a blood draw in the morning (cortisol, brain-derived neurotrophic factor (BDNF)), the Positive And Negative Affect Scale extended (PANAS-X), and a rest-electroencephalography (EEG) recording (16-channel V-Amp system, Brain Products, Munich, Germany) and were performed prior, during, as well as after isolation. A control group (N=18, aged 32.8 years) completed the same protocol of C3, but under non-isolated conditions.
RESULTS: The control group did not show any significant changes. Both isolated groups showed a significant elevated cortisol level during isolation compared to pre and post ($p= .001$), while cortisol of group C3 was higher than group C4 ($p=.01$). BDNF did not change for group C3, but decreased significantly in C4 towards post isolation ($p< .05$). Preliminary cortical current density and frequency analyses of EEG revealed no significant changes for both groups. Negative affect differed between groups ($p= .01$), and slightly increased for group C4 during isolation. Positive affect decreased towards the end of isolation and post isolation for both groups ($p= .01$).
CONCLUSION: Isolation caused stress reflected by increased cortisol levels and decreased positive affect. Daily exercise seems to cause higher cortisol response, while it might prevent from disturbances of BDNF and negative affect. Future studies controlling for multiple stressors of space analogue missions are required to confirm the effects of different exercise protocols on neuro-psychophysiological health under isolated conditions.

EFFECTS OF ALTERATIONS IN VISUAL FLOW ON PHYSIOLOGICAL AND PSYCHOLOGICAL RESPONSES TO EXERCISE

ANDO, S., YASUKAWA, K., KOIKE, Y., KONNO, T., SUDO, M., OHKAWARA, K.

UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: It has been suggested that alterations in visual flow influence human locomotion (1). However, it is unclear as to whether and to what extent altered visual flow influences physiological and psychological responses to exercise. Recently, virtual reality exercise is advanced (2), which allows us to test the hypothesis that altered visual flow affects physiological and psychological responses to dynamic exercise. The purpose of this study was to clarify the effects of altered visual flow on physiological and psychological responses to exercise at the same intensity.
METHODS: The participants (n =18, 23.1±1.9yrs) cycled an ergometer at 80W for 5 min while watching the first-person images at three different speeds thorough VR goggles. The speed of visual flow corresponded to 7.5 km/h, 15 km/h, and 22.5 km/h. The order of speed was randomized in a counterbalanced manner, and participants completed three different speed conditions on the same day. Heart rate, oxygen intake, respiratory exchange ratio (RER), and cadence were continuously measured during exercise. Ratings of perceived exertion (RPE) were recorded immediately after exercise. Mood states were evaluated before and after exercise using questionnaires (3-5).
RESULTS: We observed no differences in heart rate, oxygen uptake, cadence, and RPE among different speed of visual flow. Speed of visual flow significantly affected RER ($P<0.01$). In mood states, speed of visual flow significantly affected vitality, pleasure, pleasantness, anxiety, and positive enrollment (all $Ps<0.05$). The participants exhibited positive mood states in the 22.5 km/h condition as compared with the 7.5 km/h condition (all $Ps<0.05$).
CONCLUSION: The present study indicated that faster visual flow induced positive mood states after exercise at the same intensity. The altered mood states are possibly ascribed to altered brain activity. Hence, exercise intervention using VR may be effective to improve mood states, particularly for individuals with mental illness.

THE IMPACT OF CAMERA STABILITY ON CYBER SICKNESS, PRESENCE AND PSYCHOPHYSIOLOGICAL RESPONSES DURING A VIRTUAL WALK IN NATURE

LITLESKARE, S., CALOGIURI, G.

INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Physical activity in natural environments (green exercise) is believed to provide greater health benefits compared to physical activity in built environments, but research in this area is limited by methodological issues. Immersive virtual environments based on modern virtual reality technology can potentially overcome some of these limitations by simulating green exercise in standardized laboratory conditions. Virtual green exercise might also increase intention to engage in actual green exercise and act as a supplement for people who are unable to visit natural environments. However, virtual reality is known to induce cyber sickness, which limits its application in green exercise research and highlights the need for scientific strategies to optimize virtual experiences.
METHODS: We assessed the impact of camera stability on cyber sickness, presence and psychophysiological responses to virtual green exercise. Fifty participants were assigned to watch one of two 9,5 minutes 360˚ videos characterized by either high or low camera stability. Both videos were presented using a head-mounted display and showed a first-person walk in a natural environment. The simulator sickness questionnaire (SSQ) and physical activity affect scale (PAAS) were administered before and after the videos. Heart rate (HR) was recorded during exposure to the videos, while presence, enjoyment, perceived environmental restorativeness (PER) and a dichotomous evaluation of cyber sickness were administered after.
RESULTS: Significantly less participants reported occurrence of cyber sickness after the high stability video compared to low stability. The total SSQ score was also lower after high stability, while levels of enjoyment where higher. The low stability video had a negative impact on all PAAS components, while these measures were unchanged after the high stability video. Video stability did not influence presence, PER or HR. SSQ score was significantly correlated with all PAAS components and enjoyment, but not with presence, PER or HR.
CONCLUSION: These findings demonstrate that high camera stability in 360˚ videos is crucial to reduce negative affective responses and both occurrence and severity of cyber sickness. The lack of positive impact on presence, PER, PAAS and HR suggest that other aspects of 360˚ videos must improve to create life-like virtual green exercise experiences.

ENDURANCE TRAINING IMPROVES SKELETAL MUSCLE MITOCHONDRIAL FUNCTION IN OBESE SUBJECTS

MAGNESA, B., COMELLI, M., MAVELLI, I., VACCARI, F., PASSARO, A., LAZZER, S., GRASSI, B.

UNIVERSITY OF UDINE

INTRODUCTION: The aim of this study was to evaluate the effect of the exercise on skeletal muscle mitochondrial function in obese subjects, considering the recognized alteration of mitochondria in obesity and the beneficial effects of exercise on oxidative and energy metabolism.
METHODS: Skeletal muscle biopsies were obtained from the vastus lateralis of healthy obese volunteers (age 38.03±8.56 years, BMI 35.57±4.29 kg/m2). Subjects (sedentary) underwent a supervised protocol consisting of 3 months of two different type of exercise training walking on a treadmill: i) low intensity endurance training, ET (60% VO2 peak) and ii) high-intensity interval training, HIIT (100% VO2 peak). Before and after the training period, biopsies were obtained using a microneedle (Histocore, 12 G), immediately frozen in liquid nitrogen and stored at -80°C until the moment of analysis by high-resolution respirometry (Oroboros-2k oxygraph). To measure mitochondrial respiration, a substrate-uncoupler-inhibitor-titration protocol was applied (1). Upon completion of the measurements, muscle fibers were

immediately homogenized and analyzed for citrate synthase (CS) activity by a spectrophotometric method (2). Further, the subjects performed an incremental test on the treadmill to obtain the whole body V'O2 peak. The V'O2 was measured breath by breath through the metabolimeter CPET, COSMED.
RESULTS: Maximal ADP-stimulated respiration sustained by complex I and II, of biopsies from twenty-seven subjects (13 men and 14 women) were measured and normalized for either wet weight or CS activity. Data showed a statistically significant improvement with respect to controls before exercise only in ET group. ADP-stimulated mitochondrial respiration resulted higher in ET group (7.83±3.36 pmol O2· s-1·IU-1) with respect to the controls (4.76±2.87 pmol O2· s-1·IU-1), while HIIT group was not significantly different from the controls (6.57±3.11 pmol O2· s-1·IU-1). Intriguingly, CS activity was not affected by neither exercise protocols. In fact, mean data from controls were 0.31±0.05 IU/mg protein, while after exercise were: 0.27±0.05 IU/ mg protein in ET group and 0.26±0.05 IU/ mg protein in HIIT group. The whole body V'O2peak is improved in both groups but significantly more in HIIT compared with ET (respectively 16% and 6%).
CONCLUSION: Overall, these data suggest that ET induced an improvement of mitochondrial function (ADP-stimulated respiration), while HIIT did not. No mitochondrial bioegenesis was hypothesized based on unchanged CS activity, suggesting that OXPHOS complexes activity/assembly regulation, or remodeling of mitochondrial inner membrane, could be triggered by ET in obese subjects. The whole body V'O2 peak is improved more in HIIT, suggesting a contribution of factors linked to central circulation more in HIIT than in ET beside mitochondrial factors.

INTERFERENCE EFFECTS IN CONCURRENT TRAINING - COMPARISON OF ENDURANCE EXERCISE AND HIGH INTENSITY INTERVAL TRAINING AFTER RESISTANCE EXERCISE -

SHIRAI, T., HANAKITA, H., TAKEMASA, T.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Concurrent training (CT) is combination of two different modes of training. Interference effect is induced by CT combined with resistance and endurance exercise, but that effect is not induced by CT combined with resistance exercise and high intensity interval training (HIIT). Therefore, there must be a conflict of molecular signal caused by different combination of CT. In this study, we focused on mechanistic target of rapamycin complex1 (mTORC1) which plays the central role of interference effect. The purpose of this study was to investigate interference effect of CT in skeletal muscle and its influence on molecular signals.
METHODS: 7 weeks of age male ICR mice were divided into 3 groups: Control (con), RE-EE (Resistance Exercise and subsequent Endurance Exercise), RE-HIIT (Resistance Exercise and subsequent HIIT). After 3-week training (3 times / week), mice were sacrificed and plantaris muscles were dissected out quickly from each mouse for the following analyses.
RE-protocol
The mice were positioned with their foot on a footplate (the ankle joint angle was positioned at 90°) in the prone posture. The triceps calf muscle was stimulated percutaneously with electrodes which were connected to an electric stimulator and isolator. The gastrocnemius muscle was isometrically contracted (10 times 3-s stimulation, with a 7-s interval between contractions, for 5 sets with 3-min inter-set intervals). The voltage (30 V) and stimulation frequency (100 Hz) were adjusted to produce maximal isometric tension.
EE-protocol
The mice were familiarized with running on a rodent treadmill at 10–20 m/min for 3 days prior to the experiment. After familiarization, they were placed on a horizonal treadmill and made to run for 30 min at a speed of 20m/min.
HIIT-protocol
Mice were performed a 20-s swimming exercise at most 10 times or until exhaustion, with a weight equivalent to 10% of their body weight. The weight tied at the proximal ends of their tails. After each swimming exercise, mice were landed from water, and a 10-s rest period was allowed. A barrel filled with water to depth of 60 cm was used for the swimming pool, and water temperature was maintained 30°C during the exercise.
RESULTS: We analyzed the changes in signal molecules. Protein expression levels of RAPTOR, which is one of the mTORC1 components, was increased in RE-HIIT group, but is not increased in RE-EE group. Protein expression revels of TSC2, which is thought to be a major reactor of interference effect, were unaltered in all groups.
CONCLUSION: We observed the difference in the expression levels of mTORC1 component by different combination of CT. These data suggest that RE followed by HIIT does not cause interference effect, whereas RE followed by EE does.

ELECTRIC PULSE STIMULATION PROTOCOL AS A MODEL OF RESISTANCE EXERCISE IN HUMAN MYOTUBES

VALERO, M., DELDICQUE, L., ZBINDEN-FONCEA, H.

UNIVERSITY FINIS TERRAE

INTRODUCTION: Electrical pulse stimulation (EPS) has been considered a useful method to investigate in greater detail and clarity the mechanisms related to the exercise-induced health benefits (1). Although there is some evidence about the effects of different myotubes stimulation protocols, not all the mechanisms involved in the adaptations to EPS are completely well-known. Previous studies have shown that mTORC1 signaling plays a central role in the regulation of protein synthesis and degradation (2). Therefore, this study aimed to determine the response to an acute and chronic EPS protocol as a model of resistance exercise in human myotubes. We hypothesized that phosphorylation of mTORSer2448 and S6K1Thr389 proteins would be an indicator of the activation of protein synthesis pathway induced by EPS.
METHODS: After cell differentiation, an intervention with EPS in two different protocols was used: The acute protocol consisted in a single intervention stimulating at 100 Hz, 15 V, 0.4 ms with 4 seconds of rest for 30 minutes. The chronic protocol consisted in a stimulation at 100 Hz, 15 V, 0.4 ms with a rest of 4 seconds for 30 minutes and during three consecutive days at the same time every day. In both protocols, once the last stimulation period was over, the plates were washed in sterile cold PBS and cell lysis performed 0, 1 and 3 hours after the intervention. The Western Blot technique was used to analyze the expression of mTORSer2448 and S6K1Thr389 proteins. All blots were analyzed using the ImageJ software. The phosphorylation ratios were calculated by dividing the phosphorylation levels by red ponceau. The sample considered a n=5 and the EPS and control groups were compared using an unpaired Student t-test.
RESULTS: The acute EPS protocol induced significantly activation of mTORSer2448 from 0 to 3 hours after intervention (60-90%;$p<0.05$) compared to control. The S6K1Thr389 activation increased at 1 hour after EPS ($p<0.05$) only compared to control. The chronic EPS protocol

did not induce an activation of mTORSer2448, but showed a greater activation of S6K1Thr389 at 1 and 3 hours after EPS (62-76%) compared to control ($p<0.05$).
CONCLUSION: These results suggest that the EPS at high frequency generates an activation of mTORSer2448 and S6K1Thr389 at different times after an acute electric stimulus. Furthermore, activation of mTORSer2448 and S6K1Thr389 was different after the chronic electric stimulus. This is in line with previous studies reporting that mTOR Ser2448 is activated during a relatively long period of time after a single episode of resistance exercise. However, this activation is decreased after training with the same intensity. Thus, a high frequency stimulus in vitro models could be similar to an anabolic response. The parameters of stimulation used in our research are useful for future studies intended to investigate the molecular responses of resistance exercise.

EFFECTS OF EXERCISE ON EXPRESSION OF MYOD、MYOGENIN、MEF2MRNA IN HINDLIMB-SUSPENSION RAT SKELETAL MUSCLE

WANG, Y.
SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: It is well established that MyoD、myogenin、MEF2mRNA elevates muscle protein synthesis in skeletal muscle.(1) However, the mechanisms by which MyoD、myogenin、MEF2mRNA are sensed in skeletal muscle are as yet unknown. (2)The primary aim of this study was to determine the model of weightlessness that was simulated in this study - hindlimb suspension in order to study the phenomenon of skeletal muscle atrophy caused by hindlimb suspension and molecular mechanism of the occurrence. A secondary aim was to establish endurance training model of exercise-induced MyoD, myogenin, MEF2mRNA change in the role of dystrophin.
METHODS: Skeletal muscle biopsies were obtained from Sprague-Dawley rats, weighing134.02g.They were randomly divided into 4 groups, control group (C, n = 7); treadmill group (E group, n = 7); suspension group (CU, n = 7); treadmill suspension group (EU, n = 7). Treadmill Group: the first 3 days, adaptive training, half an hour a day, and then 1.2KM / h, gradient of 5 , Every Monday to Saturday , a total of six days, an hour a day, breaks at weekend, trained a total of 8 weeks. Weighed once every week. suspension group: without any special treatment for 8 weeks, suspension for the 9,10-week.Treadmill suspension group: programmed by treadmill training group, then suspension for the 9,10-week.After 8-week treadmill training, taking blood tests of blood lactic acid; suspended after 2 weeks, HE for measuring cross-sectional area, Using RT-PCR method for measuring expression of MEF2mRNA , MyoD, myogenin mRNA.
RESULTS: Compared with the control group, the body weight of treadmill group reduced, there was significant difference in body weight of two groups of rats ($P<0.05$).. Hindlimb suspended for 2 weeks, compared with the suspension group, the decrease margin of gastrocnemius muscle wet weight and cross sectional area of treadmill suspension group is smaller than that in suspension group, and there was significant difference ($P<0.05$). After 8 weeks of treadmill training, compared with the control group, the expression of MEF2mRNA, MyoD and myogeninmRNA have risen, and there was significant difference ($P<0.05$).
CONCLUSION: These data suggest hindlimb suspension can cause reduction in body weight, muscle weight , cross-sectional area and the model of hindlimb suspension is successful. Treadmill exercise has some effect on prevention of muscle atrophy after suspension .And the trend of expression of MyoD and MEF2mRNA is similar, indicating the mechanism of these two factors in the fight against muscle atrophy is coordinated. The change of expression of these three factors before and after suspension also shows that they can be used as the molecular biology of muscle atrophy.

TIME COURSE EFFECTS OF VOLUNTARY RUNNING EXERCISE ON PROTEIN PRODUCTS OF IMMEDIATE EARLY GENES IN MURINE HIPPOCAMPUS

YOKOKAWA, T.1, HAYASHI, T.1, FUJITA, S.2
1: KYOTO UNIVERSITY, 2: RITSUMEIKAN UNIVERSITY

INTRODUCTION: Exercise is a potent physiological stimulus that improves diverse brain functions. However, the molecular mechanisms remain largely unclear. After neural activation, the expression of immediate-early genes (IEGs) is rapidly enhanced, and subsequently these protein products are induced. The protein products of IEGs are involved in neural activity dependent brain adaptations (1). Accordingly, exercise might induce the expression of IEG protein products. However, although exercise is reported to increase some IEGs such as brain-derived neurotrophic factor (BDNF) (2) and ΔFosB (3), exercise-induced expressions of other IEGs are unknown. Therefore, we investigated whether running exercise increases the IEGs protein products.
METHODS: Male C57BL/6J mice, 8 weeks old, were housed either under standard sedentary conditions (Sed) or with running wheel (Runner) for 1 day or 8 weeks. In order to evaluates whether running exercise increases IEG protein products, the protein expression levels of BDNF, FosB, ΔFosB, early growth response protein 1 (EGR1), protocadherin-8 (PCDH8)/Arcadlin, and activity-regulated cytoskeleton-associated protein (Arc) were measured by western blotting. Comparisons between the Sed and Runner were performed using two-tailed Welch's t-test.
RESULTS: The adipose tissue and body weight of Runner after 8 weeks, but not 1 day, was significantly lower than those of Sed. Single day exercise significantly upregulated the protein expression of Arc, FosB, EGR1 in hippocampus. On the other hand, the protein expression of BDNF, PCDH8/Arcadlin, FosB, and ΔFosB in hippocampus was significantly increased after 8-week running exercise.
CONCLUSION: These results suggest that running exercise upregulates protein products of IEGs at exercise-length dependent manner, which may mediate exercise-induced molecular adaptations and improvements of brain health.

AEROBIC EXERCISE TRAINING AND DEHYDROEPIANDROSTERONE ADMINISTRATION INCREASE TESTICULAR SEX STEROID HORMONES AND ENHANCE REPRODUCTIVE FUNCTION IN OBESE RATS

TATARA, K., SATO, K.
KOBE UNIVERSITY

INTRODUCTION: Obesity and type 2 diabetes are risk factors for coronary artery disease, hypertension, and hyperlipidemia as well as impairment of reproductive function. Consequently, it may cause erectile dysfunction, especially in men. In fact, individuals with higher

body mass index (BMI) tend to have a lower progressive sperm count and a higher morbidity rate of oligozoospermia compared to individuals with normal BMI. Moreover, obesity patients have a lower sperm amount, count, concentration and motility (1). Therefore, obesity is one of the risk factors of reduced number of motile sperm and increased occurrence of abnormal sperm form, and may cause impairment of reproductive function and erectile dysfunction. However, it is unclear that obesity-induced decline in sex steroid hormone level would cause impairment of reproductive function. Therefore, present study assessed the effects of chronic dehydroepiandrosterone (DHEA) administration and/or exercise training on testicular sex steroid hormone levels and reproductive function in high-sucrose induced obese rats.
METHODS: After 14 weeks of a high-sucrose diet, Wistar male rats were assigned randomly to the control, exercise training (running at 25 m/min for 1 h, 5 days/week), DHEA administration, and combined exercise training and DHEA administration groups (n = 7 each group). As a index of sperm maturation and protection, procathepsin L and GPx4 protein expressions were measured following the administration of DHEA and/or exercise training. ,Moreover, steroidogenesis-related enzyme expressions such as 3β-hydroxysteroid dehydrogenase (HSD), 17β-HSD, and 5α-reductase, which are enzymes for converting DHEA to testosterone, were measured.
RESULTS: Six weeks of DHEA administration and/or exercise training significantly increased plasma concentrations of DHEA and DHT and epididymis DHEA concentrations; however, the expression of steroidogenic enzymes, such as 3β- HSD, 17β-HSD, and 5α-reductase, did not change following any interventions. Procathepsin L expression, which involved sperm maturation, was significantly lower in the DHEA and combination groups, and GPx4 expression, which plays a role in protecting sperms from oxidative stress, was significantly increased in the DHEA administration group. Additionally, exercise training and/or DHEA administration-induced increase in GPx4 expressions were significantly correlated to the epididymis DHEA concentrations.
CONCLUSION: These findings suggest that exercise training and/or DHEA administration-induced increase in epididymis DHEA concentration may improve impairment of reproductive function in high-sucrose obese rats.

THE EFFECT OF ACUTE BOUT OF RESISTANCE EXERCISE ON SKELETAL MUSCLE PROTEIN SYNTHESIS DURING LOW AMINO ACID CONCENTRATIONS IN RAT SKELETAL MUSCLE.

SASE, K., KIDO, K., YOSHII, N., FUJITA, S.
RITSUMEIKAN UNIVERSITY

INTRODUCTION: Malnutrition causes skeletal muscle atrophy through the activation of protein breakdown by autophagy. Decrease in blood amino acid concentrations attenuate anabolic response by insulin in malnutrition. On the contrary, it is well established that resistance exercise (RE) increases protein synthesis and inactivates protein breakdown by autophagy. However, the effect of RE on skeletal muscle protein metabolism during low blood amino acid concentration is remain unclear. Therefore, the aim of this study was to investigate the effect of RE on muscle protein metabolism during acute fasting in rat skeletal muscle.
METHODS: Male Sprague-Dawley rats were divided into 2 groups: 12 h fasting group (C) and 72 h fasting group (F). The animals were sacrificed and muscle samples were taken at rest and 3 h after RE in both conditions. RE was induced by percutaneous electrical stimulation in right gastrocnemius muscle. Western blotting analysis was used to measure phosphorylation status of signaling proteins associated with mammalian target of rapamycin complex 1 (mTORC1) signaling proteins, and surface sensing of translation (SUnSET) method was used to measure protein synthesis. High performance liquid chromatography was used to measure plasma and muscle amino acid concentrations.
RESULTS: RE significantly phosphorylated p70S6K (Thr389) and rpS6 (Ser240/244) 3 h post-exercise as compared with resting condition in both groups, but F group showed lower magnitudes of phosphorylation as compared with C group. Muscle protein synthesis rate was significantly increased by RE in C group, but not in F group. 72 h fasting significantly decreased plasma total amino acids. However, RE restored amino acid concentrations in F group such that no significant group difference was observed. Plasma branched chain amino acid (BCAA) concentrations were not modified by 72 h fasting at rest, while RE increased BCAA concentrations only in F group. Muscle total amino acid concentrations were not affected by fasting or RE. Fasting significantly decreased muscle BCAA and essential amino acid (EAA) concentrations, but RE recovered them.
CONCLUSION: These data suggest that low blood amino acid concentrations after 72 h fasting might have suppressed RE-induced protein synthesis in rat skeletal muscle. Our data also suggest that decrease in muscle BCAA and EAA concentrations might be partly involved in the suppression of RE-induced protein synthesis.

IRISIN PREVENTS DEXAMETHASONE-INDUCED ATROPHY IN C2C12 MYOTUBES

CHANG, J.1, KONG, I.2
YONSEI UNIVERSITY WONJU COLLEGE OF MEDICINE

INTRODUCTION: Irisin is a myokine that leads to enhanced energy expenditure by facilitating the browning of white adipocytes, and contributes to glucose and lipid metabolism by improving glucose tolerance and insulin sensitivity. Regarding skeletal musculature, irisin is not only correlated with muscle mass and strength, but also promotes myogenesis and muscle growth. However, the protective role of irisin against muscular wasting remains unclear.
METHODS: To evaluate the expression and secretion levels of FNDC5/irisin in response to excitation-contraction coupling, we applied electrical pulse stimulation (EPS) separately to the myotubes as an exercise mimetic in vitro models. To determine the signaling mediators underlying myotrophic effects of irisin, we applied an in vitro model using recombinant irisin treatment on C2C12 myotubes. To identify anti-atrophic effect of irisin, C2C12 myotubes were subdivided into four groups as follows: i) control group incubated in serum-free medium containing antibiotics; ii) dexamethasone (DEX) group (100 μM); iii) irisin group (100ng/ml); and iv) DEX + irisin group (co-treatment). Here, we assessed the morphological differences, and evaluated the expression or activity levels of muscle growth related factors, forkhead box O (FoxO)-mediated expression of muscle-specific ubiquitin ligases, and 26S proteasome.
RESULTS: Irisin secretion was upregulated by EPS of an in vitro exercise mimetic model. Irisin treatment activated the phosphorylation of Akt and ERK1/2 and upregulated the protein expression of IGF-1 in dose- and time-dependent manners. Irisin effectively prevented the dephosphorylation of FoxO3α and upregulation of muscle specific ubiquitin ligases in the DEX-treated myotubes. The protective effect of irisin on DEX-mediated myotube atrophy were partially regulated by IGF-1-dependent signaling. Moreover, irisin treatment not only prevented the atrophic remodeling, but also attenuated the elevated proteasome activity in DEX-induced atrophic myotubes.
CONCLUSION: These results suggest that irisin, an exercise-induced myokine, may prevent glucocorticoid-induced muscle atrophy by inhibiting the FoxO-mediated ubiquitin-proteasome overactivity.

METABOLOME ANALYSIS OF SKELETAL MUSCLE BEFORE AND AFTER EXERCISE IN THOROUGHBRED HORSES

OHMURA, H., MUKAI, K., TAKAHASHI, Y., TAKAHASHI, T.

JAPAN RACING ASSOCIATION

INTRODUCTION: Thoroughbred horses are considered to be elite athletes because their mass-specific maximum oxygen consumption (VO2max) is approximately twice as high as that of elite human athletes. It has been reported that Thoroughbred horses experience severe hypoxemia and hypercapnia when exercising supramaximally, with PaO2 < 75 mmHg and PaCO2 > 50 mmHg. However, there is less information on muscle metabolism under exercise conditions which induce severe hypoxemia and hypercapnia. We hypothesized that such a severe exercise would be associated with marked changes in the metabolomics of the glycolytic pathway and citric acid cycle in fatigued muscle. To compare the muscle metabolomics in Thoroughbred horses before and after supramaximal exercise to fatigue.
METHODS: After warming up, 6 well-trained horses galloped on a treadmill at speeds that increased every 2 min until fatigued. VO2max was measured throughout exercise and biopsy samples for 92 metabolites were taken from the gluteus medius muscle before and after exercise. Data were analyzed with Welchs t-test (P<0.05).
RESULTS: Glucose 6-phosphate (320 vs. 2529 nmol/g), acetyl CoA (0.1 vs. 4.1 nmol/g), and succinic acid (77 vs. 197 nmol/g) were increased after exercise. However, glutamic acid (2488 vs. 713 nmol/g) and carnitine (5881 vs. 1474 nmol/g) were decreased after exercise. There are no changes in branched-chain amino acids.
CONCLUSION: Strenuous exercise to fatigue increased metabolites of the glycolytic pathway and the citric acid cycle in muscle. Some pathways did not change. Finding changes in the muscle metabolome may help clarify whether exercising muscles adapt to hypoxemia and hypercapnia.

PHYSICAL INTERVENTION AND MYO-MICRORNA EXPRESSION ON SATELLITE CELLS OF ELDERLY

PIETRANGELO, T., DI FILIPPO, E.S., BONDI, D., DORIA, C., JANDOVA, T., VERRATTI, V., FULLE, S.

UNIVERSITY OF CHIETI-PESCARA

INTRODUCTION: The muscle mass and function decrease during ageing. The skeletal muscle regeneration is promoted by adult muscle stem cells named satellite cells by physiological stimuli as exercise. The exercise could promote cellular and molecular adaptation mediated by exerkine modulation by the meaning of microRNA. The aim was to determine whether endurance and resistance training and neuromuscular electrical stimulation (NMES) affect muscle regeneration modulating microRNA in healthy elderly.
METHODS: The enrolled healthy male and female elderly were divided randomly into four groups: endurance training (ET n=8), resistance training (RT n=10), NMES (n=10) and control (n=12). All the tests were executed before (t0) and after (t1) the completion of the training protocols (8-12 weeks). The ET consisted on pedaling on a cycloergometer at constant intensity. The RT consisted of three series of 12 repetitions at increasing intensities. NMES (Genesy 1200 Pro; Globus) consisted on 18 mins with 40 passive isometric bilateral contractions set to a maximum-tolerable intensity. The maximum voluntary isometric contraction (MVC, assessed by dynamometry), the functional tests Timed Up-and-Go (TUG) and Five Times Sit-to-Stand Test (FTSST) were performed along with anthropometric measurements at to and t1. Myogenic precursor cells (MPCs) from the Vastus lateralis skeletal muscle of healthy elderly subjects were obtained using Tiny Percutaneous Needle Biopsy (1) at t0 and t1. The MPCs were analyzed for their myogenic characteristics as desmin+, differentiation (2,3). PureLink miRNA isolation kits were used for the miRNA extractions (Invitrogen). The miRNA relative quantification was carried out using the ΔCt formula. The specific miRNA sequence probes used have the following catalog numbers: hsa-miR-16-5p, #000391; hsa-miR-1, #002222; hsa-miR-206, #000510; hsa-miR-133b, #002247; hsa-miR-133a, #002246. miR-16 was the housekeeping gene.
RESULTS: We found significant effects for gender, time and time x protocol (p<0.01, p<0.001 and p<0.05) both for FTSST and TUG; with post-hoc ameliorating effect for RT (p<0.05) and NMES (p<0.001) on FTSST, and for ET (p<0.05) and NMES (p<0.001) on TUG. MVC increase from t0 to t1 with a time effect (p<0.01) and an interaction effect (p<0.01); post-hoc analyses revealed a specific positive effect for RT and NMES. We analyzed the myo-microRNA (miR133a, miR133b, miR-1, miR206) on MPC samples and found that they were specifically down- or up-regulated by the training typologies.
CONCLUSION: CONCLUSION: Medium-term physical intervention as endurance, resistance and even passive NMES significantly and specifically modified functional characteristics and myo-microRNA expression of MPCs of elderly. We should suggest to study the effect on combined training for a personalization of physical proposals.

CP-PM11 Obesity and weight loss

EFFECT OF AEROBIC EXERCISE ON PLASMA 3-HYDROXYISOBUTYRATE LEVEL IN OVERWEIGHT AND OBESE MEN - COMPARISON BETWEEN NON-INSULIN RESISTANCE, PRE-INSULIN RESISTANCE AND INSULIN RESISTANCE-

MYOENZONO, K.1, YOSHIKAWA, T.2, PARK, J.1, ZEMPO-MIYAKI, A.2, MIYAZAKI, T.3, HONDA, A.3, SHIMOJO, N.1, MAEDA, S.1

INTRODUCTION: Recent studies have shown that a higher circulating level of 3-hydroxyisobutyrate (3-HIB; a catabolic intermediate of valine), which is observed in obesity adults, causes insulin resistance (IR). Aerobic exercise training has been recognized as an established strategy for improvement of IR. We reported that the plasma 3-HIB level significantly decreased after 12-week aerobic exercise training in overweight and obese men at 23rd annual European College of Sport Science. However, the mechanism has not been elucidated. We compared exercise training effects with classified into three groups, according to baseline values of homeostasis model assessment for IR in the present study. Therefore, we investigated whether aerobic exercise training-induced changes in plasma 3-HIB level are influenced by the degree of IR in overweight and obese men.

METHODS: Twenty-one overweight and obese men (age, 49 ± 2 years; body mass, 80.8 ± 2.0 kg; body mass index, 27.7 ± 0.5 kg/m2; mean ± SE) completed a 12-week aerobic exercise training program under the supervision of exercise instructors (walk/jog, 60-80%HRmax, 30-60 min/day, 3 days/week) and were asked to maintain their dietary habits during the intervention. The participants were classified into three groups according to baseline values of homeostasis model assessment for IR: <1.6 (non-IR; n = 8), 1.6-2.5 (pre-IR; n = 8), and >2.5 (IR; n = 5). Plasma 3-HIB levels were measured before and after the exercise program.
RESULTS: Baseline plasma 3-HIB levels were 18.4 ± 2.0 μM in non-IR group, 24.2 ± 2.6 μM in pre-IR group and 31.7 ± 4.1 μM in IR group. Plasma 3-HIB level were significantly higher in IR group than in non-IR group (p = 0.014). After the 12-week exercise program, plasma 3-HIB levels were significantly decreased in IR group (31.7 ± 4.1 vs. 19.9 ± 2.6 μM; p = 0.014) and were not significantly changed in non-IR (18.4 ± 2.0 vs. 13.4 ± 2.9 μM; p = 0.238) and pre-IR (24.2 ± 2.6 vs. 20.0 ± 3.5 μM; p = 0.165) groups. Thus, plasma 3-HIB levels were significantly decreased after aerobic exercise training in IR.
CONCLUSION: These results suggest that the increased IR-caused elevation of plasma 3-HIB level was significantly decreased after the 12-week aerobic exercise training in overweight and obese men. Therefore, the 12-week aerobic exercise training contributes to reduce the risk of IR from the perspective of 3-HIB.

CHANGES AND FOLLOW UP IN FITNESS, FATNESS AND PERCEIVED HEALTH AFTER A BRISK WALKING PROGRAM ONCE AGE AND LEVEL EDUCATION ARE CONSIDERED IN MODERATELY OBESE WOMEN

GARNIER, S., HERBET, I., JOFFROY, S., THON, B., AUNEAU, G., MAURIEGE, P.

UNIVERSITÉ PAUL SABATIER

Introduction
Being regularly physically active is an important action that helps to promote health, quality of life, functionality and longevity. However, the most important determinant of a healthy long life "is where we sit on the social scale within our society" (Ball, 2015). The lower our socioeconomic position – the worse our health and the more likely we are to die prematurely (WHO, 2008). Moreover, although the physical activity practice rate declines with advancing age (Haskell et al., 2007), it is highly recommended at all ages (Nelson et al., 2007). Follow-up of an active walking program is a factor of improvements in cardiorespiratory fitness (CRF), weight and fat losses as well as in perceived health in moderately obese postmenopausal women (Garnier et al., 2013). However, is this type of program more effective for the highest social classes women and the youngest women? Will it not increase social inequalities in health?
The aim of this study is to determine the changes in CRF, body composition and perceived health after a brisk walking program and two years later once age and level education are considered.
Methods
72 sedentary and overweight-to-obese (mean body mass index, BMI = 30 ± 5 kg/m2) postmenopausal women (61±6 yr-old) were subjected to a 4-month endurance-training program (3 sessions of 45 min walking/week at 60 % of their heart rate reserve) and two years follow-up.
Following measurements were performed at both study-periods:
. CRF assessed by the 2-km walking test,
. Body weight, height and waist circumference measured using standardized procedures (Roussel et al., 2009; Garnier et al., 2013),
. Fat mass and lean mass determined by bioelectrical impedance
. Perceived health estimated by a questionnaire (six items) using a visual analogue scale (Garnier et al., 2013)
Results
Four months later and after two years, the decrease in body weight and fat mass, the increase in CRF, changes in waist girth and in three items of perceived health, physical fitness, sleep quality and general health (p<.001) were not significantly different once social classes and educational levels were considered. The changes in lean mass and in perceived healthy balanced diet were significantly different (p<.01) once age and level education were considered.
Discussion
Taking into account both age and education level, this active walking program does not show any sign of health inequalities in moderately obese postmenopausal women.

CARDIORESPIRATORY FITNESS ASSOCIATIONS WITH METABOLIC RISK FACTORS IN A COHORT OF 18-YEAR OLD ESTONIANS

MÄESTU, E., JÜRIMÄE, J., HARRO, J., LOIT, H.M., MÄESTU, J.

UNIVERSITY OF TARTU

INTRODUCTION: It is unclear whether cardiorespiratory fitness (CRF) remains associated with metabolic risk if controlled for central adiposity and other confounders. The aim of this study was to investigate the independent effect of CRF on metabolic syndrome risk factors in relatively homogeneous age group of young adults.
METHODS: In this cross-sectional study 828 participants (age 18±0.5-yrs; male=354) performed a cycle-ergometer test with progressively increasing workload until exhaustion and was defined as maximal power output (Wmax) and calculated for kg body mass (Wmax/kg). According to sex-specific tertile values of Wmax/kg, participants were divided into low fitness group (men ≤ 2.72 W/kg; women ≤ 1.94 W/kg), average fitness group (men 2.71-3.26 W/kg; women 1.95-2.24 W/kg), and high fitness group (men ≥3.27 W/kg; women ≥2.25 W/kg). Body mass index (BMI) was calculated based on body mass and height, and waist circumference (WC) was measured. Continuous metabolic syndrome risk score (MetS-score) was calculated as the sum of standardized scores of five metabolic syndrome risk factors, glucose, mean arterial pressure, low-density lipoprotein cholesterol, triglycerides and total cholesterol/high-density lipoprotein cholesterol ratio.

RESULTS: Low fitness group had higher values in all measured metabolic syndrome parameters, except for cholesterol parameters, compared to high fitness group. The unadjusted linear regression model indicated that CRF was negatively associated with clustered metabolic risk (β=-.116, p=.001). After the adjustment of smoking habits, sports training participation and waist circumference, the association between CRF and MetS-score slightly increased (β=-.126; p<.001). Participants in low fitness group were about 2.6 (95% CI 1.50-4.41; p = .001) and average fitness group were about 1.9 (95% CI 1.07-3.22; p = .028) times more likely to have high MetS risk compared to high fitness group after adjustment for potential confounders (smoking, sports training participation and WC).
CONCLUSION: Our results show that despite central adiposity being a strong predictor of metabolic risk and that CRF is also influenced by genetic factors, the independent effect of fitness significantly contributes to the metabolic syndrome risk score. Therefore, in the modern society where obesity and sedentary lifestyle are highly prevalent, it is highly important to improve CRF through regular exercise and everyday physical activity in young adulthood in every weight status group. Furthermore, the assessment of cardiorespiratory fitness could be a part of regular health monitoring system for higher self-awareness and for the prevention of the development of metabolic syndrome risk factors at an early stage of life.

EFFECT OF EXERCISE ALONE ON HEPATIC STEATOSIS: ARE BENEFITS SEEN BY META-ANALYSIS?

BAKER, C.J., MARTINEZ-HUENCHULLAN, S., D'SOUZA, M., JOHNSON, N.A., TWIGG, S.M.

UNIVERSITY OF SYDNEY

INTRODUCTION: The burden of non-alcoholic fatty liver disease (NAFLD) on health care systems is considerable and is set to grow with the globally increasing obesity prevalence [1]. Lifestyle interventions involving exercise and dietary modification have been shown to be effective in reducing NAFLD [2]. However, exercise may be more practical, as dieting often has high attrition rates and poor long-term maintenance of weight-loss [3]. Another consideration with the rising rates of NAFLD, and the expense and invasiveness of liver biopsy, is the need for biomarkers that correlate with changes in intrahepatic lipid (IHL) and allow assessment of the efficacy of therapeutic interventions. The primary aim of this study was to systematically review the effects of exercise without dietary intervention on NAFLD and examine the correlation between changes in IHL and metabolic markers.
METHODS: Online databases (AMED, Medline, Scopus, Psychinfo, Cinahl, EMBASE, Web of Science from the earliest record to October 2018) were searched by two researchers (CB and SH). Studies were included if: participants were adults; exercise intervention was greater than 4 weeks; no dietary intervention was carried out; and the effect of the intervention on IHL was quantified via MRI/MRS.
RESULTS: Of the 19,482 studies retrieved, 17 were included involving 447 participants. Exercise was found to have a beneficial effect on IHL levels without diet (-2.75%, -3.46 to -2.04) (mean, 95% Confidence Intervals). Aerobic exercise had a greater effect on IHL than combined modality exercise (-3.88%, -4.81 to -2.87% versus -1.37%, -2.67 to -0.07%, respectively). Pearson's correlations showed significant relationships between change in IHL and changes in weight (r =0.68 p<0.001), liver enzymes AST (r= 0.67, p=0.003) and ALT (r=0.85, p<0.001), and cardiorespiratory fitness (r= -0.81, p<0.001). No significant correlation was observed between changes in IHL and change in HOMA-IR, triglycerides, HDL-C, LDL-C or total cholesterol.
CONCLUSION: This systematic review found that exercise without dietary intervention can improve IHL. Furthermore, we found that reduction in body weight, ALT, AST and greater cardiorespiratory fitness are significantly correlated with less in IHL and may be useful proxies for quantifying IHL changes without invasive or expensive scans.

COMBINED ASSOCIATION OF CHRONOTYPE AND EXERCISE HABITS ON CENTRAL OBESITY IN MIDDLE-AGED AND ELDERLY JAPANESE ADULTS: THE WASEDAS HEALTH STUDY

ITO, T.1, KAWAKAMI, R.1, TANISAWA, K.1,2, USUI, C.1, QIWEI, Z.1, MIYAWAKI, R.1,3, ISHII, K.1, SAWADA, S.S.1, TORII, S.1,2, SUZUKI, K.1,2, SAKAMOTO, S.1,2, MURAOKA, I.1,2, OKA, K.1,2, HIGUCHI, M.1,2

WASEDA UNIVERSITY

INTRODUCTION: Although chronotype and lifestyle factors are independently associated with health outcome, knowledge on the combined association of chronotype and exercise habits on central obesity is limited. Therefore, the aim of this study was to investigate the combined association of chronotype and exercise habits on central obesity in middle-aged and elderly Japanese people.
METHODS: A cross-sectional study was conducted in 854 adults (574 men and 280 women), aged 40–87 years, who participated in the Waseda Alumni's Sports, Exercise, Daily Activity, Sedentariness, and Health Study (WASEDAS Health Study). Chronotype was assessed by the Japanese version of Morningness-Eveningness Questionnaire (MEQ). Based on MEQ-score, participants were categorized as being a morning type (MT: 59-86), neither type (NT: 42-58), or evening type (ET: 16-41). Visceral fat area (VFA) was measured using magnetic resonance imaging. Exercise habit was assessed by self-reported questionnaire. Sleep quality was assessed by the Pittsbergh Sleep Quality Index. Dietary intakes were assessed by a validated brief-type self-administered diet history questionnaire. We compared VFA between the groups with different chronotypes in each gender by analysis of covariance after adjusting for age, sleep quality, exercise habit, smoking, energy intake, and alcohol intake. The trend associations were assessed using multiple linear regression analysis.
RESULTS: Chronotype was classified as MT in 52.1%, NT in 44.6%, ET in 3.3% of men, and MT in 46.1%, NT in 48.9%, ET in 5.0% of women. Although there was no significant association between chronotype groups and VFA after adjustment for covariates (P for trend = 0.964), the interaction between gender and chronotype on VFA was significant (P for interaction = 0.007). As the result by gender, VFA on MT group was significantly higher than the other type groups in men (P for trend = 0.024), but VFA on MT group was significantly lower than the other type groups in women (P for trend = 0.002). There was significant interaction between chronotype and exercise habits in men (P for interaction = 0.037), but not in women (P for interaction = 0.944). In men without exercise habits, VFA on MT group was significantly higher than the other type groups (P for trend < 0.018), but not in men with exercise habits (P for trend = 0.963).
CONCLUSION: Our results suggest that MT was associated with lower VFA in women regardless of exercise habits, but was associated with higher VFA in men without exercise habits.

EFFECTS OF TIME RESTRICTED FEEDING (16/8) ON ENERGY EXPENDITURE, BODY COMPOSITION AND PERFORMANCE

HAUPT, S., GADELMEIER, Y., WACHSMUTH, N., SCHMIDT, W.

UNIVERSITY OF BAYREUTH

INTRODUCTION: Due to increasing overweight and obesity, fight against this trend becomes more important. Nutrition plays a crucial role as it becomes one of the major risk factors not only for the development of obesity, but also its associated diseases belonging to the metabolic syndrome. Therefore, many different diets especially those leading to an effective reduction of body fat while fat-free mass remains constant were discussed in the literature. One of them – with increasing interest on it in the recent years – is intermittent fasting (IF). One subcategory of IF is time restricted feeding where eating ad libitum is allowed for 4-14h followed by a consecutive fasting period. Postulated benefits to this diet are body weight management and positive health related effects, which are rarely investigated. Therefore, the aim of the study was to investigate the effects of a 16:8 hours IF-form (16h fasting; 8h eating ad libitum) on body composition, energy metabolism, endurance performance and physical activity.
METHODS: 11 female participants (age: 22 ±3y, height: 1.65 ±0.06m, weight: 63.1 ±7.3kg), with an average BMI of 23 ±2kg/m2 and a body fat percentage of 31.5 ±3.5%, switched their diet for 5 weeks to a 16:8 IF cycle. Food intake was allowed in an 8-hour period, followed by 16h fasting. Body composition was determined using bio-impedance analysis, the physical activity was determined with an ActiGraph (wGT3X-BT). The energy intake was logged by the participants. Endurance performance and the resting metabolic rate (RMR) were measured by spiroergometry. Data collection took place before, during and 6 weeks after the intervention.
RESULTS: Energy intake and physical activity during the fasting period remained constant. Body weight decreased by 1.9 ±2.0% ($p<0.05$), body fat by 6.3 ±4.0% ($p<0.01$) and visceral fat by 6.5 ±4.4% ($p<0.01$). The fat-free mass, in contrast, remained unchanged (43.4 ±3.5kg before and 43.4 ±3.2kg after IF). RMR did not change under time restricted feeding (normal diet: 1754 ±520kcal/d; IF: 1789 ±346kcal/d). However, a change in the metabolism of the substrates could be determined. Thus, 34 % more fats were metabolized after IF (normal diet: 57 ±26g/d; IF: 76 ±23g/d) under resting conditions, while carbohydrates decreased by 18% (normal diet: 203 ±66g/d; IF: 167 ± 45 g/d). The endurance performance was not affected by the diet, the maximum oxygen uptake remained constant.
CONCLUSION: In contrast to many other diets, it was possible to prevent the degradation of the fat-free mass, whereas a reduction in body fat, in particular the health-related visceral fat, could be measured. Even 6 weeks after the fasting period, there was no yo-yo effect – weight loss was persistent. Therefore, IF seems to be an effective way to fight obesity and overweight without decreasing physical performance. For more detailed insights into the effects on metabolism, body composition and endurance performance, however, further investigations with a larger cohort of subjects are needed.

ENERGY REPLACEMENT DIMINISHES THE POSTPRANDIAL TRIGLYCERIDE-LOWERING EFFECT FROM ACCUMULATED WALKING IN POSTMENOPAUSAL WOMEN

NAGAYAMA, C.1, YAMAMOTO, R.1, NAMURA, S.1, HAMADA, Y.1,2, FUJIHIRA, K.1,2, TAKAHASHI, M.3, BURNS, S.F.4, THACKRAY A.E.5, STENSEL, D.J.5, MIYASHITA, M.1

1: WASEDA UNIVERSITY , 2: JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE , 3: WASEDA UNIVERSITY , 4: NANYANG TECHNOLOGICAL UNIVERSITY , 5: LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Immediate dietary replacement of an acute exercise-induced energy deficit offsets the postprandial triglyceride (TG)-lowering effect of exercise in young boys and middle-aged men (1, 2). It is unclear whether these findings are observed with different patterns of exercise and in older adults. The present study examined the effect of multiple short bouts of exercise, with and without dietary replacement of the exercise-induced energy deficit, on postprandial TG in older women.
METHODS: Seventeen postmenopausal women (mean ± S.D. age 70 ± 3 years, body mass index 23 ± 3 kg/m2) underwent three, 8-hour laboratory-based trials in a random order: 1) control, 2) accumulated walking and 3) accumulated walking with energy replacement. During the control trial, participants rested for 8 hours. The accumulated walking trial comprised twenty 1.5 min bouts of brisk walking performed at a pre-determined self-selected pace (4.1 ± 1.0 km/h) with 15 min seated rest between walks (gross energy expenditure: 625 ± 112 kJ). In each trial, participants consumed a standardised breakfast (0800, 0 h) and lunch (1100, 3 h). The breakfast in the accumulated walking with energy replacement trial included replacement of the same energy deficit induced by exercise. Venous blood samples were collected fasted and at 2, 4, 6 and 8 h after breakfast.
RESULTS: There was no difference in fasting concentrations of TG among trials (1.06 ± 0.60 vs 0.95 ± 0.58 vs 1.03 ± 0.57 mmol/L: control, accumulated walking and accumulated walking with energy replacement respectively). Time-averaged postprandial serum TG concentrations over 8 hours were lower after accumulated walking than control and accumulated walking with energy replacement (1.46 ± 0.93 vs 1.71 ± 1.01 vs 1.60 ± 0.98 mmol/L respectively, main effect of trial: $P = 0.022$). There was little difference between control and accumulated walking with energy replacement.
CONCLUSION: Replacing the energy expenditure induced by accumulating 30 min of brisk walking in short (1.5 min) bouts diminishes the postprandial TG-lowering effect in postmenopausal women. This underscores the importance of maintaining an energy deficit induced by exercise to augment the reduction in postprandial TG (3) even when exercise is accumulated in short bouts during the day.

THE CHALLENGES OF MEETING ENERGY NEEDS - A CASE STUDY OF A SEMI-PROFESSIONAL FEMALE JIU-JITSU ATHLETE

HAUDUM, J.

DEPARTMENT OF SPORT AND EXERCISE SCIENCE, UNIVERSITY OF SALZBURG

INTRODUCTION: This case study aims at examining the challenges of a Jiu-Jitsu athlete (female, 31 yrs, 173 cm, basal weight 89.8 ± 0.5 kg) to meet daily energy and nutrient requirements. The athlete has a long experience in the sport and won several medals at international championships. She is competing in the open weight class (> 70 kg), hence does not have to cut weight prior to competition. As a semi-professional athlete she is practicing a day-time job with high activity level. Training sessions usually follow in the evening on weekdays and in the morning on weekends with one rest day (usually Sunday). She presented herself with sings of stagnation in performance and complained about an increase in body weight and body fat. She was interested in receiving nutrition counseling. The goal was to

analyse her energy requirements for both training and her day-time profession and evaluate whether her energy intake (EI) meets the needs. Because, due to work, time for food intake is restricted to only a few short 20-minute-windows during the day and sometimes is omitted when she is running late with appointments, we expect a concentration of EI in the second part of the day, i.e. after work, when there is more time for eating.
METHODS: For a thorough analysis of EI, the athlete completed a seven-day food diary with additional digital photography using a cell phone camera. To measure energy expenditure (EE) during the day, especially during her day-time job, she wore an activity sensor (movisens MOVE II, Germany). To measure her resting metabolic rate (RMR), an indirect calorimetry was done (COSMED, Italy). Skinfold measurements (sum of seven, according to the ISAK protocol (SS7)) and a bioelectrical impedance analysis (BIA) were performed as well. A compete blood test was requested also.
RESULTS: Values of a complete blood test showed all values within normal ranges, including those usually linked to iron deficiency. Body fat measurements provided a SS7 of 160.5 mm. Indirect calorimetry showed an RMR of 2670 kcal. The nutritional assessment suggested the daily EE exceeded EI. Diet during the day was generally poor with a high consumption of energy dense foods with low nutritional value. Distribution of the EI during the day confirmed a high concentration in the later second half of the day.
CONCLUSION: The athlete clearly underestimated her energy needs. Besides an energy deficit, the even distribution of meals during the day seems to be a challenge. The constantly low EI in combination with a concentrated EI intake prior to bed time highlight the challenge of coordinating a sporting career, a day-time job and proper nutrition when basic knowledge is missing. Furthermore, it highlights the issue of low energy availability in sports. Education and training of the athlete on energy needs, nutrient timing and nutrition quality as well as proper time management have been initiated.

EFFECTS OF RAPID WEIGHT LOSS ON IMMUNE FUNCTION IN COLLEGE JUDO ATHLETES

HIRAOKA, H., HANAOKA, Y., KIMURA, F., SHIMIZU, K., SUZUKI, N., WATANABE, K.

UNIVERSITY OF TSUKUBA[*].WASEDA INSTITUTE FOR SPORT SCIENCES[*][*].JAPAN INSTITUTE OF SPORTS SCIENCES[*][*][*]

INTRODUCTION: The purpose of this study was to investigate the effects of weight loss in athletes during training camp on salivary secretory immunoglobulin A (SIgA) as an index of immune function.
METHODS: Object: Fourteen college judo athletes were recruited in this study, and divided into two groups: weight loss group (n = 7); and control group (n = 7). Judo training camp was performed for 5 days.
Survey contents: Saliva samples from each subject were collected and the level of SIgA secretion was measured by enzyme-linked immunosorbent assay (ELISA). Body weight, profile of mood states (POMS), and subjective fatigue and symptoms of dehydration were measured.
RESULTS: 2% weight loss was found in weight loss group during training camp. The rate of change in salivary SIgA secretion rate was significantly decreased by 51% in the weight loss group during training camp. In addition, total moods score in POMS in the weight loss group was significantly
increased after training camp(pre; 9.9 ± 4.4, post; 19.4 ± 6.7). Subjective fatigue were significantly increased, with no significant differences observed between the two groups.
CONCLUSION: These results suggest that 2% rapid weight loss might induce a decrease in salivary SIgA secretion and change mental condition in judo athletes.

CP-SH08 Teaching and coaching effects on children

EFFECTS OF LONG-DISTANCE RUNNING IN SCHOOL PHYSICAL EDUCATION CLASSES WITH A FOCUS ON COMPETITION

MATSUMOTO, Y., SAITO, K.

HIROSHIMA UNIVERSITY

Introduction
In the Japanese course of study for physical education classes, long-distance running is indicated as one of the contents students should engage in physical education classes. Therefore, in most Japanese physical education classes in schools, students run for long distances. However, Japanese students tend not to have a positive attitude toward long-distance running in physical education classes. To address this difficult situation, many studies on long-distance running in physical education classes have been conducted in Japan. However, most of them focus on improving students' records. In other words, little is known about the effects of long-distance running in school physical education while focusing on competition (Takashima et al., 2017). The purpose of this study was to analyze the effects of long-distance running in school physical education classes with a focus on competition. Considering the purpose of the study, we set the following research question: Do participants' attitudes toward long-distance running improve when they engage in long-distance running in school physical education classes with a focus on competition?
Methods
The participants of this study were 72 third year junior high school students, consisting of 41 boys and 31 girls. A questionnaire was developed for this study based on Koiso et al. (2018), conducted as pre- and post-tests. This questionnaire included Likert items based on a 4-point scale and open-ended questions. The questionnaire was given to participants at the beginning and at the end of the learning unit on long-distance running. By analyzing the results of the pre- and post-tests, we examined whether the participants' attitudes toward long-distance running improved after long-distance running in school physical education classes focusing on competition.
Results
The results of the questionnaire survey indicated that there was a statistically significant difference ($p < 0.01$) between the pre- and post-test for long-distance running physical education classes with a focus on competition due to factors of "engagement." On the other hand, there was no statistically significant difference between the pre- and post-test for factors of "achievement," "collaboration," "favorability," and "unpleasantness."
Conclusion

Long-distance running in school physical education classes with a focus on competition is effective for helping students to develop a positive attitude toward long-distance running.

PHYSICAL ACTIVITY, PHYSICAL EDUCATION AND THE WATER IN WHICH WE SWIM

SPACEY, H.L., HUGHES, R., BROPHY, S., STRATTON, G.

SWANSEA UNIVERSITY

Introduction
Physical activity (PA) has numerous positive effects on health and wellbeing during adolescence but engagement remains low (Foster et al., 2017). Females are repeatedly reported as achieving lower levels of PA than males, with this finding being replicated in physical education (PE) participation. Recommendations urge that more attention should be paid to specific barriers faced by adolescent girls (Martins et al., 2014). The aim of this study was to investigate barriers to engagement with 13-15-year-old girls who were not currently taking part in PE lessons.
Methods
This paper applies a feminist lens to explore the shared narratives surrounding PA and PE. Focus groups were studied using theories of self-objectification (Fredrickson and Harrison, 2005) and normative social behaviour (Rimal and Real, 2005) and draws on previous works in PE and gender (Scraton, 1992).
Results and Discussion
Girls discussed a number of barriers to taking part in PE including; negative treatment by peers, constant messages of physical inferiority and inequalities in accessing activities due to gender bias (Beasley, 2013). Girls were aware of the health benefits of PA but did not feel others expected them to be physically active and most girls did not prioritise PA in daily living. When active, girls chose to be in private spaces to avoid the gaze of others and negative body appraisals (Prewitt, 2013). In public spaces, girls experienced stigmatization, cat-calling and risked being filmed on social media apps while active. When faced with these daily realities, is it any wonder girls aren't engaging in PA and PE?

THE MOTOR PROFICIENCY ASSESSMENT USING THE BRUININKS-OSERETSKY TEST, SECOND EDITION AT CZECH SCHOOL CHILDREN

ŠEFLOVÁ, I., KALFIRT, L., INDRÁCKOVÁ, K.

TECHNICAL UNIVERSITY OF LIBEREC

Introduction: A sufficient level of movement competence which is indicated by motor coordination and development of fundamental movement skills is a significant health and psychosocial factor. A lower level of movement competence in childhood is reflected in physical activity participation and engagement in physical activity later in life (Loprinzi et al. 2012).
The Bruininks-Oseretsky, 2nd version, test is considered the most comprehensive diagnostic tool. It is used in the field of psychomotricity diagnostics in the Czech Republic. However, there are no Czech normative criteria. The aim of this pilot study was to estimate a cross-cultural validity of the Bruininks-Oseretsky Test of Motor Proficiency, 2nd version in a sample of czech school children.
Methods: The research sample was made of 83 school children (43 girls and 40 boys) of average age 10.15 ± 1.66 years (7 – 13 years old). For the estimation of a motor proficiency we used the Bruininks – Oseretsky test, 2nd version - complete form with German normative criteria. In the area of fine and gross motor development we evaluated 4 motor area composites (fine manual control, manual coordination, body coordination, strenght and agility) with 8 subtest comprised of 53 items. Scores for the test are reported as total point scores, standard, scale scores and percentile ranks.
Results and discussion: The results of our tested group show that the group's motor proficiency is in the lower part of the average level in the area of total motor composite (standard score - total motor composite = 46.4 ± 11.8, mean = 50, SD = 10). On average, the weakest performance was recorded in the area of fine manual control. The group's results were below average in this area (standard score = 42.1 ± 12.1). More in-depth analysis showed that the weakest subcomponent of the area of fine manual control was fine motor precision (scale score = 10.1 ± 5.5, mean = 15, SD = 5). The second weakest result of the area of motor composite was manual coordination (standard score = 45.3 ± 11.4). The rest of components in composite score profile was analyzed and placed in the average level. The group's most successful area was the component concerning strength and agility (standard score = 51.2 ± 12.9).
Conclusion: 7 children from the overall number of 82 children were diagnosed with severe insufficiency in some of the subcategories, which requires necessary motoric intervention. 13 children were diagnosed with mild insufficiency, which requires motoric intervention aimed at specific area of motoric behavior. Total below average results of our sample group can be related to testing in the geographic area with the lower level of socioeconomic status.
for evaluative purposes.

EMPLOYING AN INTERDISCIPLINARY TEACHING APPROACH TO PHYSICAL EDUCATION ON CHILDREN'S ENGLISH AND MOTOR PERFORMANCES IN ELEMENTARY SCHOOL

CICHY, I., WAWRZYNIAK, S., PAWLIK, D., RUBAJCZYK, K., KORBECKI, M., ROKITA, A.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION IN WROCLAW

INTRODUCTION: The aim of this paper is to investigate the effects of PE program integrated with EDUballs on
childrens English skills, and development of selected motor coordination skills and fundamental movement skills in elementary school in Poland.
METHODS: The research used a one-year pedagogical experiment method and a rotation groups technique (experimental and control groups: E1-C2 and C1-E2). The study involved 28 children (12 girls and 14 boys) from second grades in elementary school in Wrocław, Poland. The research were carried out in 2017/2018 school year. The study obtained the written consent from the University Ethics Committee, the school's headmaster and children's parents/guardians. The academic and motor performances of children were assessed in October, February and June. After the second measurement (in February 2018), there was a change of the experimental and control groups.
English achievements were tested by a Cambridge Tests for elementary school children. Selected motor coordination (temporal-spatial orientation) was diagnosed by Smart Speed System and fundamental movement skills by the Test of Gross Motor Development (TGMD-2).
The experimental factor was a PE program integrated with English language plays, exercises, and games with EDUballs. The goals of the program for both groups were based on school's PE program according to the core curriculum of the Polish National Ministry of Education.
The experimental groups followed a standard PE program enhanced with EDUballs twice per week for 50-60% of teaching time, the remaining time (40-50% of teaching time) teacher followed the aims and goals of PE program but without EDUballs. In the experimental groups, PE activities were based on earlier prepared lesson plans, integrated with English language exercises. The plans were prepared in accordance with the school's cycle of weekly activities and each day's topic
The control group followed the same standard PE program but without EDUballs.
RESULTS: Children in experimental and control groups (E1-C2 and C1-E2) improved fundamental movement skills and temporal-spatial orientation, however there was no significant differences between experimental and control groups. However, children participating in PE with EDUballs (E2) demonstrated significantly higher English achievements than control group (C2).
CONCLUSION: Participation in PE integrated with EDUballs had a significant influence on children's English achievements. Integrating PE with academic content with EDUballs had also a positive influence on the motor performances of the children. The interdisciplinary model for PE with EDUballs may facilitate teaching-studying-learning process in elementary school.

ANALYSIS OF THE TECHNICAL INTERACTIONS OF A BASKETBALL TRAINING COACH: A CASE REPORT STUDY

NIETO GUISADO, A., IBAÑEZ SERGIO, J., SOLANA-TRAMUNT, S., MORALEZ, J.

FPCEE BLANQUERNA RAMÓN LLULL UNIVERSITY

INTRODUCTION: The role of the coach represents a fundamental part in learning any sports, so the study of their behaviors aroused great interest in this specific area. The coach has very important responsibilities, since he guides the child physically, mentally and emotionally from childhood (Saiz y Calvo, 2010). The role of the coach in the base categories must be that of an educator, thus differentiating from the expert role of the high-performance coach(Pérez Turpin, 2003).The aim of this study was characterize the technical interaction carry out by a female basketball coach.
METHODS: The design of this research is classified as an exploratory study, with quantitative, descriptive and observational methodology. A basketball coach was analyzed in his team of players formed by 10 girls between 11-12 years. The behavior of the coach was evaluated through the Arizona State University Observation Instrument (ASUOI) test(Cushion y Jones, 2001). This instrument analyzes 14 behavioral variables. For the study of these variables, 18 training sessions, 165 tasks in the 2014/2015 season, were analyzed. First, a descriptive analysis of each variable was done before identifying the autocorrelation of each and persistence of these over time.
RESULTS: The results showed that the coach finds more useful positive actions such as Modeling Positive, Hustle and Praise, which spend more time in the Pre-instruction, and they are more directed to individual players. Autocorrelations were found in technical interactions: tiempo de pre-instrucción; número de información concurrente; número de ayuda física; número de modelado positivo y negativo; número de alabanza y regaño; y tiempo de organización. At the same time, the coach tries toinsist in the technical interactions in which autocorrelations are meaningful. Regarding the type of autocorrelation, it is important to highlight that most of the techniques interactions have positive autocorrelations, so that large values of these interactions correspond to large values in the 16 delays analyzed.
CONCLUSION: Regarding the descriptive analysis, we obtain the average result of interventions to individual players is greater than the group or team; there is not many interrogations and physical aids; greater use of positive than negative modeling; more repetitions of praise and bustle than the scolding; more use of pre-instruction time than organization; and scarce use of silence and other behaviors recorded by the variables analyzed. The coach is the central figure in the sports environment, assuming the responsibility of teaching his experience to the players.

LOAD CHARACTERISTICS OF SMALL-SIDED GAMES IN SOCCER FROM THE VIEWPOINT OF IMPROVEMENT IN PHYSICAL FITNESS: THE EFFECT OF RULE CHANGES

TSUDA, R.

KANAZAWA MEDICAL UNIVERSITY

Introduction

The majority of studies on ball games in PE classes have focused on techniques and tactics, factors determining skill levels (Griffin et al., 1997). However, under the current Japanese physical education curriculum, it has been necessary to enhance physical fitness even in sport and dance exercises (Mext, 2018). From this point, it is important to examine the load characteristics of ball games in terms of physical fitness. This study focused on small-sided games, commonly used as teaching material in soccer classes, and examined the effects of rule changes on load characteristics from the viewpoint of improvement in in physical fitness.
Methods
Eight elementary school children participated in the present study. They played in two types of small-sided games: a normal game (coat area : 30m length ×20m width, player number : 4vs4, goal : normal, game time 5min) and 4goal game(coat area : 30m width×20m length, player number : 4vs4, goal : 4goal, game time 5min). The ratio of appearance time of each movement speed(zone1: 0〜6.0km/h, zone2: 6.0〜10.0km/h, zone3: 10.0×16.0km/h) and the total movement distance were measured using a GPS(GPSPORTS, 4assist Co., Ltd). In addition, questionnaires were conducted regarding technical skills, physical fitness and psychological aspects.
Results
The main results were as follows.
1) There was no significant difference in the ratio of appearance time of each movement speed during the games.
2) There was no significant difference in the total movement distance.
3) The results of questionnaire showed partial significant differences in technical and psychological aspects.
Conclusion
These results suggest that the load characteristics of the small-sided game from the viewpoint improvement in physical fitness could not differ greatly when the rule of the game are changed. In addition, 4 goal game might be available to appreciate to the fun of the game.

COGNITIVE AND MOTOR EFFECTS OF A 9-WEEK TRAINING INTERVENTION WITH COMPLEX COORDINATION EXERCISES AND CONCURRENT COGNITIVE TASKS IN CHILDREN AGED 6 TO 10: A PARTLY RANDOMISED, CONTROLLED STUDY.

SANTNER, A., KOPP, M., FEDEROLF, P.A.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Through physical exercise interventions (acute and chronic cardiovascular and motor coordination training) cognitive abilities in children tend to improve – training with higher cognitive load may increase impacts. This study investigated effects of a concurrent motor coordination and cognitive task training in children aged 6 to 10 under repetitive conditions (Kort.X program). It was hypothesised that a group receiving concurrent motor coordination and cognitive task training (A) will gain higher attentional and motor agility benefits than groups participating in a multi-sport program without (B1) and with concurrent cognitive task trainings (B2).
METHODS: In a partly randomised, controlled intervention study, children aged 6 to 10 (n=443) completed the German Motor Performance Test 6 – 18, the TDS Match-4-Point Test, the d2 R test of attention and the Kasel-Concentration-Task for children aged 3-8 years. After pre-testing (T0) a 9-week-intervention-period followed; after this period post-testing (T1) and after another 3 months retention-testing of regular school education were performed (T2). Due to different amounts of regular sport lessons, participants were divided into two groups (1st-/2nd-grade and 3rd-/4th-grade) and analysed separately with Kruskal-Wallis test and Bonferroni correction (effect sizes calculated via Cohen´s r).
RESULTS: Children in 3rd- and 4th-grade classes receiving the Kort.X program (group A) showed significant increases in focused attention compared to the control groups B1 and B2 with small and medium effect sizes (A-B1: r=0.20; A–B2: r=0.35). Significant differences in long-term development were observed between group A and B2 (medium effect size, r=0.32) and B1 and B2 (r=0.24). Students of 1st- and 2nd-grade classes showed no differences in attentional development during the intervention phase but significant increases post-intervention for groups who concurrently trained cognitive tasks (A-B1: r=0.27; B2-B1: r=0.25). Agility performance in jumping sideways significantly increased for all students of group A during and after the intervention period and overall with medium and high effect sizes. There were no differences in flexibility, balance, reaction time and cardiovascular ability for any of the groups. However, a significant decreasing performance for group A between pre- and post-test was detected for sit-ups, push-ups and sprinting, but differences disappeared in the retention test.
CONCLUSION: A 9-week concurrent training of complex coordination exercises and cognitive tasks under repetitive conditions led to significant improvement of agility performance in children aged 6 to 10 and lasting effects in focused attention abilities in children aged 8 to 10 years. Additional training of cognitive tasks may provoke significant attentional effects post-intervention in younger children (6 – 8 years).

THE EFFECTIVENESS OF PSYCHOLOGICAL WORKSHOPS FOR COACHES IN INCREASING WELL-BEING OF CHILDREN PRACTICING SOCCER AND GYMNASTICS

WILCZYNSKA, D., HOPKINS, W.G., LYSAK-RADOMSKA, A., PODCZARSKA-GLOWACKA, M., SKROBOT, W., KRASOWSKA, K., LIEDTKE, E., PIETRZAK, S.

UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Coach workshops based on seven principles (inspiration, explanation, expectation, support, reward, appreciation, growth and winning) enhance the sport experience of adult athletes (Poczwardowski et al., 2016). Here we report effects of such workshops with coaches of child athletes.
METHODS: Study participants were coaches of 57 9- to 12-year old girls (practicing gymnastics) and boys (practicing soccer). Three coaches of 28 children attended three workshops over 12 weeks, while a control group of 5 coaches of 29 children attended no workshops. Measures of well-being and psychomotor performance were taken on the children before and after the intervention; differences in mean changes between intervention and control groups were adjusted for baseline, standardized, and assessed with magnitude-based inference.
RESULTS: There were clear substantial effects of the workshop on motivation averaged across several dimensions (girls, large, most likely beneficial; boys, moderate, likely beneficial), on dispositional coping (girls, small, likely beneficial), on state anxiety (girls, small, possibly

harmful; boys, small, possibly beneficial), and on a decision test (girls, trivial-small, possibly harmful; boys, small-moderate, very likely beneficial).
CONCLUSIONS: The workshop was generally beneficial, but the unclear and potentially harmful effects could be coach- or presenter-specific and need to be investigated further in a larger sample of coaches before the workshop is recommended for implementation.

DIFFERENCES IN SPLIT-TIMES AND STROKE COUNTS BETWEEN JUNIOR AND SENIOR KAYAKERS DURING CANOE SLALOM COMPETITION

HIRANO, T.1, KASHIWAGI, Y.2,3, HAKAMADA, N.4, SOMA, M.5,3, FUNATO, K.1

1: NIPPON SPORT SCIENCE UNIVERSITY, 2: SENSHU UNIVERSITY, 3: GRADUATE SCHOOL OF HEALTH AND SPORT SCIENCE, 4: JAPAN INSTITUTE OF SPORTS SCIENCES, 5: JUMONJI UNIVERSITY

INTRODUCTION: In canoe slalom competition, the results are assessed for both their technique in passing through hung gates in both up- and down-stream directions as well as the time taken to complete the course. According to previous studies, race analysis during canoe slalom has only been performed for senior kayakers by Hunter et al. [1, 2], and there have been no studies on performance improvement of junior kayakers. In addition, it is unclear whether there are differences between the split-times of senior and junior competitors as for up- and down-stream gates, respectively. Therefore, the purpose of this study was to clarify the difference between split-times and stroke counts during canoe slalom competition between junior and senior kayakers.
METHODS: We analyzed 10 junior and 12 senior male kayakers. Video was shot at the 2016 Canoe Slalom Japan Cup in Tokyo using three separate video cameras (Sony Handycam HDR-PJ800, Sony inc., 60fps). QuickTime (Apple Inc.) was used for footage analysis. The split-time between each gate was defined as the time from when a kayaker's trunk passed through a gate to the point at which the next gate was passed. The split-time at the upstream gate was calculated as the time from the moment the kayaker's trunk passed the gate to when the gate passed across the gate after the end of the turn. In addition, the number of strokes between each gate was counted from the first post-gate paddle entry to the final paddle entry prior to passing the next gate. An unpaired Students t-test or Welchs t-test was performed to compare split-times and stroke numbers between junior and senior kayakers, and difference where considered to be statistically significant at $P < 0.05$. Statistical analysis was executed using SPSS (IBM SPSS Statistics Version 24, SPSS Inc.).
RESULTS: The official race times of the senior kayakers were significantly shorter than those of their junior counterparts ($P < 0.001$). The split-times of the senior kayakers were shorter than those of the juniors between most gates ($P < 0.05$ to 0.001), but there was no difference in the number of strokes taken between both groups when paddling downstream. In addition, the split-times of the senior at upstream gate with a turn to the upstream were significantly shorter than those of the juniors ($P < 0.05$ to 0.001), and the number of strokes taken by senior kayakers tended to be lower at that time ($P < 0.05$).
CONCLUSION: The results of this study suggested that acquisition of paddling technique to improve the distance of each stroke as well as improvement of upper-limb muscular strength are important factors for improving the performance of junior kayakers.

PEAK HEART RATE ANALYSIS IN AMATEUR SURFERS DEPENDING ON THE NUMBER OF MANEUVERS CARRIED OUT ON A WAVE.

SANTISTEBAN, A.

DEUSTO UNIVERSITY

INTRODUCTION: The physiological requirements of athletes during a surfing session have been analysed (Furness et al., 2018), although we can find very little information about physiological responses of these athletes while they are riding a wave. However, some research has focused on assessing heart rate (HR) and the time spent on each action, making differences between paddling, waiting time, paddling to catch the wave and surfing (Secomb, Sheppard, & Dascombre, 2015). The aim of this research was to evaluate the HR response related to the number of maneuvers (Nm) within each wave as a changing stimulus.
METHODS: Twenty amateur (with a minimum of three training sessions per week) surfers took part in the research (23,85 ± 6,65 years; 175,86 ± 8,02 cm; 70,30 ± 6,18 kg). Two tests were carried out by the athletes: 1) an incremental paddling test in an adapted ergometer for surfers, recording the peak heart rate (HRpeak); and 2) a 60 min surfing session, where the highest waves were about 1,5 meters and the smallest ones were around 1 meter. In this second test, apart from HR, the Nm while riding different waves were measured. The whole session was recorded, and the camera was synchronized with the HR monitor at the beginning of the test.
RESULTS: A total of 255 waves and 603 maneuvers were analyzed. 27 waves with a single maneuver and 84.81% of the HRpeak, 76 waves with two maneuvers and 88.65% of HRpeak, 72 waves with three maneuvers and 90.89% of HRpeak, 45 waves with four maneuvers and 93.49% of HRpeak, 3 waves with five maneuvers and 93.37% of HRpeak, 1 wave with six maneuvers and 95.88% of HRpeak and 1 wave with seven maneuvers and 94.62% of HRpeak. Significant differences in HR were found ($p<0.01$) among waves with different Nm. The Cohen´s d effect size was used to compare the waves on which surfers made 1 or 2 maneuvers, 3,84 % (d= 0.68) differences in HR were found, between 2 and 3 maneuvers, the difference in HR were 2,24 % (d= 0.40), and to finish, between 3 and 4 maneuver waves, 2,61 % (d= 0,54) differences in HR were found. Nevertheless, after 4 maneuvers in a wave, the Nm do not increase HR significantly.
CONCLUSION: The results show that the more maneuvers carried out on a wave, the more the athletes' HR increased to a certain threshold. These findings suggest that the session´s internal load is higher on the athletes that make more maneuvers, however it appears to be a threshold, where HR seems not to increase anymore.

DIFFERENCES IN CHANGES OF PHYSICAL FITNESS AND ANTHROPOMETRICS OF FEMALE AND MALE RECRUITS DURING MILITARY SERVICE

SANTTILA, M., PIHLAINEN, K., KYRÖLÄINEN, H.

NATIONAL DEFENCE UNIVERSITY

INTRODUCTION: It is generally known that gender differences exist between male and female recruits in physical fitness. Military tasks with heavy loads are particularly more demanding for female recruits (Nindl et al 2017). Several studies have shown that the physical fitness of recruits increases during military service, especially among recruits with overweight as well as lower aerobic and muscle fitness (Mikkola et al. 2012). The purpose of the present study was to investigate possible differences in the changes in physical fitness and anthropometrics of female and male recruits during Finnish military service from 2005 to 2015.
METHODS: The data consisted anthropometrics (body mass, height, waist circumference) and physical fitness tests (12-min running test, standing long jump, 1-min sit-up and push-up) conducted in the beginning and at the end of individual military service. A total number of 249279 healthy male and 3875 female recruits (approx. 20 yrs.) voluntarily participated in the fitness tests during their military service, which varied between 5.5 to 11 months. Differences between male and female recruits were adjusted by service time and branch, age group, and measured variables of the first tests.
RESULTS: Mean height, BM, BMI, and WC of male and female recruits did not change during their military service. However, female recruits decreased their WC by 2.5 cm (95% CI 2.0-2.8 cm) more than males. Mean distance in 12-min run of male recruits increased by 4.3% (2461 vs. 2565m, p≤ 0.001), and in female by 2.3% (2187 vs. 2234m, p≤ 0.001). Improvement in running test was 158m (95% CI 142-173m) higher in male than female recruits. The mean number of push-ups in male recruits increased by 15.9% (32 vs. 37 reps/min, p≤0.001), and in females by 18.5% (21 vs. 25 reps/min, p≤0.001). Male recruits improved their push-ups by 5 reps/min (95% CI 4.7-5.8) more than females. Mean number of sit-ups in male recruits increased by 10.2% (37 vs. 41 reps/min, p≤0.001), and in females by 9.0% (34 vs. 37 reps/min, p≤0.001). Improvement in sit-ups was 2 reps/min higher (95% CI 2.8-2.8) in males than females. Mean distance in standing long jump increased by 1.0% both in male (2.18 vs. 2.20 m, p≤0.05) and female (1.76 vs. 1.78, p≥0.05) recruits. Improvement in male recruits was 0.12m (95% CI 0.11-0.13m) higher than females.
CONCLUSION: This study demonstrated that almost all of the measured physical fitness variables of male and female recruits improved during the military service using same training program. No changes were observed in body anthropometrics. However, improvements in aerobic capacity and muscle fitness were higher in male recruits compared to females. Therefore, it can be concluded that adaptations to military training may differ between sexes and more specialized training programs for female recruits are warranted.

ACUTE EFFECTS OF 300 SECONDS OF STATIC AND DYNAMIC STRETCHING ON FLEXIBILITY, MUSCLE EXTENSIBILITY AND THE SHEAR ELASTIC MODULI OF THE GASTROCNEMIUS MUSCLE-TENDON UNIT

MATSUO, S.1, SUZUKI, S.2, IWATA, M.1, TSUCHIDA, W.1, ASAI, Y.1

1: NIHON FUKUSHI UNIVERSITY, 2: ASAHI UNIVERSITY

INTRODUCTION: Static and dynamic stretching are commonly performed as a part of a warm-up exercise routine. Previous studies have reported that static stretching increases range of motion (ROM), passive torque at pain onset (PT) and muscle extensibility, and decreases passive stiffness and the shear elastic modulus (Matsuo et al., 2015, Nakamura et al., 2013, Nakamura et al., 2017). Moreover, other studies have reported that dynamic stretching increases ROM, PT and the shear elastic modulus (Mizuno et al., 2016, Pamboris et al., 2018). However, it is still unclear which stretching method has the greatest effects on flexibility, muscle extensibility and the shear elastic moduli. Therefore, the current study sought to compare the effects of static and dynamic stretching on these measurements.
METHODS: In this randomized crossover trial, seven healthy young men undertook a total of 300 s of static and dynamic stretching (10 sets of 30-s static and dynamic stretching) of the right plantar flexors. The two stretching sessions were performed on separate days, and the order of stretching method was randomly determined. The criterion measures were the ROM of dorsiflexion, PT, passive stiffness, the shear elastic moduli of the belly and the aponeurosis of the medial gastrocnemius muscle (MG), and myotendinous junction (MTJ) displacement. Each measurement was obtained using an isokinetic dynamometer, ultrasound shear wave elastography, and B-mode ultrasonography immediately before and after both stretching sessions (Matsuo et al., 2015, Nakamura et al., 2013, Nakamura et al., 2017).
RESULTS: Both stretching methods significantly increased ROM and PT, and significantly decreased passive stiffness, the shear elastic moduli of the belly and the aponeurosis of MG after each stretching session. Only static stretching significantly increased the MTJ displacement. Moreover, the decrement in the shear elastic modulus of the aponeurosis of MG after static stretching was significantly greater than that after dynamic stretching.
CONCLUSION: Both stretching methods improved flexibility, including ROM, PT and passive stiffness. However, static stretching was associated with greater improvement of the shear elastic modulus of the aponeurosis of MG (as an index of the aponeurosis stiffness) and MTJ displacement (as an index of muscle extensibility) compared with dynamic stretching. Therefore, the current results suggested that static stretching is more effective for improving muscle extensibility and aponeurosis stiffness compared with dynamic stretching.

EFFECT OF NUMBER OF EXERCISE TRAINING SESSIONS ON ENOS EXPRESSION

HIEDA, M., TAKAKURA, H., KATO, H., IZAWA, T.

TOYOHASHI UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Nitric oxide (NO), which is formed by the constitutive endothelial nitric oxide synthase (eNOS), plays an important role in vascular health. Previous studies show that eNOS may be associated with the mitochondrial function (1). Exercise training increases eNOS expression and NO production (2). Nowadays, our leisure time physical activity decreases and any exercise training program must be effective and efficient to promote physiological health. The aim of this study was to investigate the effect of the number of exercise training sessions on eNOs expression.
METHODS: Male Wister rats were randomized into three groups, control (CN) group, TR1 group and TR2 group. The TR1 group was trained once a day whilst the TR2 group was trained twice a day, every other day. After nine weeks, the animals were euthanized, their aortas were analyzed for eNOS expression by western blotting. COX IV expression in the aorta was analyzed by western blotting as a mitochondrial biogenesis marker.
RESULTS: Compared with the control group, the RT2 group showed higher levels of eNOS protein expression ($p<0.05$). RT2 tends to higher levels of eNOS protein expression than that of the RT1 group ($p=0.06$). The COX IV expression level was higher in the RT2 group than in the other two groups ($p<0.05$).
CONCLUSION: The results of this study suggested that exercising twice in one day is more effective than once a day for vascular health.

THE EFFECT OF STATIC STRETCHING PROGRAM ON PASSIVE AND ACTIVE PROPERTY OF GASTROCNEMIUS MUSCLE TENDON UNIT

NAKAMURA, M., SATO, S., HIRAIZUMI, K., KIYONO, R., FUKAYA, T., NISHISHITA, S.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: Static stretching (SS) program is usually performed to increase range of motion (ROM) and decrease the muscle stiffness. The previous study reported that SS program decreased the muscle stiffness (1), whereas there was no significant change in muscle stiffness after SS program (2). In addition, the study reported that SS program increased the muscle strength (3), whereas there was no significant change in muscle strength after SS program (4). Therefore, the aim of this study was to investigate the effect of SS program on muscle stiffness and muscle strength of gastrocnemius muscle.
METHODS: Twenteen young-male were participated in this study. Dorsiflexion ROM, muscle stiffness, isometric and isokinetic plantarflexion strength, muscle thickness, and fascicle length of medial gastrocnemius muscle were assessed by dynamometer and ultrasonography before and after 6 week SS program. 120 seconds of SS were performed every three times per week, meaning every two to three days using stretching board. The significant differences between before and after SS program were determined using a paired t-test.
RESULTS: The dorsiflexion ROM was increased, whereas muscle stiffness was decreased after 6 week SS program. However, there were no significant changes in isometric and isokinetic plantarflexion strength between before and after SS program. In addition, there were no significant difference in muscle thickness and fascicle length between before and after SS program.
CONCLUSION: Our results suggested that 6 week SS program using stretching board caused to increased ROM and decrease muscle stiffness, whereas there were no changes in muscle strength and muscle architecture.

REDI (ROBUST EXPONENTIAL DECREASING INDEX): AN ADAPTIVE AND ROBUST METHOD TO COMPUTE ACCUMULATED WORKLOAD

MOUSSA, I., LEROY, A., SAULIÈRE, G., SCHIPMAN, J., TOUSSAINT, J.F., SEDEAUD, A.

INSTITUT NATIONAL DU SPORT ET DE LEXPERTISE DE LA PERFORMANCE

INTRODUCTION: In the literature, there are different ways to analyze the training load. They all have their advantages but none is robust in the face of the missing data that are so legion in high-level sport. The purpose of this work is to define a new index (REDI, Robust Exponential Decreasing Index) as an alternative to overcome missing data limiting the application of present load indices.
METHODS: 200 cumulative workloads were simulated in two ways (Gaussian and uniform distributions) to test the robustness and flexibility of the REDI, as compared to classical methods (ACWR, EWMA). Theoretical properties have been highlighted especially about the decreasing parameter.
RESULTS: The REDI allows to consistently analyse a load monitoring with up to 30% missing data. The relative average error between a full data set and a 30% incomplete data set is low (range: 2.39% - 7.48%). Adjusting the decreasing parameter allows to choose the weight to give to each daily workload. The REDI makes it possible to explicitly consider periods when data collection cannot be done (weekends, international training sessions, national selections, injuries...) with no effect on the computation of the index.
CONCLUSION: REDI allows to analyze training load even in the presence of missing data and periods. It is flexible for all situations, depending on a specific coefficient for each event. The robust and adaptable nature of the REDI positions it as a credible alternative for the analysis of the training load.

INTRA- AND INTERRATER RELIABILITY OF RANGE OF MOTION TESTS USING A DIGITAL INCLINOMETER OR A MEASURING TAPE AND INERTIAL MOTION CAPTURE

MALTRY, L., HOLZGREVE, F., BRINKBÄUMER, M., DZIUBA, A., FRIEBE, D., KLEMZ, S., SCHMITT, M., THEIS, A.L., TENBERG, S., OHLENDORF, D.

GOETHE UNIVERSITY FRANKFURT

INTRODUCTION: Range of motion (ROM) tests are frequently used in medical assessment using cost effective measurement systems like digital inclinometers (DI) and measuring tapes (MT). A more precise kinematic measuring system for scientific analysis is inertial motion capture. Therefore, the aim of this study is to compare these methods in terms of intra- and interrater reliability.
METHODS: 22 (10m/12f) sport students without injuries participated in the study (age 25.3±1.94 years; BMI 21.9±2.0 kg/cm²).
Each subject performed three ROM tests, which were measured either via MT or DI, in a randomized order. Fingertip-to-floor test (FtF) and Lateral Inclination (LI) were tested using a MT, while the Retroflexion (RF) of the trunk modified after Janda was evaluated holding a DI on the subjects sternum. Simultaneously, data of each test was collected with an inertial motion capture system (Xsens MVN Biomech Link).
Two trained raters carried out the measurements independently of each other. For intrarater reliability subjects performed each exercise 20 times of which only the last five trials were analyzed to control for acute effects. For interrater reliability the second rater carried out five additional trials. The assignment of the two raters to the subjects was organized alternately.
RESULTS: Intrarater reliability showed substantial to almost perfect results for all the described tests and all measuring instruments. The comparison of the left and right side varies only slightly (ICCs: FtF: MT: 0.95-0.97; IMC: 0.85-0.94; LI: MT: 0.89-0.98; IMC: 0.88-0.96; RF: DI: 0.89-0.91; IMC: 0.96-0.97; (ICCs include both raters and left and right side for LI)).
Similarly, interrater reliability was also consistent, showing substantial to (almost) perfect results for all tests and all measuring systems (ICCs: FtF: MT: 0.92; IMC: 0.91; LI: MT: 0.94(right)-0.96(left); IMC: 0.80(left)-0.95(right); RF: DI: 0.84; IMC: 0.90).
CONCLUSION: Intra- and as well interrater reliability was predominantly (almost) perfect for the evaluated tests, which represent global movements in the three body axes. As the results for the DI and the MT are as good as those of the IMC, their use in medical assessment is justified. DI and MT are reliable and cost effective measuring systems for visualization of individual training progress in the evaluated ROM tests. IMC on the other hand provides more detailed information on selected body segments and joints.

CP-MI15 Ageing

PHYSICAL ACTIVITY TO SLOW DOWN THE AGEING PROCESS; A LARGE CROSS-SECTIONAL POPULATION STUDY (THE LIFELINES COHORT)

VAN DE ZANDE, S., DE VRIES, J., VAN DEN AKKER-SCHEEK, I., ZWERVER, J., SMIT, A.

UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: Physical Activity (PA) has substantial health benefits and is important in chronic diseases, which have been associated with elevated levels of Advanced Glycation End products (AGEs). An association between PA and AGEs has been reported. We aimed to investigate the relationship between PA and AGEs, measured by skin-autofluorescence (SAF), in healthy subjects and patients with chronic diseases.
METHODS: Personal, PA and SAF data of adult (>18 years) participants from the LifeLines-database were used. BMI, blood pressure, smoking and hours of watching television were retrieved as confounders. Healthy individuals and patients with diabetes, renal and/or cardiovascular diseases were included. AGEs were measured non-invasively using a validated SAF device (AGE-reader, DiagnOptics). PA was assessed using the validated SQUASH questionnaire.
RESULTS: Data of 72586 participants (healthy n=66335, chronic disease n=3701) were analysed. The healthy population was significantly younger (44 ± 12 yr) and had significantly lower SAF-values (1.90 ± 0.42 AU) compared to the diseased population (age 56 ± 12 yr; SAF-value 2.29 ± 0.51 AU). Multivariable regression analysis showed that age, PA, BMI and smoking are significant predictors of SAF in the healthy population. Increase in hours of PA per week associated with lower SAF.
CONCLUSION: This study demonstrates an inverse relation between PA and AGE-accumulation. Since SAF-value normally increases with 0.02 AU/year of age, the observed difference of 0.06 AU in SAF for physically active persons might be translated in 3 years health-profit. So, PA may reduce AGE-accumulation, resulting in health benefits and prolonged longevity.

DO STEP LENGTH AND STEP FREQUENCY ASSOCIATE TO VO2 AND WALKING EFFICIENCY IN ELDERLY ACTIVE WOMEN?

BLASCO-LAFARGA, C., CORBI, J., ROLDÁN, A., GARCÍA-LUCERGA, C., CORDELLAT, A., MONTEAGUDO, P., BLASCO-LAFARGA, N.M.

UNIVERSITY OF VALENCIA, SPAIN

INTRODUCTION: Gait analysis is a quick and cheap way to get insights of quality of life, neural adaptability, cognition and physical function, as well as disability and life expectancy in elderly. Gait improvement is also an important issue in health interventions. Since cardio-respiratory fitness has already shown to be strongly associated to gait speed with aging [1], this study aims to analyze the association between basic gait kinematics, cardio-respiratory fitness and walking efficiency in a group of healthy elderly women.
METHODS: 17 active women (70.83±4.69 years, 61.68±6.72 kg) undergoing EFAM-UV© multicomponent training program [2], were assessed for body composition, health parameters and PAR-Q questionnaire, followed by the 6-minute walking test (6MWT). Based on Punt et al. [3], 10% under the 6MWT speed was considered a Comfortable Walking Speed (CWS). 48-72 hours later, women performed a standardized walking treadmill test at three speeds: 15%CWS (SWS) [3]. Optogait system (Microgate, Italy) registered Step length (SL) and frequency (SF), while K4B2 gas analyser (Cosmed, Italy) provided VO2 at the CWS (VO2CWS) and supra (VO2SWS), this latter only in 7 women who were able to keep high speed in safe conditions. Heart Rate (HR) was continuously recorded during both tests (RS800, Polar Electro, Finland) jointly with pre-post lactate (Lactate Pro, Japan) and RPE. Resting HR was registered previous to the test, with women

seated, closed-eyes and silence condition. Energy Expenditure Index (EEI) was further calculated for walking efficiency: (Walking HR - Resting HR) / Walking Speed [4].
RESULTS: Women confirmed to be well trained (VO2CWS: 21.50±3.82 mil/min/Kg; 6MWT: 578.06±45.56 m, 1.61±0.13 m/s) and efficient (EEI= 0.67±0.14 ua). Although the sample reduced to 7 women, SL and SF increased from CWS to SWS (127.85±12.54 vs 142.14±10.42 cm and 131.35±6.83 vs 143.02±9.57 Hz) and were negatively associated, but only in SWS (r=-0,811; p=0.027). 6MWT was strongly associated to VO2CSW (r=0.735, p=0.004) and SF_CSW (r=0.603; p=0.029), but not to VO2SWS, nor to any other gait parameter or EEI.
CONCLUSION: VO2 confirmed to be associated to gait speed and step frequency in active elderly women. Cadence more than step length seems the important resource to keep gait velocities in these healthy women, although gait training programs should maintain step length and use different intensities. Walking efficiency showed no association, may be because this parameter is useful mainly in moderate efforts, and well-trained women in the study performed the tests at high intensities. New protocols and larger samples will help fitness professionals and general practitioners to improve gait specific training and testing.

STUDY ON THE BODY SHAPE, LOWER LIMB STRENGTH, FLEXIBILITY AND BALANCE ABILITY OF ELDERLY RESIDENTS IN BEIJING

SUN, J.

BEIJING INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Beijing entered the aging city as early as 2000.However, there were few studies on the physical fitness of the elderly aged 70 and over in China during the 20 years. The purpose of this study was to clarify the physical fitness and gender differences of the elderly residents in Beijing, and provide data reference for the future research .
METHODS: A total of 1090 elderly from 6 districts of Beijing participated in the study. they were classified into 6 age and gender groups ,that is,Male 65-59 years old(M1group,n=171), 70-74 years old(M2 group,n=107),75-79 years old (M3 group,n=87),Female 65-59 years old(F1 group,n=387), 70-74 years old(F2 group,n=214),75-79 years old (F3 group,n=124).Height, weight, waist circumference, hip circumference, 30-sec chair stand test(CS-30),chair sit-and-reach test(CSR),and 8-foot up-and-go test(UG) were tested. Derived indices included body mass index（BMI） and waist-to-hip ratio(WHR).
RESULTS: BMI results, M1 group 25.9±2.9kg/m2, M2 group 26.0±3.2 kg/m2, M3 group 25.3±3.0 kg/m2; F1 group 25.9±3.5 kg/m2, F2 group 25.6±3.2 kg/m2, F3 group 26.3 ± 4.4 kg / m2. WHR results , M1 group 0.92±0.05 , M2 group 0.91±0.06 , M3 group 0.91±0.06, F1 group 0.87±0.06 ,F2 group 0.88±0.07 ,F3 group 0.88±0.06. The average WHR of males in all ages was higher than that of female elderly, and the difference was statistically significant (P<0.05). CS-30 results, M1 group 17.9±5.6, M2 group17.1±4.6,M3 group 16.1±4.6 , F1 group16.9±4.2 , F2 group16.6±4.6, and F3 group 16.2±4.5 . The average number of CS-30 of male and female elderly decreased with age. CSR results, M1 group 1.9 ± 13.3 cm, M2 group -1.9 ± 11.9 cm, M3 group - 2.9 ± 9.7 cm; F1 group 6.7 ± 9.5 cm, F2 group 4.8 ± 9.6 cm, F3 group 1.5 ± 10.4 cm. The average CSR in male and female elderly decreased with age. The average CSR in all age groups was lower than that in women, and the difference was statistically significant (P<0.05). UG results,M1 group 6.1 ± 1.5 s ,M2 group 6.4 ± 1.4 s , M3 group7.1 ± 1.7 s , F1 group 6.2 ± 1.5 s, F2 group 6.3 ± 1.2 s, and F3 group 7.4 ± 2.6 s. The average number of UG for male and female elderly increased with age.
CONCLUSION: From the body shape indicators, according to the current Chinese adult weight judgment (WS/T428-2013) criteria, the elderly in all ages in the study were in the overweight range. According to the value of WHO recommended standard WHR, the elderly in the study were all central obesity levels. The problem of overweight and obesity among the elderly in Beijing, which required urgent attention and active intervention. From the strength, flexibility and balance of the lower limbs, the male and female elderly in the study decreased with age. From the perspective of gender differences, the lower limb strength and balance ability of male and female elderly were not much different, while the flexibility of male elderly was significantly worse than that of female elderly.

HANDGRIP STRENGTH AMONG MANUAL WORKERS IN THEIR FIFTH AND SIXTH DECADE OF LIFE

NORHEIM, K.L., SAMANI, A., BØNLØKKE, J.H., OMLAND, Ø., MADELEINE, P.

AALBORG UNIVERSITET

INTRODUCTION: Natural ageing is associated with a progressive loss of muscle strength. Indeed, starting from the sixth decade of life maximal strength decreases by about 10-15% per decade (1). Physical activity is an important aspect of everyday life and manual workers often need to complete physically demanding tasks that require high degrees of force (2). We investigated the association between handgrip strength (HGS) and age by comparing absolute HGS values among older manual workers with available normative values from the general British population.
METHODS: Maximal isometric HGS was measured in male manual workers aged 50-59 yrs (n=44) and 60-69 yrs (n=45). The largest value out of three trials separated by two minutes was used. Normative HGS data from twelve British studies (3) of participants aged 50-59 yrs (n=3743) and 60-69 yrs (n=3947) were used to compare absolute values. Z-scores were calculated to show the number of standard errors between the reference population and the collected sample means.
RESULTS: Among manual workers, maximal HGS was 52.5±8.1 kg and 51.0±8.9 kg, whereas normative HGS values were 46.2±9.8 kg and 42.3±8.6 kg for those aged 50-59 yrs and 60-69 yrs, respectively. HGS was significantly higher among manual workers aged both 50-59 yrs (z-score 4.25, p<.001) and 60-69 yrs (z-score 6.81, p<.001). The mean difference in HGS between manual workers and the general population for those aged 50-59 yrs was 6.3 kg and for 8.7 kg for those aged 60-69 yrs.
CONCLUSION: The present study suggests that manual workers are stronger than the general population in terms of HGS. Interestingly, HGS also seems to be preserved to a larger extent among manual workers compared with the general population. Further studies should investigate whether other markers of physical performance follow the same trajectory and follow-up studies should investigate how much of the effect is due to training effects and how much is due to selection processes.

RELATIONSHIP BETWEEN HANDGRIP STRENGTH, SIT-TO-STAND PERFORMANCE, AND OTHER COMMON PHYSICAL VARIABLES IN HEALTHY, ACTIVE, OLDER CZECHS

STEFFL, M., OMCIRK, D., MALECEK, J., STASTNY, P., VETROVSKY, T., TUFANO, J.J.

CHARLES UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: The relationship between body composition, physical performance, and strength is often examined as researchers and clinicians seek to determine how physical abilities correlate with other variables. Specifically, handgrip strength is often used as a strong predictor of various health and performance variables. However, many of these studies have been done in special populations such as diseased populations, and even if they are completed in non-diseased populations, physical characteristics of "healthy" adults can largely vary between countries and regions. Therefore, we sought to determine if similar relationships would be found in older, but healthy and active adults in the Prague region: a city where older adults continue to live independently until very old ages and may not have the same relationships as "healthy" adults who live more sedentary lives in other regions.
METHODS: Twenty-four women (67.9 ± 5.5 years; 67.6 ± 8.7 kg; 163.7 ± 5.6 cm) and eight men (67.3 ± 10.4 years; 86.0 ± 14.8 kg; 172.6 ± 11.9 cm) participated in the measurements. Body fat percentage (BF%), fat free mass (FFM), skeletal muscle mass (SMM), height (HT), and body mass (BM) were measured via via bioelectrical impedance (InBody 720, Biospace Co., Ltd. Korea). Handgrip strength (GRIP) was measured via handgrip dynamometer (Takei A5401). Lower extremity strength-endurance was measured via the 30-second sit-to-stand test, from which the number of repetitions performed was used for analysis (30STS). We then calculated the Spearman correlation coefficients among GRIP, 30STS, and the other variables according to gender.
RESULTS: Absolute GRIP was 27.9 ± 4.5 kg in females and was 41.9 ± 9.5 kg in males. In women, GRIP was positively correlated with SMM ($r = 0.508$; $p = 0.011$) and FFM ($r = 0.497$; $p = 0.013$), and GRIP was negatively correlated with AGE ($r = -0.411$; $p = 0.46$). In men, GRIP was positively correlated with FFM ($r = 0.853$; $p = 0.007$) and HT ($r = 0.762$, $p = 0.28$), and GRIP was negatively correlated with AGE ($r = -0.749$, $p = 0.033$). GRIP did not significantly correlate with any other variable in either gender. 30STS did not correlate with any variable.
CONCLUSION: GRIP was generally greater in our population compared to normative values from other countries, which may partly explain why GRIP did not show stronger correlations or correlations with other variables. Interestingly, 30STS did not correlate to any variable, which is surprising as it would be assumed that greater bodyweight performance would occur in older adults with more SMM and less BF%. Although the sample sizes were small in these measurements, this study provides insight into the notion that standardized tests such as GRIP and 30STS may not always be appropriate predictors of other physical or functional tests in all populations.

INFLUENCE OF COGNITIVE INTERFERENCE TASKS ON GAIT PERFORMANCE BEFORE AND AFTER SUSTAINED COGNITIVE ACTIVITY IN OLDER ADULTS

GUBE, M.1, WEIPPERT, M.1, FELDHEGE, F.2, MITTLMEIER, T.2, BRUHN, S.1, BEHRENS, M.1

1 UNIVERSITY OF ROSTOCK; 2 UNIVERSITY MEDICINE ROSTOCK

INTRODUCTION: Numerous studies have shown that cognitive interference tasks (IT) as well as poor cognitive functioning can have negative effects on the gait performance (GP) of older people, which in turn correlates with the risk of falling. However, there are few systematic studies on (I) the influence of different types of IT on GP and (II) the effects of sustained cognitive activity (SCA) (impairing cognitive resources by mental fatigue) on GP during single-task (ST) and dual-task (DT) walking in older adults.
METHODS: Twenty-three healthy elderly adults completed ST and DT walking on a treadmill before and after SCA. Spatio-temporal gait parameters were determined at a constant, self-selected walking speed using the Gait Real-time Analysis Interactive Lab (GRAIL, Motekforce Link, Netherlands). Different cognitive IT were performed to investigate the influence of the type of IT on GP. These included an arithmetic task, a word list generation task and the Stroop test. A digital version of the Stroop test (30min) and reading (30min) in a magazine served as SCA. Profile of Mood States-Fatigue (POMS-F) and the Multidimensional Mood Questionnaire (MDMQ) were used to assess subjective mood before and after SCA.
RESULTS: No significant differences in GP could be observed depending on the type of IT. ANOVA showed a significant main effect of time on step-, stride length and step width during ST and DT walking ($P \leq 0.05$). Post-hoc analysis showed that reading increased step length ($P \leq 0.02$), stride length ($P \leq 0.03$) and reduced in step width ($P \leq 0.04$) during DT walking. Stroop test reduced step width during DT walking ($P \leq 0.001$). Analysis of psychometric data showed a major effect of time for POMS-F ($P \leq 0.05$). Only reading increased subjectively perceived fatigue ($P=0.05$). Condition × time interaction in the dimension calm-nervous in MDMQ could be shown ($P=0.04$). Here, the Stroop test increased the mood of nervous ($P \leq 0.05$), while no significant changes in the condition of reading were found.
CONCLUSION: Discrimination within the different IT with regard to their impact on GP could not be established. Regardless of the type of IT, SCA were found to have an influence on subsequent GP in older adults. The increase in step and stride length after reading can be regarded as both positive and negative depending on the hypothetical destabilization situation (fall event - falling forward/ backward) or the subsequent fall recovery reaction. An increase in step and stride length can be seen as a deterioration of GP in view of a loss of balance to the rear. Both SCA lead to a reduction of step width and thus to a decrease of laterally directed dynamic stability. Results of a preliminary study carried out by us showed contradictory results in younger adults with the same SCA and IT. For this reason, age group-dependent and task-specific modulations of mood and GP can be assumed.
This study was partly funded by the DFG (INST 264/137-1 FUGG).

CHANGES IN THE COGNITIVE FUNCTION OF THE FINGERS AND TOES ASSOCIATED WITH AGING

KUNISA, S., SEKI, K., TAKAHARA, T., MURATA, M., AMAOKA, H., KURACHI, N., YAMAGUCHI, H.

KIBI INTERNATIONAL UNIVERSITY

INTRODUCTION: When a human feels pain, a reflexive response is appeared to escape the pain. Previous studies reported that the sensitivity of the cutaneous sensation of the fingers is less susceptible to aging. However, there are few reports focused on the sensitivity of the cutaneous sensation of the toes. Toes play an important role in fundamental motion for human, and it is considered that sensory degradation of toes induces the decreasing of the physical activity. There is the possibility that the cutaneous sensation of the toe is decrease with aging, but it is not clear. The purpose of this study was to clarify the changes in the cognitive function of the fingers and toes associated with aging.
METHODS: 243 men and women (aged 21 to 82) were volunteered to participated in this study. Informed consent was collected from all participants per the Declaration of Helsinki and consent to participate in research was obtained from participants both orally and in writing. This study was conducted after receiving approval from the Kibi International University' Ethical Review Board (No. 16-56). In sitting

posture and closed eyes, the subjects were measured sensory cognition of the fingers and toes in both right and left side by cutaneous stimulation. Cutaneous stimulation was induced using a brush for each of the fingertips of both limbs. The cutaneous sensory cognition was evaluated by the deduction method for the number of correct answers. The stimulation of each finger or toe was measured at randomly.
RESULTS: The cutaneous sensory cognitive score in finger was almost 100% correct answers in all ages and not observed with age-related changes. This result supports the previous study. Compared to the sensory cognition scores of the fingers and toes, the sensory cognition score of toes in any age showed a lower than that of fingers, and decreased significantly with age ($p<0.05$). It is suggested that the functional degradation of sensory receptors associated with aging. An erroneous answer to the sensory cognitive score of toes showed a significantly higher in the second toe, third toe and fourth toe ($p<0.05$). This result suggests that the position of the second toe, third toe and fourth toe may not be recognized correctly.
CONCLUSION: It was suggested that the cutaneous sensory function of the toes may decrease with aging.

POSTURAL CONTROL DURING UNILATERAL AND BILATERAL EXTERNAL PERTURBATIONS IN YOUNG AND OLDER ADULTS

IVANOVA, T.D., ARSENAULT, D., SIEDLECKI, P., COHEN, J.W., GARLAND, S.J.

WESTERN UNIVERSITY

INTRODUCTION: Balance is an important determinant of physical function and falls risk. Withstanding external perturbations, particularly slips of the support surface, is important when walking on icy or uneven surfaces. Most experimental protocols involving perturbations of the support surface are performed with both legs being perturbed. It is unclear how the postural responses are influenced by unilateral perturbations. Furthermore, the addition of a cognitive load simulates a more real-life scenario, where a loss of balance occurs when the mind is focused on another task. This study sought to determine the effect of unilateral and bilateral perturbations, with and without cognitive load, on leg muscle activity in 20 healthy young adults compared to 20 older adults.
METHODS: Using a split-belt treadmill system, participants experienced 12 unilateral (left belt only) and 12 bilateral backward accelerations of the treadmill, which caused anterior movement of the centre of mass but no stepping reaction. Participants completed the perturbation tests a second time while performing the Stroop cognitive task. Surface electromyography (EMG) from eight muscles medial gastrocnemius (MG), lateral gastrocnemius (LG), soleus (SOL), tibialis anterior, rectus femoris, vastus medialis, vastus lateralis, biceps femoris (BF) was recorded from the right (stance) leg. The latency of muscle activation was determined in relation to the acceleration onset. A composite latency measure was calculated by averaging across all eight muscles. Root mean square (RMS) EMG amplitude was calculated for 500 ms prior to acceleration onset (baseline) and for the first 100 ms of the muscle burst produced by each perturbation. Burst RMS normalized to baseline was averaged across perturbations. The RMS of the posterior muscles (BF, MG, LG, SOL) were collapsed to provide a composite EMG amplitude measure. Differences in muscle latency and amplitude between perturbations (unilateral, bilateral), age (young, old) and task (regular, cognitive load) were examined using ANOVA.
RESULTS: In young adults, the composite latency was 18.5 ms earlier (82.1 ± 27.3 ms vs. 100.6 ± 48.8 ms; $p<0.001$) and the composite EMG amplitude was larger (6.6 ± 4.4 au vs. 4.4 ± 4.0 au; $p<0.001$) with bilateral than unilateral accelerations. In older adults, the composite latency did not differ by perturbation type (73.0 ± 7.0 ms vs. 70 ± 8.0 ms); however, the composite EMG amplitude was larger (1.9 ± 0.4 au vs. 1.4 ± 0.4 au; $p=0.004$) with bilateral than unilateral accelerations. With the addition of a cognitive load, there was no change in the composite EMG latency or amplitude in young adults. In older adults, a cognitive load increased average muscle activity (2.9 ± 0.7 au) only during bilateral perturbations ($p<0.001$) but did not influence the muscle latency.
CONCLUSION: Balance recovery mechanisms depend on the perturbation type. The addition of a cognitive load influences balance differently during unilateral than during bilateral perturbations.

LOWER EXTREMITY MUSCLE QUALITY IN RELATION TO GAIT PARAMETERS IN COMMUNITY-DWELLING MIDDLE-AGE AND OLDER ADULTS

CHEN, L.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: A major challenge into old age is to maintain mobility which is corresponding to age-related neuromusculoskeletal deterioration normally starting from midlife. Sarcopenia, the age-related decline in muscle mass (MM), is found to be associated with mobility limitations in older adults. However, recent studies show that the onset of dynapenia may precede sarcopenia. The concurrent assessment of MM and muscle strength (MS), the muscle quality (MQ), may provide a better indication in muscle function and mobility impairment. Thus, the aim of the study was to investigate the associations of lower extremity MQ with gait parameters in community-dwelling middle-aged and older adults.
METHODS: A cross-sectional design was conducted. Fifty-nine 50-year-old and above community dwellers resided in Taoyuan and New Taipei City were recruited (age = 66.5 ± 7.17). Optogait photoelectric system (Optogait, Microgate, Italy) was used for the assessment of spatiotemporal gait parameters. Lower extremity MS and MM were collected by MicroFET2 (Hoggan, USA) and dual energy X-ray absorptiometry (DXA), respectively. MQ was defined as MS / MM (watt / kg) as developed by Shimokata et al. (2014). Statistics analysis was performed using SPSS 20.0. Pearson product-moment correlation and partial correlation (adjusted for age) were conducted to analyze associations between lower extremity MQ and gait parameters. Statistical significance was set at $\alpha<0.5$.
RESULTS: Lower extremity MQ in knee extensor (KE), knee flexor (KF), ankle plantar flexion (PF), and dorsiflexion (DF) were significantly associated with step length ($p<.01$), stride length ($p<.05$), and gait speed ($p<.01$); step length ($p<.05$), stride length ($p<.05$), cadence ($p<.05$), and gait speed ($p<.01$); cadence ($p<.01$), and gait speed ($p<.05$); and step length ($p<.5$), cadence ($p<.05$), and gait speed ($p<.01$), respectively. Less significant relationships were found among the aforementioned variables according to statistics from partial correlation analysis adjusting for age.
CONCLUSION: Lower extremity MQ in KE, KF, PF, and DF were significantly correlated with some gait parameters. After adjusting for age, the associations were weakened indicating age was an important factor in the relationship between lower extremity MQ and gait parameters. Gait speed was the only one common variable that was significantly associated with all lower extremity MQ in KE, KF, PF, and DF. It is concluded that the improvement of lower extremity MQ may play a role in the mutual concern of sarcopenia and frailty in mobility degeneration for similar ageing population in Taiwan.

EFFECTS OF EXERCISE TRAINING ON HANDGRIP STRENGTH IN SENIORS: A META-ANALYTICAL REVIEW

MORAT, M., LABOTT, B., BUCHT, H., MORAT, T., ZIJLSTRA, W., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Exercise training interventions induce a variety of strength, balance and endurance improvements in the elderly population. Handgrip strength is a feasible and applicable measurement for seniors and a reliable indicator for vitality, physical function and several risk factors in the ageing process. The pooled transfer effects of exercise training on handgrip strength have not been investigated to date. Thus, the objective of this meta-analytical review was to examine the effects of different exercise training interventions on handgrip strength in healthy community-dwelling seniors of 60 years or older.
METHODS: Literature search was conducted in three databases (PubMed, Web of Science and SPORTdiscus) using the following search strategy with Boolean conjunction: (hand grip* OR grip strength OR grip power) AND (sport* OR train* OR exercis* OR strength OR intervention OR endurance OR resistance OR balance OR aerob*) AND (old* OR elder* OR senior*). Non-randomized and randomized controlled trials with an exercise training intervention including handgrip strength as one outcome parameter were screened. Study quality was independently assessed by two researchers using the PEDro scale. Comparison of grip strength in control and intervention groups was conducted by using the hedges g (including adjustment for small sample sizes), calculating standardized mean differences (SMDs). A random effects inverse-variance model was applied for statistical analysis.
RESULTS: Twenty-four trials (mean PEDro score 5.8±0.9) with a total of 3018 participants (age: 73.3±6.0 years) were included in the meta-analytical review. Small but significant effects ($p<0.001$) on hand grip strength were observed (SMD: 0.28, 95% CI 0.13; 0.44). Study heterogeneity (I2: 56%) and the funnel shape for publication bias analyses were acceptable.
CONCLUSION: Meaningful but small transfer effects of a multitude of different training approaches to hand grip strength occur in healthy community-dwelling seniors aged 60 years or older. Handgrip strength serves as a solid surrogate parameter to verify effects of exercise training in the elderly population, particularly in the long term.

ASSOCIATION BETWEEN ANKLE DORSIFLEXION RANGE OF MOTION AND KNEE KINEMATICS DURING SINGLE-LEG LANDING BY SUBJECTS WITH CHRONIC ANKLE INSTABILITY

DAIRA, M.1, OSE, S.2 KAGAYA, Y.3

1:SHOWA UNIVERSITY FUJIGAOKA REHABILITATION HOSPITAL, 2:ATAGAWA ONSEN HOSPITAL, 3:SHOWA UNIVERSITY

INTRODUCTION: Chronic ankle instability (CAI) has been associated with several mechanical impairments in ankle function, including reduced dorsiflexion range of motion (ROM). Some researchers suggest that less dorsiflexion ROM may increase anterior cruciate ligament (ACL) loading and injury risk since it is associated with less knee flexion angle and greater knee valgus angle. However, little has been reported about whether CAI is associated with ACL injury risk. The purpose of this study was to determine whether dorsiflexion ROM is associated with knee kinematics during single-leg landing by subjects with CAI.
METHODS: Fifteen university students (10 men, 5 women) participated in this study. Their legs were divided into two groups according to functional ankle instability as assessed by the Ankle Instability Instrument and Foot Ankle Ability Measure. There were 5 legs in the CAI group (2 men, 1 woman, age: 21.3 years, height: 169.7 ± 9.2 cm, mass: 61.7 ± 14.0 kg) and 16 legs in the healthy control group (8 men, 4 women, age: 20.8 years, height: 168.5 ± 7.5 cm, mass: 62.6 ± 8.4 kg). Static dorsiflexion ROM was measured using the weight-bearing-lunge test (Bennell et al., 1998). Knee valgus, knee flexion, ankle eversion, and ankle dorsiflexion angle were performed at maximum ankle dorsiflexion during single-leg landing from a 30-cm high box, and evaluated using a three-dimensional motion analysis system (Vicon, Oxford, UK). Independent t-tests were used for statistical analysis. The level of significance was set at $p < 0.05$, and statistical analysis was performed using SPSS 22.0 statistical software.
RESULTS: During single-leg landing, the CAI group demonstrated less static dorsiflexion ROM (32.4 ± 3.7° vs 44.3 ± 7.6°, $p = 0.003$) and greater knee valgus angle at the point of maximum ankle dorsiflexion (26.0 ± 7.4° vs 15.0 ± 8.7°, $p = 0.02$). However, there were no significant between-group differences in knee flexion, ankle eversion, and ankle dorsiflexion angle.
CONCLUSION: CAI legs demonstrated less static dorsiflexion ROM than healthy legs. The results of this study are consistent with previous reports that 30-74% of legs with CAI have at least a 5° deficit in dorsiflexion ROM (Beazell et al., 2012). Additionally, knee valgus angle during single-leg landing was greater in the CAI group. Dynamic knee valgus has been identified as a predictor of ACL injury in a prospective study (Hewett et al., 2005). Hence, these findings suggest that less dorsiflexion ROM in legs with CAI may be associated with ACL injury risk.

THE EFFECT OF FOOT TAPING ON GAIT AND STATIC POSTURE OF YOUNG HEALTHY MALES

INOUE, Y., OKUBO, S.

OSAKA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Foot taping is used for prevention of injuries during exercise. However, it has not been clear how the foot taping affects gaits or static posture and arch height. In this study, we investigated the relation between walking efficiently and taping effectively by measuring the planter pressure of young healthy males.
METHODS: 24 healthy male college students (age 22±1 years) were participated in the experiment that was done on three conditions: taping only on the plantar fascia (sole taping condition), taping all over the foot arch (full taping condition), and no taping (CON condition). A kinesiology tape with a width of 50mm was used. To measure the contact pressure and the center of pressure (COP), each participant

was required to keep standing on the plate-type pressure sensor (Footscan 2D plate, RS International) for 20 seconds on each condition. To measure the plantar pressure of the fourth and fifth steps with a sampling rate of 300Hz, each participant was asked to walk ten steps at natural speed.
RESULTS: The walking experiment showed a typical ground reaction force curve. The first peak tended to be larger on the sole taping condition than on the full taping condition. The foot contact area and the total traveling distance of the COP on static posture were almost the same under any conditions, and no significant difference was shown. However, the arch height was shown to be the highest on full taping condition of the three conditions (P<0.05).
CONCLUSION: The two peaks of the planter pressure suggest that it is easier to walk on the sole taping condition than the full taping condition. According to previous studies (Inoue et al. 2008, Hessert et al.2005, Genevieve et al., 2007), the two peaks, which were shown by young people's walking or walking fast whereas were not by elder people's walking or walking slow, suggest walking efficiently. Thus, it seems to be easier to walk on the sole taping condition. On the other hand, taping fully on the foot raises the arch height, which normally would not cause physical fatigue. It would be better to take a longer walk. Depending on the purpose, it is necessary to choose the kind of taping.

STRENGTH PROFILE, UNILATERAL AND BILATERAL IMBALANCES OF SOCCER PLAYERS DEPENDING ON AGE CATEGORY.

IŽOVSKÁ, J., MIKIC, M., DRAGIJSKÝ, M., ZAHÁLKA, F.

CHARLES UNIVERSITY IN PRAGUE

INTRODUCTION: Introduction: Strength training plays an important role in ensuring that young athletes are more coordinated, more stable and stronger than they are through a sporting career (Haff & Triplett, 2015). Soccer players may experience unequal development between the right and left legs as a result of certain technical activities performed in the game, and such uneven development may cause functional or even structural asymmetries (Haff & Triplett, 2015). The domination of one side of the body over the other creates a better ability of the dominant part and can create the asymmetry of strength of the various muscles that depend on the activities required for sport. Some soccer players have shown differences in strength and flexibility between dominant and non-dominant legs (Rahnama, Lees & Bambaecichi, 2005) and even biomechanical asymmetry between them (Dörge et al., 2002).
METHODS: The exemined group consists of soccer players (n = 1200) playing in elite Czech soccer clubs, both in youth and senior categories, who meet the selection criteria. The isokinetic strength parameters was monitored using Cybex Humac Norm isokinetic dynamometer (Cybex NORM ®, Humac, CA, USA). We investigated the maximum force (PT) of the extensor and knee flexor of the dominant and non-dominant limb at concentric contraction at angular velocities of 60, 180, 300°.s-1 and compare the unilateral or bilateral asymmetry of lower extremites.
RESULTS: In all age categories and at all measured angular velocities of 60°.s-1, 180°.s-1 and 300°.s-1 we observe higher rates of bilateral asymmetries in knee flexors compared to knee extensors. The percentage of players with hamstring asymmetry is up to 40% for some categories is more than half of the players with pre-seasonal imbalances. For knee extenors this level is about 25%.
CONCLUSION: We observed a high percentage of players with imbalances between the dominant and non-dominant lower limbs, with more players displaying imbalances in knee flexors, possibly leading to lower limb injuries of predominantly ACL rupture and other parts of the knee, pointing to the need to develop intervention programs within the training process to eliminate asymmetries not only in soccer, but also in other sports.

INJURY INCIDENCE AND INJURY BURDEN IN U14 SOCCER PLAYERS OF A PROFESSIONAL CLUB ACCORDING TO THE MATURITY STATUS

GIL, S.M.1, BIDAURRAZAGA-LETONA, I.1, DIAZ-BEITIA, G.1,2, SANTISTEBAN, J.1,2, MONASTERIO, X.1, LEKUE, J.A.1,2, LARRUSKAIN, J.2

1:UNIVERSITY OF THE BASQUE COUNTRY (UPV/EHU), 2:ATHLETIC CLUB BILBAO

INTRODUCTION: The influence of the rapid growth that occurs during puberty on injuries remains unclear. Thus, the aim of this project was to study the injuries of high-level soccer players around peak height velocity (PHV).
METHODS: Injuries and exposure time were prospectively recorded following the FIFA consensus (1) over the last seven seasons in 161 male U14 soccer players of the Athletic of Bilbao. Total, training and match exposure hours and injuries were recorded. Skeletal age was calculated using the Tanner-Whitehouse 2 method (wrist radiograph). PHV was estimated as the 88-96% of the predicted adult height (2) and players were grouped accordingly: Pre- (<87.9%), Mid- (88-95.9%) and Post-PHV (>96%).
Injury incidence and injury burden per 1000h of soccer participation, with 95%CIs were calculated. The rate ratio and 95%CIs were calculated to compare the three groups of players.
RESULTS: Mean chronological and bone age were 13.7±0.4 and 14.07±1.08 years old, respectively.
Most players were in the Mid-PHV group (77%), 10.5% and 12% were in the Pre- and Post-PHV groups, respectively.
Injury incidence was lower in the Pre- (5.7 injuries/1000h, 95%CI 3.7-8.7), than in the Mid- (7.6 injuries/1000h, 95%CI 6.6-8.8) and Post- (7.2 injuries/1000h, 95%CI 4.8-10.6), differences were statistically non-significant.
Injury burden was lower in Pre- (148.1 absence days/1000h, 95%CI 136.2-161.0) than in Mid- (169.8, 95% CI 164.9-174.8), RR= 0.87 (95%CI 0.8-0.95), p<0.001. It was also lower in Pre- than in Post- (251.4 absence days/1000h, 95%CI 235.3-268.6), RR= 0.59 (95%CI 0.53-0.66) and Mid- than in Post- (RR= 0.68, 95%CI 0.63-0.73, p<0.001).
Growth injuries caused more absence days in Pre- (105 absence days/1000h) than in Mid- (67.4 absence days/1000h) and Post- (50.3 absence days/1000h), p<0.001. In contrast, muscle injuries produced a greater burden in the Post- than the Mid- and Pre-PHV (57.8, 28.2 and 16.7 absence days/1000h, respectively), p<0.001.
From the total absence days in the Pre-PHV 71% were due to growth injuries, while only 40% in the Mid-; whereas, the injuries causing most absence days in the Post-PHV were muscle injuries (23%).
CONCLUSION: A different injury profile was observed according to the maturity status. While growth injuries were more common before PHV, players after PHV particularly suffered muscle injuries. Moreover, their injury burden was larger than the rest of the players. There-

fore, different prevention strategies should be undertaken in players of the same team but different maturity status. We also demonstrated the relevance of reporting not only injury incidence but also injury burden (3).

RAPID BUT NOT MAXIMAL FORCE RATIOS ARE SIGNIFICANTLY REDUCED BY A PROFESSIONAL SOCCER MATCH

PINTO, R.S.1, LOPEZ, P.1, ANDERSEN, L.L.2, MACHADO, C.1, VEECK, F.1, INÁCIO, M.1, CADORE, E.1, GRAZIOLI, R.1, PINTO, M.1,3

1. FEDERAL UNIVERSITY OF RIO GRANDE DO SUL, PORTO ALEGRE, RS, BRAZIL. 2. NATIONAL RESEARCH CENTER FOR THE WORKING ENVIRONMENT, COPENHAGEN, DENMARK. 3 EDITH COWAN UNIVERSITY, JOONDALUP, AUSTRALIA.

INTRODUCTION: There is important controversy about the use of hamstrings and quadriceps strength ratios for future injuries prediction in sports. In the past years, the match-induced fatigue has been proposed as a singular injury determinant in soccer (EKSTRAND et al., 2011), and the maximal strength ratios (i.e., peak Torque) pointed as a poor risk factor of hamstring injuries (GREEN et al., 2017). In this sense, once power motor skills have been increasing in contemporary soccer (BARNES et al., 2014), specific neuromuscular evaluations (THORLUND et al., 2009) and hamstring to quadriceps ratios (ZEBIS et al., 2011) considering power contractions must to be treated with caution. However, there is a lack of data in relation to the acute responses of the maximal and rapid hamstring to quadriceps strength ratios induced by a professional soccer match. The current study investigated the effect of a single professional soccer match regarding maximal and rapid hamstring to quadriceps strength ratios.
METHODS: Professional soccer players (n = 17; 77.3±6.8 kg; 179.4±43.1 cm; 24.0±1.5 BMI; 11.6±1.9 % body fat) were tested before and after a soccer match (53.7±11.9 min) for maximal knee extensor and flexor isometric strength and rate of force development (RFD). Both maximal (MSR) and rapid explosive hamstring to quadriceps ratios (RFDR) (i.e., 0-50ms and 0-200ms) were assessed.
RESULTS: Knee flexor and extensor maximal strength did not decrease after the match ($p>0.05$) and MSR did not change either ($p>0.05$). Knee flexion RFD0-50 significantly decreased ~ 14% while knee extension RFD0-50 increased ~ 16% following soccer match play ($F=8.406$; $p=0.007$). Furthermore, the RFDR0-50 ($p=0.002$) and RFDR0-200 ($p=0.047$) were interestingly altered, increasing in 35.3 and 40.6% the muscle imbalance by rapid force, respectively.
CONCLUSION: The present study observed that acute neuromuscular responses induced by a professional soccer match increases the rapid muscle strength imbalance, and may represents a negative performance marker. Besides, rapid/explosive force ratios assessment provides different and perhaps more important/realistic neuromuscular testing outcomes data and a unique measure to take into account for future investigations that aim to explore rapid force and injury prevention programs.

INJURIES IN ADOLESCENT SCHOOL BOY RUGBY PLAYERS: ARE THE CORRECT INJURY PREVENTION STRATEGIES BEING IMPLEMENTED?

ROBINSON, B., POTE, L., CHRISTIE, C.

RHODES UNIVERSITY

INTRODUCTION: Rugby appears to have a higher risk of injury than many other team sports, which is commonly attributed to the contact nature of the game. Furthermore, numerous concerns have been raised worldwide with regards to the safety of the sport due to its physical, high-impact nature and the increased number of injuries that occur. The level of play also has a significant impact on the incidence of injuries. International level rugby has the highest incidence of injury however it is crucial to investigate the nature of rugby union injuries at all levels to ensure a reduction in injury risk. Therefore, the purpose of this investigation was to determine the injuries that occur at a school boy level as well as specific injury prevention strategies that may be implemented to decrease risk of injury.
METHODS: An online survey or in person interview (depending on the school) was conducted with 43 responses; including 28 schools among the top 100 rugby schools in South Africa for 2016 and 15 non-fee paying public schools in the Eastern Cape Province of South Africa. The survey consisted of two sections namely an injury and injury prevention division as well as a general comments section which allowed coaches an opportunity to include any information they might deem useful to the study.
RESULTS: The most commonly injured position was the back row followed by the centres, with the most common site of injury being the shoulder, followed by the ankle and hamstring. The most popular injury prevention exercises overall were strengthening target areas (which included exercises used to strengthen the soft tissues in the shoulder and the neck). Eccentric work and balance, stability and movement exercises were also used for injury prevention. Injury prevention strategies were mostly implemented in the pre-season, followed by the in-season and lastly the off-season.
CONCLUSION: Overall it would seem as if injury monitoring and injury prevention strategies are areas that require a significant amount of focus. While the majority of coaches do some form of injury prevention the techniques reported are limited and thus probably need to be adjusted according to specific individuals or teams. Thus, developing an injury prevention protocol can assist players in benefiting from one of the most crucial aspects of a strength and conditioning program: reducing the risk of injury to the players.

CONTACT SPORTS: DENTAL INJURIES, MOUTHGUARDS USE AND STAPHYLOCOCCUS AUREUS INFECTIONS. PILOT STUDY.

IONA, T.1, TORNELLO, F.1, MASCARO, V.1, AMMENDOLIA, A.1

UNIVERSITY OF CATANZARO

INTRODUCTION: Sports-related accidents are common causes of facial injuries, accounting for approximately 33% of all dental injuries in athletes. Athletes practicing contact sports have noticeable probability of contracting Staphylococcus aureus infections. Methicillin-resistant Staphylococcus aureus (MRSA) infection is caused by a type of staph bacteria that are become resistant to a lot of the antibiotics used to treat ordinary staph infections. Lack Italian-based epidemiological information exists about the incidence of dental injury in sports and correlation with MRSA exposure and/or infection. Aim was to evaluate occurrence of dental traumas, level of knowledge of the participants about preventive measures, management of dental trauma during sports and to correlate with MRSA exposure in Italian contact sport athletes.

METHODS: A cross-sectional study was conducted to 244 young athletes from different contact sports (taekwondo (n=81; 33,19%); judo (n=27; 11,06%); Kick boxing (n=24; 9,83%); Boxe (n=38; 15,57%) and Other Sport (n=74; 30,32%). Tow standardized questionnaires were used about socio-demographic characteristics, specific sport activities, participants's health conditions, dental trauma (occurrence; circumstances regarding the dental trauma; area of incidence of trauma), habits regarding the use and type of mouthguard. Swabs were collected from the nares, oropharynx and hand fingers, and tested for S. aureus isolation and antimicrobial susceptibility. The statistical analysis involved descriptive and inferential statistical measures.
RESULTS: 89% of participants (25±9,7 yrs; 66,09±13,01 kg; 1,70±0,1m; 6.00±3.1 years/experience) reported that no to suffer of dental injury, while 26 athletes (11%) reported higher rate of dental injuries in taekwondo (6,33±2,05) (P=0.005). Most participants were aware of mouthguards for dental trauma prevention and considered them efficient to prevent dental injuries during sports activities, 76% used them. Statistically significant difference was in the mouthguards characteristics: model was single arc (58%), boilt&bite type (93 %), standard misure (86%), gel material (55%) (P<0.001). S. aureus was carried by 42% of 244 enrolled athletes. Of all athletes, 1.7% carried methicillin-resistant S. aureus (MRSA); MRSA were 4% of all S. aureus isolates. Date showed no statistical correlation between MRSA and dental injury.
CONCLUSION: A high prevalence of dental trauma in the enrolled athletes was not found. Participants were aware of mouthguards for dental trauma prevention but not so informed about the specific characteristics. Data showed a high prevalence of S. aureus carriage and a relevant resistance to antimicrobials frequently used for the treatment MRSA infections, but no correlated to dental trauma.

CP-PM07 Hypoxia

RESPIRATORY EXERCISES DURING HIGH ALTITUDE (HA) EXPOSURE, HELP TO MAINTAIN A BETTER OXYGEN SATURATION IN NON-PROFESSIONAL CLIMBERS COUNTERACTING THE EFFECTS OF PROGRESSIVE HYPOXIA.

BALLERIO, F.1, SORINO, N.1, MERLO, C.1, FRANCHI, M.1, PIZZOLATO, M.1, SALVI, E.2, PRATALI, L.2, COGO, A.1
1 UNIVERSITY OF FERRARA, ITALY: 2 CNR, PISA, ITALY

INTRODUCTION: At HA, the reduced barometric pressure and the consequent reduced PIO2 induce a progressive decrease in oxygen saturation (SpO2). The fall in SpO2 is the main cause of acute mountain sickness (AMS) and of development of interstitial lung edema. Ventilatory pattern (i.e. the ratio between tidal volume (TV) and respiratory rate (RR)) is a key point for the efficiency of ventilation in term of gas exchange; the adoption of a breathing pattern characterized by higher TV and lower RR is known to increase SpO2 at altitude (1). In healthy subjects, both exercise training and respiratory muscle training have been shown to improve the breathing pattern toward a more efficient one. AIM: To evaluate the effect of a specific respiratory training on SpO2, AMS and interstitial lung edema during the ascent to Regina Margherita Hut (4559 m), Mount Rosa.
METHODS: 18 non-professional climbers (13 M, 5 F) age 22-61 yrs, performed an 8 weeks respiratory training (RT) before the excursion. RT= 30 minutes/day; quadratic ventilation featured by inspiratory and expiratory apnea of the same duration. The length of apnea started from 4 sec and arrived to 15 sec in the last trainings. In addition, they performed 3 sets of 5 minutes of forced ventilation with maximal inspiration and expiration. After the training, they reached Gressoney (1635 m.a.l.s.) and were randomized in trial (T) and control (C) group. Due to personal problems, 2 subjects had to give up; therefore, the groups were of 7 and 9 people respectively. Stage 1: to Mantova Hut (3498 m.a.l.s.); stage 2: to Giordani bivouac (4167 m.a.l.s.); stage 3: to Regina Margherita Hut and back to Gressoney. The 2 groups climbed separately; every 3 hours (during the climb or at rest) T stopped for 1 hour to perform RT. Both groups during the 3 days of climb underwent: lung ultrasound analysis to detect the presence of B lines (sign of interstitial lung edema), 24h SpO2 monitoring and Lake Louise Scoring System (LLS) for the diagnosis of AMS.
RESULTS: SpO2 was significantly higher in T during both the climb and the nights through all three days ($p<0.001$), ($p<0.05$) respectively. No difference was found in LLS between C and T even if 1 subject in C stopped at stage 1 due to severe AMS and another subject in C suffered of moderate AMS at stage 2; nevertheless he reached the goal. B lines were significantly higher in C only in stage 3 ($p < 0.05$). (ANOVA for repeated measures)
CONCLUSION: The fall in SpO2 is the main cause of AMS and interstitial lung edema during HA exposure; specific respiratory exercises performed during HA ascent, helps to maintain a better SpO2 especially during the climb and the sleep. This better oxygenation reduces the evidence of B lines after a long exposure. This is the first step of assessment of a new mean to counteract HA hypoxia. 1. Bernardi L. Eur J Appl Physiol. 2007

MODERATE HYPOXIA PROMOTES SKELETAL MUSCLE CELL GROWTH AND HYPERTROPHY

SAKUSHIMA, K.
RITSUMEIKAN UNIVERSITY

INTRODUCTION: Exercise, specifically resistance (weight) training, has been shown to be an effective way to improve/maintain physical function by means of arresting decline of muscle mass and eliciting muscle hypertrophy. Basically, such effects of resistance training are caused by a mechanical stress. However, scant attention has been paid to the effect of oxygen molecules on muscle morphological characteristics.
Previous studies demonstrated that the region of lower oxygen concentration during resistance training showed a higher rate of muscle hypertrophy [1][2]. KAATSU training involves the restriction of blood flow to exercising muscle [3] and induces muscle hypertrophy even at low intensity [4]. These previous studies suggest that, in addition to mechanical stress, the hypoxic environment in the muscle to be a factor influencing muscle hypertrophy. In fact, resistance training under hypoxic conditions improves muscle strength and induces muscle hypertrophy rather than normoxic conditions [5]. However, the direct effect of hypoxia on muscle grows and associated mechanisms remains unknown. The purpose of this study was to examine the effect of 10% oxygen environment on skeletal muscle morphological characteristics and its associated mechanisms.

METHODS: C2C12 skeletal muscle cells were divided into two groups: control group cultured in 20.9% oxygen environment (CON) while hypoxia group cultured in 10% oxygen environment (HYP) during differentiation. We analyzed expressions of differentiation-related proteins Myogenin, using Western blotting. As well, we analyzed expressions of hypertrophy-related proteins (e.g., mTOR and p70s6 kinase). We also conducted immunocytochemical analyses to assess myotube diameter and Differentiation Index (DI), an indicator of muscle differentiation [6].
RESULTS: The myotube diameter in the HYP was significantly greater than that in the CON ($p < 0.05$). The DI was significantly higher in the HYP than in the CON ($p<0.05$). The protein expression of myogenin was significantly higher in the HYP than in the CON ($p < 0.05$). The expression level of phosphorylated mTOR and p70s6K was significantly higher in the HYP than in the CON ($p < 0.05$).
CONCLUSION: Moderate hypoxia may promote skeletal muscle cell hypertrophy by promoting the cell differentiation (myogenesis).

ELECTROENCEPHALOGRAM AND PHYSIOLOGICAL RESPONSES TO ACUTE NORMOBARIC HYPOXIA

UCHIMARU, J., CHEN, F.
SENDAI UNIVERSITY

INTRODUCTION: It is well known that hypoxic stress causes various physiological responses and/or adaptations. Hypoxia also affects brain activities such as cognition and judgment, and it is thought that the influence on EEG is great, which is thought to affect EEG. However, there are few researches related to the change of EEG to hypoxic stress, and it is thought that examining the physiological responses including brain activity of hypoxic stress will be useful for improvement of competition performance, health-physical fitness promotion, and countermeasures against hypoxic stress such as acute mountain sickness. The purpose of this study was to examine that electroencephalogram and physiological responses to different normobaric hypoxic environments.
METHODS: Eleven college-age male subjects were participated in this study. We measured electroencephalogram of left forehead (EEG), heart rate (HR), and oxygen saturation (SpO2) when subjects continuously inhaled different oxygen cont. air (normoxia, 17.5% hypoxia and 14.5% hypoxia) for each 10 minutes. Measurement was carried out in a quiet environment, and subjects measured with their eyes closed and relaxed. The measured EEG was classified into 4 frequency bands. In other words, it was classified into δ wave 3 to 3.5 Hz, θ wave 4 to 7.5 HZ, α wave 8 to 13 HZ, β wave 13.5 to 30 HZ. The average value (μV) of the amplitude of the EEG and the total amplitude of the EEG in the entire frequency band (3 to 30 Hz) were obtained for each measurement for 10 minutes. From the classification of EEG of each frequency, in order to examine the ratio of stagnation and active state of brain activity, the total brain wave amplitude of the low frequency band (δ wave and θ wave) considered as the stagnation state of brain activity, the total brain wave amplitude of the high frequency band (α wave and β wave) considered to be active state of the brain, and the ratio were evaluated. Repeated measures ANOVA were performed across treatments.
RESULTS: SpO2 was significantly decreased with decreasing oxygen concentration (normoxia; 96.5±0.5%, 17.5% hypoxia; 93.8±1.4% and 14.5% hypoxia; 87.6±2.0, $p<0.05$). At the same time the average value of the amplitude of EEG for all frequency band (δ, θ, α and β wave) also tended to increase with decreasing oxygen concentration. Rate of changes in the low frequency band EEG (total of δ wave and θ wave amplitude) at 14.5% hypoxia based on normoxia (105.8±11.0%) were tended to increase compared with 17.5% hypoxia (101.8±4.8%). There was a significant correlation between EEG (θ wave; $r=0.71$, α wave; $r=0.65$ and the β wave; $r=0.91$, respectively) and SpO2 at 14.5% hypoxia ($p<0.05$).
CONCLUSION: We clarified the relationship between EEG and SpO2 as physiological response in different hypoxic environments. It would be concern to approaches to the acclimatize to altitude and prevention of altitude sickness.

HYPOXIA DOES NOT INFLUENCE POST-EXERCISE PROTEINURIA.

JOYCE, K.E., BALANOS, G.M., FOUNTAIN, A., BRADWELL, A.R., LUCAS, S.J.E.
UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Proteinuria increases with both exercise and exposure to altitude, however the mechanism(s) that underpin this observation remain unclear. Renal tissue hypoxia is suggested as one potential mechanism, however little evidence exists to support or refute this. Therefore, the present study examined the effect of increased systemic hypoxia on the post-exercise proteinuria response.
METHODS: Using a randomised, crossover study, nine participants completed an incremental exercise test in normoxia (20.9% O2; NOR) and hypoxia (12.7% O2; HX) inside an environmental chamber. Participants acclimatised to each condition for 2hrs before the exercise test, consuming 500mL of water during this period. To limit differences in duration of exercise between conditions, workload was increased by 30W/2min in NOR and 20W/2min in HX conditions until volitional fatigue (i.e. Wattmax). Participants produced urine samples before and following (post-30, 60 and 120-min) exercise, with peripheral oxygen saturation (SpO2%) and heart rate recorded throughout. Urinary alpha-1 acid glycoprotein (uAGP) was measured as a sensitive marker of proteinuria using a novel latex-enhanced immunoassay (Optilite, turbidimetric analyser, Binding Site Ltd., UK). Paired samples t-tests and Wilcoxon signed rank tests were used where appropriate to compare differences between conditions. Data are presented as mean +/- SD.
RESULTS: Wattmax was reduced in HX compared to NOR (213+/-32W vs. 280+/-40W; $p<0.01$). SpO2 at Wattmax was lower in HX (82+/-3% vs. 94+/-2%; $p < 0.01$), as was the SpO2 nadir during exercise (77+/-3% vs. 92+/-4%; $p<0.01$). Post-30 min uAGP excretion was on average lower in HX (15.5+/-13.8ug/min) compared to NOR (18.6+/-14.6ug/min), albeit not significantly different ($p=0.07$).
CONCLUSION: Despite markedly elevated systemic hypoxia in the HX condition, post-exercise uAGP excretion was not different from normoxic conditions. These findings indicate that hypoxia per se is not the primary mechanism mediating post-exercise proteinuria.

THE EFFECTS OF BEETROOT JUICE ON APPETITE, ACYLATED GHRELIN AND ENERGY INTAKE AT 4300M SIMULATED ALTITUDE

MATU, J.1, DUCKWORTH, L.1, SHANNON, O.M.2, ELIA, A.1, BRADLEY, R.1, KIMBLE, R.1, HINSON, G.1, SIERVO, M.2, WILLIAMS, E.1, STAVROPOULOS-KALINOGLOU, A.1, O'HARA, J.P.1

1 LEEDS BECKETT UNIVERSITY, 2 NEWCASTLE UNIVERSITY

INTRODUCTION: Acute exposure to very high altitude (> 3500 m) is associated with a suppression of appetite, acylated ghrelin (AG) and energy intake. Appetite suppression at altitude is likely caused by the reduction in arterial oxygen saturation (SpO2), consequent to the low oxygen tensions present at altitude. Beetroot juice (BRJ) has shown to minimise the altitude-related reductions in SpO2 and may therefore provide relief of altitude-induced suppression of AG and appetite. The present study investigated the effects of BRJ supplementation on appetite, AG and energy intake at 4300 m simulated altitude.
METHODS: Ten healthy males (mean (SD); age 24 (7) years, body mass index 25 (3) kg·m-2) completed two 6 h 30 mins experimental trials in normobaric hypoxia, simulating an altitude of 4300 m (~11.7 % FiO2). Trials were conducted in a randomised, double blind, counter-balanced fashion. After an overnight fast, participants arrived at the laboratory and completed baseline measures. Following cannulation, participants consumed a porridge breakfast accompanied by 140 ml concentrated BRJ (Beet It, James White Ltd., UK) or placebo. Participants entered the hypoxic chamber 90 mins after breakfast, where they rested for 2 h 30 mins. Participants then completed a 60 min treadmill walk at 10 % gradient and 50 % of relative $\dot{V}O_2$max, whilst carrying a 10 kg rucksack. After exercise, participants consumed a snack and 70 ml concentrated BRJ or placebo. Participants then rested inside the chamber until 6 h 30 mins. After leaving the chamber, the participants were given an ad-libitum homogenous pasta meal. Fractional exhaled nitric oxide (FeNO) provided a marker of nitric oxide bioavailability. Composite appetite score (CAS) and AG were measured throughout; results are presented for four area under the curve (AUC) periods of: pre-hypoxic, hypoxic rest, exercise and post-exercise.
RESULTS: At baseline there were no differences in any variables between conditions ($P \geq 0.382$). There was no significant difference in FeNO between conditions upon entry to the chamber ($P = 0.110$), however FeNO was significantly elevated in BRJ immediately prior to exercise, compared with placebo ($P = 0.034$). There were no differences between conditions during any of the AUC periods for SpO2 ($P \geq 0.746$), AG ($P \geq 0.231$), or CAS ($P \geq 0.730$). Energy intake at the ad-libitum buffet meal did not differ between BRJ (3542 ± 1306 kJ) and placebo (3980 ± 1342 kJ; $P = 0.270$).
CONCLUSION: This study suggests that acute BRJ supplementation has no effect on appetite, AG, or energy intake at 4300 m simulated altitude. However, other methodological approaches which may elevate SpO2, such as chronic BRJ loading, require further investigation.

EXERCISE-INDUCED HYPOXEMIA LEADS TO SPECIFIC ADAPTATIONS IN CARDIOVASCULAR SYSTEM DURING ACCLIMATIZATION TO MODERATE HYPOXIA

DURAND, F., RABERIN, A., MERIC, H., MUCCI, P., LOPEZ AYERBE, J.

PERFORMANCE HEALTH AND ALTITUDE EUROPEAN LABORATORY

INTRODUCTION: Cardiovascular responses to maximal exercise at altitude are well described during short-term exposure and prolonged exposure1. Knowledge of these responses is particularly important for endurance athletes because a lot of training camps and/or competitions take place in altitude. It has been clearly established that 70% of endurance athletes exhibit a drop in arterial oxyhemoglobin saturation (SpO2) during maximal exercise at sea level, called Exercise-Induced Hypoxemia (EIH). Precedent studies highlight the impact of EIH leading to specific adaptation on cardiovascular system during exercise in acute hypoxia2. The objective of this study was to evaluate the impact of EIH on maximal cardiorespiratory parameters under prolonged moderate altitude exposure.
METHODS: Endurance trained athletes (n=17) perform exercise tests on cycloergometer to assess maximal oxygen consumption (VO2max).The first in normoxia (N), the second after 24h at 2500m (short term exposure, STH) and the third after 5 days at 2500m (prolonged exposure to hypoxia, PH). Heart rate (HR), stroke volume (SV) and cardiac output (Qc) were monitored using echocardiography.
RESULTS: 9 athletes exhibited EIH (a fall in SpO2 > 5 points between rest and maximal exercise in normoxia) while 8 didn't (noEIH). No between group difference occurred at rest in cardiac parameters. VO2max was similar in the two groups (respectively for EIH and noEIH, 69.25 ± 1.8 vs 68 ± 3.1 ml.min-1.kg-1). EIH athletes exhibited a greater HRmax than noEIH (192 ± 1.3 vs 178 ±3.8 bpm, $p<0.05$). In STH, resting SpO2 and SpO2max were significantly lower in EIH than in noEIH (respectively at rest: 94.3 ± 0.4 vs 96.3 ± 0.4 % and at max: 79.7 ± 1 vs 84.5 ± 0.8 %). EIH reported a significant greater HRrest (83 ± 4 vs 68 ± 3.3 bpm) and HRmax (185 ± 1.1 vs 175 ± 2.7 bpm). In PH, resting and maximal O2 saturation were lower in EIH (respectively at rest: 94.3 ± 0.4 vs 97.5 ± 0.4 % and at max: 81.2 ± 1.1 vs 86.2 ± 0.8 %) and the difference in HRmax still occurs (182 ± 2.6 for EIH vs 169 ± 3.6 for noEIH, $p<0.05$). EIH athletes report significant greater values than noEIH for SVrest (respectively, 80 ± 2.9 vs 71 ± 3 mL) and Qcrest (respectively 6.2 ± 0.4 vs 4.9 ± 0.2 L.min-1). In PH, Qcmax was reduced regarding N in noEIH and a significant difference occurred between EIH and noEIH (respectively, 30.1 ± 1.2 vs 24.8 ± 1.6 L.min-1, $p<0.05$).
CONCLUSION: These results highlight the fact that EIH measured in normoxia persist at least during the first 5 days of hypoxic exposure and lead to specific cardiovascular adaptations in prolonged exposure to altitude. If our results could explain at least in part the same level of VO2max achieve by the two groups in hypoxic conditions, despite the greater fall in SpO2 occurring in EIH athletes, they also clearly show that EIH impact the acclimatization to moderate hypoxia.

HIGH ALTITUDE TRAINING CAMPS OF ELITE SWIMMERS – GENETIC, BIOCHEMICAL AND PHYSIOLOGICAL ASPECTS

VESELÁ, J., NOVÁKOVÁ, M., BOLEK, E.

SPORTS RESEARCH INSTITUTE OF CZECH ARMED FORCES

INTRODUCTION: Training in the hypoxic environment has become an important element in improving the top athlete´s performance. However, each athlete responds individually to the hypoxic environment. Performance is very different during acclimatization as a result of individual readiness. The acclimatization process is among other things influenced by a hormonal response to hypoxia. Hormonal reactions of erythropoietin are known, but in the presented study we also were interested, what is the effect of hypoxia on other hormone levels in elite athletes. Another area of our interest was the genetic predisposition of athletes for adaptation to hypoxia. Lastly, we examined the influence of repeated accommodation and training in hypoxia on biochemical and physiological parameters in elite athletes.

METHODS: The study includes physiological, biochemical and genetic part. A sample of 7 healthy elite swimmers of the male sex (n = 5) and female sex (n = 2) with an average age of 21±2 was followed for 8 months in three training camps at an altitude of 1,800 and 1,900 meters above sea level. For all participants, a venous blood sample was taken before and after training camp at high altitude and analysed for markers of anemia (iron, transferrin, ferritin) and hematology parameters (hemoglobin, hematocrit, erythrocytes). At the same time participants underwent a physiological test with maximal oxygen consumption (VO2 max/kg) determination. At the training camps, a capillary blood sample was taken at 20 and 40 hours of stay at high altitude and hormones (erythropoietin, insulin, cortisol, free testosterone) were measured in the blood sample. In addition, from all swimmers, a saliva sample was taken for the analysis of two genes: ACE (associated with endurance predisposition) and ACTN3 (which is associated with sprint ability).
RESULTS: Our results show that erythropoietin concentration in blood of elite swimmers is increased at 20 hours at high altitude in comparison to normoxia. At 40 hours the level of erythropoietin decreases, while insulin and cortisol are still on the rise. Hematological parameters after training camps at high altitude tend to increase. Similarly, in the physiological test, the VO2 max/kg of swimmers improved during the followed period. Gene analysis revealed that only one of the swimmers does not have any copy of the ACE gene and all tested swimmers have at least one copy of the ACTN3 gene.
CONCLUSION: Our study showed that among hormones not only erythropoietin is affected by hypoxia during acclimatization. Monitoring these hormones can be used to assess the current state and readiness of the athlete for the sports performance at high altitude. Further, we confirmed that repeated accommodation and training in hypoxia improve hematological and physiological parameters in elite swimmers.

THE EFFECTS OF 2 WEEKS OF HIGH-INTENSITY TRAINING IN MODERATE AND MILD HYPOXIA ON EXERCISE PERFORMANCE AND AEROBIC CAPACITY IN HORSES

MUKAI, K., OHMURA, H., TAKAHASHI, Y., KITAOKA, Y., TAKAHASHI, T.

EQUINE RESEARCH INSTITUTE, JAPAN RACING ASSOCIATION

INTRODUCTION: Hypoxic training has become popular among human athletes; however, the effects of hypoxic training are widely debated and there is limited information on hypoxic training in horses. The purpose of this study was to test the hypothesis that horses trained in moderate and mild hypoxia for 2 weeks would experience greater improvements in exercise performance and aerobic capacity compared with horses trained in normoxia.
METHODS: Seven untrained Thoroughbred horses (7.9±2.0 years, 512±30 kg) completed 2-weeks (3 sessions/week) of three training protocols, consisting of 2-min at 95% of maximal oxygen consumption (VO_2max) in moderate hypoxia (H16, FIO_2=0.16), mild hypoxia (H18, FIO_2=0.18) and normoxia (N, FIO_2=0.21) using a randomized crossover study design with a 3-month washout period. Normoxic incremental treadmill tests were conducted before and after training. Data were analyzed using mixed models (P<0.05).
RESULTS: Run distance in H16 and H18 (H16, +22.7%; H18, +16.5%; N, +8.9%), VO_2max in all groups (H16, +9.3%; H18, +9.8%; N, +7.9%), peak cardiac output in H16 and N (H16, +7.8%; H18, +6.1%; N, +7.8%), and lactate threshold in H18 and N (VLA4; H16, +7.1%; H18, +10.1%; N, +11.0%) increased after 2-weeks of training. However, there were no significant differences in above variables between all groups. Peak haemoglobin concentrations in H16 and H18 were higher than that in N after training (H16, +1.4%; H18, +1.3%; N, -0.5%).
CONCLUSION: These results suggest that 2-weeks of training in moderate and mild hypoxia may induce greater improvements in exercise performance and erythropoiesis than normoxic training in horses.

EFFECTS OF HYPOXIA ON POWER OUTPUTS AND MUSCLE GLYCOGEN UTILIZATION DURING REPEATED SPRINTS

TAKUYA, O., EMI, K., HIDEYUKI, T.

JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: The performance of short-duration exercise, such as a single-sprint exercise, is little changed under hypoxic conditions. However, it is likely that the performance of repeated sprints could be decreased by hypoxia, dependent on the partial pressure of oxygen, the total exercise duration, and the balance between exercising and resting durations. One of the possibilities would be the working muscle glycogen depletion. It was reported that hypoxia increased carbohydrate utilization during a given exercise and decreased muscle glycogen after exercise. However, the relationship between repeated-sprint performance and muscle glycogen utilization under hypoxic condition was unclear. The aim of this study was to investigate the effects of hypoxia on repeated-sprint performance and the decrement of muscle glycogen.
METHODS: After warm-up exercise, eight trained male subjects (age, 24 ± 2 yr) performed 4 sets of ten 5-s maximal cycle sprint exercises, separated by 50-s no-load pedaling exercises and 5-s stop motions, under normoxic and hypoxic (FIO2 = 0.15) conditions in a random order. The rest durations between sets were 2 min, 10 min, and 2 min, respectively. Muscle glycogen from the vastus laterals was non-invasively evaluated by carbon-13 magnetic resonance spectroscopy (13C-MRS) before and immediately after each test.
RESULTS: The mean peak power output at each set were 1717 ± 140 W, 1694 ± 222 W, 1706 ± 206 W, and 1758 ± 245 W under normoxic conditions, and 1695 ± 189 W, 1606 ± 129 W, 1596 ± 116 W, and 1600 ± 159 W under hypoxic conditions, respectively. There was a significant interaction between both conditions ($P < 0.05$). However, the total amounts of work throughout the tests were not significantly different between the two conditions (normoxia: 25.6 ± 3.1 kJ, hypoxia: 24.9 ± 2.7 kJ, N.S.). The muscle glycogen concentrations after the exercises were significantly decreased under both normoxic (86.5 ± 12.9 mM to 32.5 ± 13.3 mM, $P < 0.05$) and hypoxic (85.0 ± 15.6 mM to 45.5 ± 7.2 mM, $P < 0.05$) conditions. Moreover, the decrement rates of muscle glycogen were significantly lower under hypoxic (45.3 ± 9.8%) than normoxic conditions (62.6 ± 15.1%, $P < 0.05$).
CONCLUSION: The repeated-sprint performance throughout the tests was not significantly decreased under hypoxic conditions, but the decrement rates of muscle glycogen were lower under hypoxic than normoxic conditions. These results suggest that the decrease of repeated-sprint performance under hypoxic conditions could not be influenced due to muscle glycogen depletion, and that the difference of decrement rate of muscle glycogen between the two conditions would partly be influenced by the difference of the power outputs, especially at the latter half of tests.

ANALYSIS OF THE VITAMIN D-STATUS OF YOUNG ELITE TEAM SPORT ATHLETES – STUDY CONCENTRATED ON FIELD HOCKEY PLAYERS

BROECKL-POPOLI, F., DEMARÉES, M., PLATEN, P.

RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: Vitamin D (VD) has been dubbed the sunshine vitamin because it is primarily endogenously synthesized from ultraviolet-B radiation (UVB). Current studies demonstrate that VD-deficiency is a common problem among the general population as well as in athletes. VD does not only influence bone health, but also affects mental wellness, the muscular system and the immune system [1,2]. For athletes it is also wondered if an efficient VD-level improves performance. The goal of the study was to examine the VD-status of young, elite field hockey players and to rate its impact on the athletes' physical state.
METHODS: In the month of March this study was performed with a sample size of 83 field hockey players from the German hockey association (173.3±8.9 cm; 68.8±11.0 kg; BMI: 22.6±2.1 kg/m2; VO2max: 48.9±5.1 ml/min/kg) between the ages of 16-21 (17±1 years). For further analysis the overall sample was again divided either by age groups (U18: n=56/U21: n=27) or by sex (female (f): n=47/male (m): n=36). The VD-level was studied from multiple facets. First, blood samples of all players were taken to analyze the parameter 25-OH-D3. Second, a questionnaire was completed to determine if and how they supplemented, the intake of foods rich in VD and a prior stay in UVB-intensive locations, to evaluate what factors affected their VD-status.
RESULTS: The overall sample's VD-status ranged from 6 to 60 ng/ml 25-OH-D3 (22±12 ng/ml 25-OH-D3). Comparing female and male athletes showed that female athletes had a significantly higher VD-level than their male counterparts (f: 26±13 ng/ml; m: 18±9 ng/ml; p ≤0.001). The comparison done between age groups presented a trend that the VD-status of the U21 players was higher than those of the U18 group (U21: 25±13 ng/ml; U18: 21±12 ng/ml; p =0.063). 17 players were supplementing during the examination, which resulted in significantly higher VD-levels when compared to the players who did not take supplements (n=66; 19±8 ng/ml; p ≤0.001). No correlation between the VO2max and the VD-status was found.
CONCLUSION: 82% of the overall sample had a VD-level of <30 ng/ml 25-OH-D3, which illustrates a concerningly high prevalence of insufficient VD-levels in young elite field hockey players. Additionally, the results show that even the subjects who supplemented, did not reach the recommended level of at least 40 ng/ml 25-OH-D3 [3]. It is proven that VD has an important role regarding heath, injury prevention and improved rehabilitation [1,2,3]. Further studies must clarify if an optimal VD-status influences the performance of already trained subjects and if so, how high the concentration must be.

PHYSIOLOGICAL AND PERFORMANCE RESPONSES TO BASIC MILITARY TRAINING IN CONSCRIPTS WITH DIFFERENT VITAMIN D STATUS

ÖÖPIK, V., TIMPMANN, S., RIPS, L., OLVETI, I., MOOSES, M., MÖLDER, H., VARBLANE, A., LILLE, H.R., GAPEYEVA, H.

UNIVERSITY OF TARTU

INTRODUCTION: Literature suggest existence of positive association between vitamin D status and some indices of muscle function and physical performance in young male athletic subjects (Fitzgerald et al. J Strength Cond Res 2015, 29:2513-21; Koundourakis et al. PLoSONE 2014, 9:7). However, data regarding the potential impact of vitamin D status on changes in performance occurring due to systematic training is scarce. The purpose of this study was to assess vitamin D status as well as physiological and performance responses to basic military training (BMT) in Estonian conscripts.
METHODS: Altogether 201 conscripts were included in the study. Of these, 94 (group S; age 21.0 ± 1.6 years, BMI 24.2 ± 2.9 kg·m-2; mean ± SD) passed the 10-week BMT from July to September, and 107 (group A; age 20.9 ± 1.7 years, BMI, 24.3 ± 3.1 kg·m-2) from October to December. The BMT program was identical in groups S and A and consisted of marching drills, combat training, sport training, long marches (8 – 30 km) and field camps involving overnight exercises. Venous blood samples were taken four times during BMT, each time on Monday morning after overnight fast. The results of physical performance tests carried out at the beginning (Test 1) and at the end of BMT (Test 2) were recorded.
RESULTS: During BMT, overall serum 25(OH)D concentration was higher in S compared to A (61.4 ± 16,1 and 48.5 ± 20.7 nmol · L-1, respectively; $p < 0.001$). In both groups, the ratio of serum concentrations of testosterone to cortisol significantly ($p < 0.05$) increased and that of ferritin decreased ($p < 0.05$). Pooled data (S + A) revealed significant positive relationship between serum 25(OH)D concentration and performance in three exercises (number of push-ups · 2 min-1, number of sit-ups · 2 min-1, 3200 run time) in both Test 1 and Test 2 (in all cases $p < 0.001$). However, after stratifying by serum 25(OH)D levels, association between vitamin D status and performance disappeared in vitamin D sufficient (25(OH)D ≥ 75 nmol · L-1), but was maintained in insufficient (25(OH)D ≥ 75 nmol · L-1) subgroup. Comparing improvements in performance from Test 1 to Test 2, in push-up exercise it was greater in S and in sit-up exercise in A (in both occasions $p < 0.05$). In 3200 running test the improvement was similar in S and A ($p > 0.05$).
CONCLUSION: Based on these findings we conclude that there is clear impact of season on Estonian conscripts' vitamin D status and that positive relationship exists between serum 25(OH)D concentration and physical performance. However, vitamin D status does not influence physiological and performance responses to BMT.

ASSESSMENT OF VITAMIN NUTRITIONAL STATUS IN JAPANESE FEMALE COLLEGIATE ATHLETES

NAGASAWA, T., MINATO, K.

WAYO WOMENS UNIVERSITY

INTRODUCTION: Good nutrition is necessary for conditioning of athletes. However, there are many reports of inadequate nutritional status in Japanese female collegiate athletes because they do not have a custom to eat well-balanced diets by themselves. Also, female ath-

letes are apt to restrict diets for body weight decrease. Therefore, vitamin deficiency is caused frequently in female athletes. The purpose of this study was to assess the vitamin nutritional status and physical parameters in female collegiate athletes in Japan.
METHODS: Subjects; 7 female collegiate athletes (athletes (A) group) and 14 female collegiate students (no athletes (NA) group) were participated in this study. The subjects in the A group played basketball for 120 minutes each day, 5 days a week. The subjects in the NA group had usual college life style without vigorous exercise. Investigations; Blood vitamin B1 and C concentrations were measured. The nutritional status was assessed for 3 days food habits records and photographs of their meals and snacks. The physical activity amount (daily step counts and daily energy expenditure) was measured for 1 week using triaxial accelerometer. The questionnaire survey (life style, indefinite complaints, and eating habits) was conducted.
RESULTS: Daily step counts and energy expenditure in the A group were significantly higher than in the NA group ($p<0.01$). Daily energy and most nutrients intakes in the A group were lower than the recommended adequate levels for athletes. Vitamin C intake in the A group (54±7mg) was significantly less than in the NA group (74±22mg) ($p<0.05$). The confectionary taking frequency in the A group (0.8±0.5) was significantly more than in the NA group (0.3±0.2) ($p<0.05$). Few subjects showed abnormal levels in bloods in blood test results including vitamin B1 and C concentrations in the both groups. There was a significant and positive correlation between blood vitamin B1 concentration and vitamin B1 intakes from foods in the A group, but not in the NA group. On the other hands, there was no significant correlation in the both groups between blood vitamin C concentration and vitamin C intakes. There was no difference in the number of "indefinite complaint" between the A and NA group. The rate of complaints of "easy to stomatitis" in the A group was significantly higher than in the NE group ($p<0.01$).
CONCLUSION: These results suggested that some subjects in the Japanese female collegiate athletes may be in the vitamin deficiency status. However, their blood vitamin B1 level was higher than the reference value. Athlete adequate level of vitamin B1 concentration might be higher than the usual reference value. Checking of blood vitamin B1 concentration may be useful for a nutritional assessment parameter of athletes conditioning.

DOES VITAMIN D SUPPLEMENTATION ENTAIL A 2X 2A FIBERTYPE SHIFT?

NYGAARD, H.

INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: There are indications that vitamin D supplementation can augment the shift from fibre type 2x to 2a in sedentary individuals commencing strength training (1). Theoretically, this would increase muscular endurance due to the larger endurance capacity in 2a. The purpose of the present study was to test whether vitamin D supplementation per se affects the fraction of fibre type 2x compared to placebo, during winter months, in trained persons who simply continues their exercise regime.
METHODS: It was a double blinded study with exercise trained participants who were randomized to a placebo group or an intervention group ingesting 2000 IU vitamin D per day for 12 weeks, during winter in Norway. The number of participants that completed the study were 24 in the control group and 29 in the vitamin D group. Gene expression of muscle fibre types as well as muscular maximal strength and muscular endurance (number of repetitions to exhaustion at 50% of maximal strength load) in upper- and lower-body exercises were measured pre and post the study period.
RESULTS: Vitamin D supplementation increased the vitamin D level in blood, with an effect of intervention of 36.1 nmol/L (vitamin D vs placebo, 95% CI: 33.5 to 38.6 kg). Gene expression of myosin heavy chain 2x did not change (-0.2 percent points, 95% CI: -2.3 to 2.0) and merged analysis of the results from all maximal strength exercises showed no effect of vitamin D supplementation over placebo (0.0 kg, 95% CI: -21.0 to 21.0). Merged analysis of the results from all muscular endurance exercises showed no significant effect of the intervention, although the vitamin D group had an increase from 27.6 ± 12.4 to 31.6 ± 12.5 repetitions compared to a decrease from 31.4 ± 15.2 to 31.0 ± 14.5 repetitions in placebo from pre to post (4.4 repetitions difference, 95% CI: -3.4 to 12.1).
CONCLUSION: This study do not support the notion that vitamin D supplementation entail a shift from fibre type 2x to 2a in trained persons. However, based on the numerical values from the muscular endurance results, one might not exclude an effect at the protein level despite no changes in gene expression of fibre type 2x.

ASSOCIATION BETWEEN POLYMORPHISMS IN VITAMIN D PATHWAY-RELATED GENES, VITAMIN D STATUS, MUSCLE MASS AND FUNCTION: A SYSTEMATIC REVIEW

KRASNIQI, E., BOSHNJAKU, A., WAGNER, K.H., WESSNER, B.

UNIVERSITY OF VIENNA

INTRODUCTION: An association between vitamin D level and muscle-related traits was reported frequently [1]. Vitamin D level is dependent on various factors such as season, latitude, age, clothing style, skin pigmentation, air pollution, as well as nutrition and supplementation, but also genetic factors [2]. We therefore hypothesize that Single Nucleotide Polymorphisms (SNPs) in vitamin D pathway-related genes (DHCR7, CYP2R1, CYP3A4, CYP27A1, GC, PTH, LRP2, CUBN, CYP27B1, CYP24A1, VDR, RXRA, RXRB, CASR) could contribute to muscle mass and function via an impact on vitamin D level. As a consequence, the aim of this project was to systematically review the current evidence on the association between the before mentioned genes, vitamin D status, muscle mass and function.
METHODS: This systematic review was registered on PROSPERO, available at http://www.crd.york.ac.uk/PROSPERO/display_record.php?ID=CRD42018117989. It was conducted following PRIMSA guidelines [3]. Selection was limited to articles published in English or German, in peer-reviewed journals, conducted in healthy adults or matched healthy controls. For the identification of all articles related to vitamin D pathway genes, the respective NCBI entry in the gene database was first linked to the SNP database of each gene and then to PubMed. The single SNPs were then linked to various aliases related to vitamin D level and/or muscle mass and strength.
RESULTS: The selection criteria were met by 68 studies (58 cross-sectional and 10 intervention studies), of which 56 detected an association between vitamin D level and a certain genotype. Significant associations were reported for 53 different SNPs located on 9 different vitamin D-related genes. GC, CYP2R1 and VDR genes were reported most frequently to have an impact on vitamin D level. With respect to muscle function, 13 cross-sectional studies could be selected and all of them focused on the VDR gene. Furthermore, 10 studies reported a positive association with muscle strength and/or performance. In detail, associations have been found for rs7975232 (2 studies reporting $p<0.05$ with muscle strength), rs1544410 (4 studies reporting $p<0.05$ with muscle strength, 1 study reporting $p<0.05$ with muscle strength and function, while 1 reporting $p<0.01$ with muscle strength), rs2228570 (3 studies reporting $p<0.05$ and 1 reporting $p<0.0001$ with muscle strength).

CONCLUSION: To the best of our knowledge, this systematic review presents the newest update of the association of vitamin D related genes polymorphisms and vitamin D status, and the only one focusing on healthy adults. These data could be used in various ways: (1) to use the identified SNPs as candidate genes for further studies, (2) to identify individuals at a potential risk and (3) to optimize potential interventions, but further studies are warranted to validate the results of this systematic review.

AN ANTI-OBESITY EFFECT OF FUCOXANTHIN SUPPLEMENTATION AND LOW INTENSITY/VOLUME EXERCISE IN DIET-INDUCED OBESE MICE.

YOSHIKAWA, M.1, OKUBO, S.1, OKA, A.1, KIRIYAMA, C.1, MURAI, H.2, HASHIMOTO, T.1
1.RITSUMEIKAN UNIVERSITY, 2.ORYZA OIL & FAT CHEMICAL CO.,LTD.

INTRODUCTION: Conventionally, long-term nutrition/exercise regimens are necessary to gain good results for lifestyle diseases, however large number of people drop out during the program (Miller et al., 1997). Especially, regimens for obese patients need to combine aerobic exercise with dietary restriction, while it may be difficult for patients to continue these programs. In addition, dietary restrictions to attenuate obesity may decrease muscle mass (Heilbronn and Ravussin, 2003). Therefore, development of a nutrition/exercise program reducing fat with sustainable exercise without dietary restrictions is thought to be important against obesity. Fucoxanthin (FX), a carotenoid that found in edible seaweed, has the suppressing effect of adipocyte differentiation (Maeda et al., 2006), in addition to radical scavenging activity, anti-oxidant effects and anti-inflammatory effects. In addition, FX and its metabolite induce lipolysis in human white adipocytes (Rebello et al., 2017). Moreover, FX suppresses lipid accumulation through the phosphorylation of AMP-activated protein kinase (AMPK) and acetyl coenzyme A carboxylase (ACC) in mature adipocyte (Kang et al., 2012). In vivo study, Hosokawa et al. demonstrated that dietary FX attenuates fat gain in mice (Hosokawa et al., 2010). Thus, FX can be expected to have an anti-obesity effect. To further advance such effect of FX, we tried to combine FX and "sustainable exercise" in terms of feasibility (i.e., low intensity/volume exercise). The aim of this study was to investigate the effects of combined FX treatment with low intensity/volume exercise on diet-induced obese mice.
METHODS: After 6 weeks acclimation period, ICR mice were classified into four groups: Control group (CON), Fucoxanthin group (FX), Exercise group (EX), and combine exercise with fucoxanthin group (FX-EX). The mice ran on a treadmill for 20minutes, at 10m/min with 0°inclination. The exercise program consisted for 4 weeks, 3 times per week. The mice in the FX and FX-EX group were provided with FX (0.2%) diets for 4 weeks. All exercise mice were restrained from exercise 48 hours before sacrifice. The weights of visceral fat, subcutaneous fat and muscle were measured.
RESULTS: There was no significant difference in body weight between the groups. Visceral fat mass in the FX group and FX-EX group were significantly lower than those in the CON group and EX group ($p<0.01$). However, there was no significant difference between the groups in the subcutaneous fat mass. TA mass in the FX group was significantly higher than that in the CON group ($p<0.05$).
CONCLUSION: These results suggest that FX induces drastic decrease in visceral fat mass without decrease in muscle mass in diet induced obese mice. Thus, FX may have a significant anti-obesity effect irrespective of combination with low intensity/volume exercise.

DIETARY CARNOSINE INTAKE IMPROVES OUTCOMES IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

SPAAS, J.1, FRANSSEN, W.1, VANMIERLO, T.1, BOGIE, J.1, DERAVE, W.2, EIJNDE, B.O.1
(1) HASSELT UNIVERSITY, (2) GHENT UNIVERSITY

INTRODUCTION: Carnosine (C9H14N4O3) is a naturally occurring dipeptide synthetized from histidine and beta-alanine that is mainly found in excitable tissues such as skeletal muscle and the central nervous system (CNS). In the sports community, increasing skeletal muscle carnosine content through dietary beta-alanine supplementation is a popular strategy to boost high-intense exercise performance. In the CNS, carnosine serves versatile functions that may protect glia/neurons and preserve homeostasis (e.g. antioxidant, anti-glycation, reactive aldehyde quenching). We investigated the effect of carnosine treatment in Experimental Autoimmune Encephalomyelitis (EAE), an animal model for CNS neuroinflammation and demyelination that mimics multiple sclerosis (MS).
METHODS: To induce EAE, female C57/BL6 mice were actively immunized with MOG35-55 followed by i.p. injection with pertussis toxin. Mice receiving carnosine (0.3%, 1.5%, or 3%) in their drinking water were compared with mice receiving normal tap water. All mice were sacrificed 56 days post immunization.
RESULTS: Dietary carnosine intake (3%) reduced clinical EAE severity compared to controls, 0.3% carnosine and 1.5% carnosine. Immunohistochemistry revealed a reduced number of T lymphocytes (CD3+) and microglia/macrophages (F4/80+) in the spinal cord. TNF-alpha mRNA abundance decreased and brain-derived neurotrophic factor (BDNF) increased in animals treated with 3% carnosine.
CONCLUSION: Carnosine treatment effectively reduced clinical EAE severity, which was paralleled by changes in bio- and histochemical analyses. As such, the application of carnosine reaches beyond the sports community. Future research is warranted to unravel the underlying mechanisms of carnosine treatment for neuroinflammatory and demyelinating disorders.

A COMPARISON OF THE EFFECTS OF THREE TYPES OF COMMERCIAL BOTTLED TEA BEVERAGES ON EXHAUSTIVE EXERCISE-INDUCED FATIGUE IN ACTIVE MEN

LIN, H.Y., CHANG, W.H.
KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: There is growing evidence that supplementation with foods rich in polyphenols that have antioxidant and anti-inflammatory properties may improve the recovery from exercise-induced fatigue. Green tea and its extracts have been the focus of much research over the past decades (1). Whether similar effects can be observed in other types of tea? In addition, most recreational athletes drink commercial bottled tea beverages before a workout in Taiwan. Hence, the purpose of this study was to compare the effects of 3 types of commercial bottled tea beverages consumption on endurance performance and exhaustive exercise-induced fatigue in active men.
METHODS: The study was a randomized cross-over intervention trial. Ten healthy active males were randomly assigned to either control (water) or three commercial bottled tea beverages (black tea, green tea, and oolong tea; Coca-Cola Company). They were instructed to

drink 1 bottle (580 mL) of the beverage daily at any time. Each intervention period was for 3 weeks, separated by a 1 week washout period. On the day of time-to-exhaustion exercise test, subjects consumed 5 ml/kg body weight of all beverages and 60 minutes later they were required to run for 30 minutes on a motorized treadmill at 70% HRR, then raise the speed 1 km/hr every minutes until they became exhausted. Blood samples were obtained before, at exhaustion, 30 and 60 minutes after exercise. We evaluated two key parameters: 1) exercise performance: rated perceived exertion (RPE) score was recorded every 3 min during exercise and time to exhaustion; 2) biomarkers of exercise-induced fatigue: blood glucose, creatine kinase (CK), and ammonia. Statistical analyses were performed using IBM SPSS version 20. Comparisons between the groups were evaluated by two-way ANOVA and LSD post hoc tests.
RESULTS: No significant main effect of group was observed for the time to exhaustion, but tea consumption groups showed slightly higher endurance performance than the control group (oolong vs. green vs. black vs. water: 35.7 ± 0.52, 35.6 ± 0.38, 35.3 ± 0.29, 34.7 ± 0.41 min, respectively). During exhaustive exercise, RPE score was significantly lower in oolong tea (oolong vs. water: 11.8 ± 0.61 vs. 13.6 ± 0.61 at 30 minutes, p = 0.048) and green tea (green vs. water: 13.1 ± 0.77 vs. 15.4 ± 0.73 at 32 minutes, p = 0.037) group than the control group. However, blood glucose, CK, and ammonia levels showed no significant differences among the four groups.
CONCLUSION: Consumption of one bottle of commercial tea beverages per day for 3 weeks might help to reduce mental fatigue and have the potential to improve endurance performance. The study suggested that oolong tea was more effective than green tea, black tea appeared least useful.

SUPPLEMENTATION WITH PEQUI OIL DOES NOT INDUCE BLOOD PRESSURE REDUCTION IN NORMOTENSIVE MEN AFTER STRENGTH TRAINING

DUTRA, M., LEITE, M., SANTOS, A., CARVALHO, D., ARAÚJO, L., NEMER, L., BARROS, M., JACOB, P., FEITOSA, R., DANTAS, R., MOTA, M.

FEDERAL INSTITUTE OF EDUCATION, SCIENCE AND TECHNOLOGY OF BRASILIA, IFB, BRAZIL; UNIVERSITY CENTER OF BRASÍLIA, UNICEUB, BRAZIL

INTRODUCTION: Pequi (Caryocar brasiliense) is a typical fruit of the Brazilian cerrado. The oil in its pulp contains natural antioxidants, such as different carotenoids and oleic and palmitic acids. The increase in the intake of these fatty acids is related to the reduction of blood pressure (BP). However, literature is scarce regarding the effect of pequi oil supplementation on BP responses after strength training. The aim of this study was to analyze the effect of pequi oil supplementation on systolic (SBP) and diastolic (DBP) blood pressure after a strength training session.
METHODS: Twelve normotensive, recreationally trained men (21.1 ± 2.6 years, 77.0 ± 10.5 kg, 24.3 ± 1.9 kg / m², 117.4 ± 8.5 / 68.0 ± 9.5 mmHg) were submitted to supplementation with pequi oil (400mg / day) for 14 days. Both before and after this period, volunteers performed 4 sets of 4-6 reps at 80% of 1 RM in the bench press exercise. A 1-minute rest interval between sets was adopted, with 2-second pacing in the concentric phase and 4 in the eccentric phase. BP was evaluated in 7 moments in the two exercise sessions: rest, immediately after exercise, at 10, 20, 30 and 40-min recovery, as well as 24 h after the session. Two-way ANOVA for repeated measurements with SIDAK treatment was used to analyze SBP and DBP response at all times in the two exercise sessions. P ≤ 0.05 was adopted and all analyzes were performed using SPSS 25.0.
RESULTS: At both pre (+10.6 mmHg, P = 0.03) and post-supplementation sessions (+13.1 mmHg, P = 0.02), SBP presented an increase immediately after exercise in relation to resting values. At pre-supplementation session, SBP presented a significant reduction at 10 min of recovery in relation to the moment immediately after the session (-18.2 mmHg, P = 0.02). In the session after the supplementation period, this result was repeated at 40 min of recovery (-17.0 mmHg, P = 0.02). After 14 days of supplementation, DBP presented a reduction (-11.8 mmHg, P = 0.03) at 30 min of recovery in relation to the moment immediately after the session. However, there was no significant reduction of SBP and DBP in relation to resting values at any time in both sessions. When comparing the two sessions, a significant difference was identified only at 10 minutes after exercise, with SBP (+6.3 mmHg, P = 0.04) and DBP (+5.1 mmHg, P = 0.02) being higher in the post-supplementation session.
CONCLUSION: Supplementation with 400 mg / day of pequi oil for 14 days is insufficient to induce reductions in SBP and DBP after a strength training session. Yet, it is relevant to note that BP reductions after exercise are more pronounced in hypertensive patients, which is not the case of the present investigation. Future studies are necessary for a better comprehension about pequi oil supplementation in the context of strength training.

EFFECTS OF A BRANCHED-CHAIN AMINO ACIDS-ALANINE- SUPPLEMENTATION INTAKE IN HIGH INTENSITY ENDURANCE CYCLING TESTS

GERVASI, M., SISTI, D., AMATORI, S., DONATI ZEPPA, S., ANNIBALINI, G., PICCOLI, G., VALLORANI, L., ROCCHI, M.B.L., BARBIERI, E., CALAVALLE, A.R., AGOSTINI, D., STOCCHI, V., SESTILI, P.

UNIVERSITY OF URBINO

INTRODUCTION: Sports nutritional supplements containing branched-chain amino acids (BCAA) have been, although not univocally, reported to improve psychological and biological aspects connected to central fatigue and performance in endurance exercise. Here we sought to determine, in a randomized double-blind placebo-controlled study, whether the intake of a commercially available BCAA-based supplement, taken according to manufacturer's recommendation, affects the rating of perceived exertion (RPE) and performance, at the beginning (1d) and at the end of a 9-weeks (9w) scheduled high intensity interval training.
METHODS: To this end a reliable high intensity endurance cycling (HIEC) test was used. In parallel with RPE, haematological values (creatine kinase, alanine, BCAA, tryptophan and glucose levels), diet habits, performance indexes (maximal oxygen consumption - VO2max, power at lactate thresholds - WLT1, WLT2 and time to exhaustion - TTE) and training load (Training Impulse - TRIMP), were assessed during the HIEC tests and training period.
RESULTS: The administration of the supplement (SU) significantly reduced RPE compared to placebo (PL) at 1d and 9w; at 9w, prolonged supplement intake improved also TTE and TRIMP. SU intake invariably promoted a rapid increase (within 1 h) of BCAA serum blood levels

and prevented the post-HIEC tryptophan:BCAA ratio increase found in PL group, at both 1d and 9w. Diet habits of the participants neither differed between groups nor changed over time; no difference in glycemia was found between SU and PL. VO2max, WLT1 and WLT2 values ameliorated over time, but were unaffected by supplement intake.
CONCLUSION: On the whole these results suggest that i) the intake of the BCAA-based commercially available supplement used in this study reduces RPE as a likely consequence of a favourable handling of serum tryptophan:BCAA ratio; ii) over time, reduced RPE allows to sustain higher workloads, leading to increased TRIMP and TTE; iii) HIEC test may represent a valid and sensitive method to quantify the actual efficacy of sports supplements to help training outcomes.

ACUTE EFFECT OF CAFFEINETED GUM ON SWIMMING SPRINT PERFORMANCE AND SUBSEQUENT INTERVAL SESSION

GUGLIELMO, L.G.A., SERPA, M.C., DE OLIVEIRA, M.F.M., DE LUCAS, R.D.

FEDERAL UNIVERSITY OF SANTA CATARINA, FLORIANÓPOLIS, SANTA CATARINA.

INTRODUCTION: Caffeine is a substance widely used among athletes to improve performance and reduce fatigue. Its ergogenic effect has been studied in different modalities and types of exercise, such as short duration (up to 2 min) and long duration (time to exhaustion) exercises (1). The mechanisms proposed for each type of exercise are not yet clear. Thus, the aim of the present study was to analyze the acute effects of the caffeine chewing gum supplementation in the performance of 50m and muscle force production during interval exercise of aerobic capacity of freestyle swimming.
METHODS: Ten trained swimmers (27 ± 10 years) performed all out efforts of 200m and 400m to determine the critical swim speed (CS). In randomized and double-blind trials, the subjects completed 50m on separate days (with 300mg caffeinated gum or placebo gum), followed by a set of 10 x 200m (1st to 5th intervals with intensity of CS and 6th to 10th self-paced intervals). During the protocol, before and after the 50m trials, as well as in the interval set (before, middle and after) the peak isometric torque was assessed with a swim bench ergometer (Weba Sport, Austria) on the dominant arm. The blood lactate concentration [La] was measured after the use of caffeinated gum (passive recovery), immediately following the freestyle sprints (50m), before and after 200m repetitions (1st, 3rd, 5th, 6th, 8th and 10th).
RESULTS: The average CS was 1.25 ± 0.1 m.s-1. The results showed that caffeine improved the 50m performance (28.18 ± 1.31s vs. 28.70 ± 1.21s; p = 0.004) in comparison to placebo. However, no condition-time interaction was found for blood lactate concentration [La] (p = 0.435) and muscle strength (p = 0.0304). Besides, the average interval set time was significantly lower with caffeine ingestion compared to placebo condition (158.68 ± 7.67s vs 160.93 ± 7.04s; p = 0.03). In the interval set, a significant difference between caffeine and placebo was observed for the average values of [La] (7.84 ± 1.67 mmol.L-1 vs 6.99 ± 1.63 mmol.L-1; p = 0.03). There were no significant differences between the two conditions for the average muscle force measurement (15.37 ± 1.83 kgf vs 15.20 ± 2.11 kgf, p = 0.26).
CONCLUSION: Overall, caffeine improved swimming sprint performance (i.e. 50m), despite resulting in a similar muscle strength decrement, when compared to placebo. It is important to observe that caffeine intake by chewing gum improved the interval set performance (10 repetitions of 200m), thus demonstrating an influence on swimming performance during interval exercise. These findings prove ergogenic effects and better swimming efficiency, suggesting that caffeine may have a central effect on adenosine receptors and a glycolytic pathway modulation.
1. Lara B, Ruiz-Vicente D, Areces F, et al. Acute consumption of a caffeinated energy drink enhances aspects of performance in sprint swimmers. Br J Nutr. 2015;114(06):908-914. doi:10.1017/S0007114515002573Abstract format

ASSOCIATION OF GENETIC POLYMORPHISMS WITH THE THERAPEUTIC EFFECTS OF IRON SUPPLEMENTATION IN ATHLETES WITH LOW IRON RESERVES

WANG, C.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: To investigate the influences of genetic polymorphisms in the therapeutic effects of iron supplementation in athletes with low iron reserves.
METHODS: 72 Shanghai athletes were recruited to assess their dietary iron intake and analyze their serum concentrations of Hb and SF. Athletes with SF<40ug/dl were chosen to take iron supplementation. We tested the serum concentrations of Hb, SF and CRP before and after the iron intervention, and checked the genetic polymorphisms before the intervention.
RESULTS: (1) Forty out of 72 athletes had serum SF levels below 40ug/dL; (2)There were significant positive correlations between SF level and dietary iron intake(r=0.250,p<0.05), and between Hb level and dietary iron intake(r=0.465,p<0.001); (3)Although there was no significant changes in Hb levels (p>0.05),SF level improved significantly(p<0.05). Sixteen out of 40 athletes failed to improve SF level after taking iron supplementation; (4) in each genotype CC,CT and TT on rs4901474 site of BMP4, CC homozygous genotype was significantly increased after taking iron supplementation (p<0.01). The risk of heterozygote of T on rs4901474 was 4.333 times higher than homozygote of C(p<0.05,OR=4.333,95%CI 0.978-19.20）. There was no significant difference in the distribution frequency of each genotype and alleles on rs855791,rs4820268of TMPRS6 and rs173107 of BMP2 in SF ascending group and SF descending group(p>0.05).
CONCLUSION: (1)Shanghai female athletes have insufficient dietary iron intake and low iron reserves;(2)exogenous iron intake is one of the main methods to prevent athletes from low iron reserves and iron deficiency anemia;(3) the polymorphisms on rs4901474 of BMP4 gene may have influences on the effects of iron supplementation intervention. The athletes carrying CC homozygous genotype showed more significant effects of iron supplementation on iron storage levels, while those carrying heterozygote of T showed no significant effects.

EFFECT OF CREATINE SUPPLEMENTATION ON NEUROMUSCULAR FATIGUE WHEN CYCLING ABOVE CRITICAL POWER.

SCHAEFER, L., HAYES, M., DEKERLE, J.

UNIVERSITY OF BRIGHTON

INTRODUCTION: Only recently have studies combined the critical power (CP) concept with neurostimulation techniques to further understand the neurophysiological limits of high-intensity exercise. A positive correlation between an individuals anaerobic work capacity (W) and changes in neuromuscular function have been reported (Schäfer et al., 2018). Creatine supplementation might allow to challenge this relationship by increasing an individuals W and investigating its effect on neuromuscular fatigue using neuromstimulation techniques. Therefore, the present study examined the effect of creatine supplementation on neuromuscular fatigue and exercise tolerance when cycling above CP.

METHODS: Eleven recreationally active male participants performed an incremental cycling test to determine E'O2peak, 4-5 constant-load trials to task failure to calculate CP and W', followed by three constant-load supra-CP trials set to fully deplete W' in 3 min: 1) to task failure following placebo supplementation (PLA); 2) to task failure following creatine supplementation (CRE); and 3) for an equal duration as during PLA following creatine supplementation (ISO). Neuromuscular function assessment of the right knee extensors was performed pre- and post-exercise to measure maximal voluntary contraction (MVC), twitch forces evoked by single (Qpot) and paired high- (PS100) and low-frequency (PS10) stimulations and voluntary activation.
RESULTS: Creatine supplementation increased time to task failure compared to PLA (205 ± 65 s versus 184 ± 46 s; P = 0.017) but led to similar reductions in MVC (PLA: 20 ± 9 versus CRE: 24 ± 8%), evoked twitch forces (Qpot, 32 ± 14 versus 39 ± 13%; PS10, 36 ± 13 versus 42 ± 14%; PS100, 18 ± 12 versus 25 ± 10% for PLA and CRE, respectively) and voluntary activation (PLA, 5 ± 7 versus CRE, 7 ± 8%) compared to PLA (P > 0.05). Further, no significant difference in neuromuscular changes were found between ISO versus PLA or CRE (P > 0.05).
CONCLUSION: These findings suggest that similar changes in neuromuscular fatigue can be found following cycling exercise above CP to task failure regardless of the amount of work done above CP.

EFFECTS OF EXOGENOUS KETONE SUPPLEMENTATION AND COOLING ON SUBSTRATE METABOLISM AND EXERCISE PERFORMANCE IN ACTIVE HEALTHY MALES

CLARK, D., MUNTEN, S., GAGNON, D.D.

LAURENTIAN UNIVERSITY

INTRODUCTION: Nutritional fueling strategies and thermodynamic manipulation are some key tactics to increase human performance. Independently, both supplementation of exogenous ketone bodies, under the chemical form of monoesters, and whole-body cooling have shown to increase physical performance (1,2,3). Whether more readily available ketone salts would provide similar benefits is unknown. The present study examined the efficacy of nutritional ketone salts, with and without whole-body cooling during steady state (SS) aerobic and time-trial (TT) performances.
METHODS: Nine healthy active males (age, 22.6 ± 1.5 yrs; weight, 73.2 ± 4.9 kg; height, 174.3 ± 7.3 cm; BF %, 13.2 ± 2.56%; VO2peak = 56.25 ± 2.23) participated in three experimental exercise sessions preceded by: 1) the ingestion of a placebo drink for control (CON), 2) ketone salt supplementation (0.3g/kg of β-OHB) (KET), and 3) ketone salt supplementation with whole-body cooling of 0.5°C (KETCO). Pre-exercise conditions lasted 30 min. Then participants cycled for 30 min at 60% Wmax, which was immediately followed by a 15-min time trial. Venous blood was collected at baseline (BL), at the end of the pre-exercise condition (PRE), after aerobic test (AT), and after the time trial (TT). Indirect calorimetry was used to assess substrate oxidation variables during exercise.
RESULTS: Blood β-OHB was significantly elevated in KET and KETCO conditions vs. CON at PRE, AT, and TT ($p<0.05$). Blood glucose was lower in the KET and KETCO group vs. CON at PRE only ($p<0.005$). Blood lactate was also lower in KET and KETCO vs. CON ($p<0.001$). For both SS and TT, VO2 was lower in the KETCO group vs. KET and CON. While power not different between conditions ($p=0.112$), RQ was higher in KETCO vs. other conditions, indicating a greater reliance on carbohydrates during TT.
CONCLUSION: The increase in β –OHB seen in the present study, leading to an increase in Acetyl-CoA/Co-A ratio should have theoretically inhibited the use of glucose and, combined with body cooling, increase reliance on fat metabolism, and possibly physical performance. Ketone salts supplementation only marginally increased (0.8 +/- 0.14 mmol/L) whereas ketone ester supplementation may increase blood β –OHB levels 4 fold (1). This discrepancy in ketone chemical form, and ultimately its impact of blood levels, seem to point towards the need of a large increase in blood β –OHB levels to clearly influence physical performance.

EFFECT OF RHYTHMIC LOWER LIMB MOVEMENTS ON THE PERFORMANCE OF MULTI-LIMB RHYTHMIC MOVEMENT

QI, W., KATO, K., NAKAJIMA, T., KANOSUE, K.

WASEDA UNIVERSITY

INTRODUCTION: Good performance for rhythmic movements is important for sports and music performance. Examples include clapping the hands and walking. The production of two independent rhythms with multiple limbs is considered to be very difficult (Fidali, Poudrier, & Repp, 2013). In the present study we evaluated the effect of different rhythmic lower limb movements on the independency of rhythm-keeping of multi-limb rhythmic movement.
METHODS: Twenty subjects performed rhythmic finger tapping with the right index finger and one of five different lower limb movements on a treadmill; 1) self-paced walking, 2) stepping, 3) walking by only right foot while kept left foot out of the belt of the treadmill, 4) walking by only left foot while kept right foot out of the belt of the treadmill and, 5) bilateral heels striking from a sitting position. The target intervals of finger tapping and heel strikes for walking step/heel striking were set at 375 ms and 600 ms, respectively. The even distribution of relative phases ($\phi = 360° \times (tf - ti)/(ti+1 - ti)$, in which the time interval between two consecutive heel strikes or finger tapping at ti and ti+1 was defined as one cycle (360°) (Haken, Kelso, & Bunz, 1985)) between instantaneous finger tapping and heel strike was taken as the criteria of independency for the two rhythms.
RESULTS: Results shows the CV of lower-limb movement in bipedal heels striking task was significantly higher than those of all the other tasks ($p < .05$). In the normalized distribution of relative phase of all the task except bipedal heels striking task, there was no significant difference among all the bins in the histogram. On the other hand, the significantly higher proportion of distribution around 0° and 180° were shown in the bipedal heels striking task ($p < .05$).
CONCLUSION: The present study shows the difficulty to produce multi-limb rhythmic movement in sitting position and this suggests that there are separate neural control mechanisms for finger tapping in the supra-spinal locus and for walk-liked movements in the spinal cord.

RELATIONSHIP BETWEEN PITCHING ACCURACY AND MUSCLE ACTIVITIES IN SKILLED BASEBALL PITCHERS

KUWATA, M.1, MIKI, T.2, NASU, D.2, IJIRI, T.1, KOBAYASHI, H.1, NAKAZAWA, K.1

(1) THE UNIVERSITY OF TOKYO, (2) NTT CORPORATION

INTRODUCTION: Pitching accuracy is one of key factors in order to put out a batter for baseball pitchers. In previous studies it was reported that skilled throwers have higher reproducibility of finger movement in the throwing arm than unskilled throwers (1). On the other hand, participants with less throwing errors acquired coordinated motion patterns to compensate the variability at ball release in the process of motor learning with underhand throw (2). The present study aimed to examine whether muscular activities during pitching would show the high reproducibility or rather flexible patterns in skilled pitchers.
METHODS: Eleven skilled baseball pitchers (9 college pitchers, 2 former professional pitchers; 24.7 ± 8.0 years, 2 left-handed) participated in this study. Pitchers performed 20 throws to the catcher's mitt (target) as accurately as possible. The catcher held the mitt at down and away (e.g. in the case of right-handed batter, the mitt was located left and downside from pitcher's view). Ball speed and pitching location was measured by Trackman. Wireless surface electrodes were used to record 16 muscle activities in throwing arm, shoulder, trunk, and lower limbs (2 kHz). Pitch errors were evaluated by using 95% confidence ellipse and the area was calculated as an index of pitching accuracy. Electromyographic (EMG) activities of each muscle were rectified and aligned at the ball release which was detected by a high speed camera from pitcher's side (420 fps), and coefficient of variation (CV) between -190 to 0 ms (from foot contact of lead leg to the ball release) was calculated as the variability of each muscle activity. Pearson product-moment correlation-coefficient was calculated between the area and the CV of each muscle.
RESULTS: There were significant negative correlations between the CV of flexor carpi ulnaris (FCU; $r = -0.755$, $P < 0.01$), triceps brachii (TB; $r = -0.744$, $P < 0.05$) in the throwing arm and the area of pitch locations, meaning that the pitchers whose muscle activities in the throwing arm are more variable tend to show the higher accuracy. Regarding the trunk muscle activities, on the other hand, there was a tendency that the CV was positively related to the size of area, meaning those pitchers who have the lower variability in the trunk muscle activities have the higher accuracy.
CONCLUSION: Out results suggest that in skilled baseball pitching the accurate pitching control is realized with the highly reproducible activities in trunk muscles and with rather flexible activities in the throwing arm muscles. It seems that the skilled pitchers firstly stabilize the larger parts of their body, trunk and lower limbs, and then just before the ball release they finely adjust their throwing arm motion to accurately control pitch locations.

DEVELOPMENT OF THE IMMERSIVE 3D-VR TRAINING SYSTEM FOR ENHANCING SPORTS VISION IN SPIKE RECEIVE - THE EFFECT VERIFICATION OF HAND-EYE COORDINATION -

YUKI, H., SHIMPEI, A., RYOTA, T., HIROYASU, I.

WASEDA UNIVERSITY,GRADUATE SCHOOL OF CREATIVE SCIENCE AND ENGINEERING

INTRODUCTION: It is known that Hand-Eye-Coordination (HEC) is the one of the most significant function in the sports field, on the other hand, there are few devices to train HEC. The spike receive of volleyball demands accurate positon and angle of arms. Therefore, we aimed to develop a volleyball spike receive training system by using 3D-VR. It is the representative sport that required HEC function [1]. The users receive spike in the VR, and the system provides visual biofeedback to them [2]. In this study, we conducted the verification test of this system through the training, and evaluated HEC related indexes.
METHODS: A. Development of the system
In the spike receive, it is necessary to react to the ball (1)quickly and (2)accurately. Therefore, we developed training system that (1)exhibiting of images reproducing the spike receive and (2)providing the ideal posture(e.g. the angle of the arms) by visual biofeedback to the user.
B. Training method
Based on theory of motor-learning, we constructed training method. The training program is composed of the order of blocked practice and random practice. In the blocked practice, the ball is attacked from only one direction of either front, left or right in 3D-VR environment. In the random practice, the ball is spiked from three directions in a random manner. It is said that these two practices can be effective for motor-learning [3].
C: Validation of effect by using device
We conducted trial by the above method to observe the training effect by using our system with a pre-post study. Participants were 10 healthy adult people who were beginners of volleyball (age:21.9±1.1years). In pre-test phase and post-test phase, the participants tried blocked test and random test whose settings are the same as intervention phase. As an indicator, we selected the error between the angle of arms at receive and the ideal angle of the arms.
RESULTS: In the blocked test, the mean of the angle error of the arms significant decreased ($p=0.016$). However, in the random test, the mean of the angle error of the arms did not significant changed.
CONCLUSION: We developed the system which aimed to improve the spike receive skill by using 3D-VR. As a result of validation, it suggested that our device can improve accuracy of angle of arms. On the other hand, our device was not enough to improve quickness of them.

COMPARISON OF MUSCLE ACTIVITY AND MUSCLE FATIGUE DURING RUNNING EXERCISE ON NON-MOTORIZED TREADMILL, MOTORIZED TREADMILL AND OVERGROUND.

JANG, J.S., KWON, T.D., PARK, G.D., YOON, S.D., KIM, S.Y., HYEONG, J.H., ROH, J.R.

KYUNGPOOK NATIONAL UNIVERSITY, KEIMYUNG COLLEGE UNIVERSITY, KOREA INSTITUTE OF INDUSTRIAL TECHNOLOGY.

INTRODUCTION: This study was to measure the muscle activity and muscle fatigue of the trunk and lower extremity muscles during running on the Non-motorized Treadmill, Motorized Treadmill and Overground.
METHODS: A compared muscle activity and muscle fatigue during exercise with a constant distance of self-selected constant velocity from a non-motorized treadmill, motorized treadmill and overground exercise in 15 healthy 20s.
RESULTS: First, muscle activity of Erector spinae was higher in the order of Non-motorized Treadmill, Overground and Motorized Treadmill, but there was no significant difference. Also, there was no significant difference in muscle fatigue. Second, the muscle activity of the Rectus abdominis muscle was higher in the order of Overground, Non-motorized Treadmill, and Motorized Treadmill. There was a significant difference in muscle fatigue between the exercise condition ($p < .05$) and the interaction effect ($p < .05$), but fatigue was induced in the Motorized Treadmill, but there was no significant difference. Third, muscle activity of Gluteus maximus was higher in the order of Non-motorized Treadmill, Overground and Motorized Treadmill, and there was a significant difference at the time of exercise ($p < .05$). Fatigue did not show any significant difference in all conditions. Fourth, muscle activity of the Rectus femoris was higher in the order of Motorized Treadmill, Overground and Non-motorized Treadmill, and there was a significant difference at the time of exercise ($p < .05$). The muscle fatigue showed a significant difference at the time of exercise ($p < .05$). Fifth, muscle activity of Biceps femoris was higher in the order of Non-motorized Treadmill, Overground and Motorized Treadmill, and there was a significant difference at the time of exercise ($p < .01$). There was a significant difference at the time of exercise in muscle fatigue ($p < .05$), and fatigue was not induced in all exercise conditions. Sixth, muscle activity of the Tibialis anterior was higher in the order of Motorized Treadmill, Overground and Non-motorized Treadmill. There was a significant difference at the time of exercise ($p < .01$), and exercise condition ($p < .05$). Fatigue did not show any significant difference in all conditions. Seventh, muscle activity of the Soleus was higher in the order of Non-motorized Treadmill, Motorized Treadmill and Overground. There was a significant difference at the time of exercise ($p < .01$), and exercise condition ($p < .001$). There was a significant difference at the time of exercise in muscle fatigue ($p < .05$).
CONCLUSION: This study suggests that the characteristics of each exercise condition are understood by comparing the muscle activity and muscle fatigue during Non-motorized Treadmill, Motorized Treadmill and Overground, In future studies, more data will be collected by using various age groups and various speeds. Based on this, we will be able to present effective exercise.

ELECTROMYOGRAPHIC ANALYSIS OF DIFFERENT CYCLIC LOCOMOTION IN HUMAN

SHPAKOV, A., VORONOV, A., ARTAMONOV, A., PUCHKOVA, A., ORLOV, D.

RESEARCH INSTITUTE OF SPACE MEDICINE OF THE FEDERAL RESEARCH CLINICAL CENTER

INTRODUCTION: The purpose of the study was to study the electromyographic characteristics of cyclic human locomotion in various conditions.
METHODS: In the period 2007-2019 research involved cosmonauts before and after long-term space flight (SF) on the ISS (n=18); volunteers in ground-based dry-immersion model experiments (DI) (n=21); anti- (HDBR) and orthostatic hypokinesia (HUBR) (n=30); under various conditions of the weight load on the musculoskeletal system (MSS) (n=48). As the test exercise used walking on a treadmill at a pace of 60, 90, 120 steps/minute, running at a speed of 10 km/h and load test on a bicycle ergometer. In studies with a modified weight load on the MSS, the creation and regulation of the weight load 70, 38, 16% of body weight support (BWS) was carried out by the method of vertical hanging. We registered electromyographic activity (EMG-A) of mm. Vastus lat., Rectus fem., Biceps fem., Tibialis ant., Soleus, Gastrocnemius med. and analyzed the shape of the EMG during double step cycle, the maximum amplitude of the EMG (EMG-max), electromyographic cost (EMG-cost), the spectral characteristics of the EMG.
RESULTS: In studies involving cosmonauts, the effectiveness of various training regimes for cosmonauts on a treadmill during SF was evaluated by the biomechanical parameters of walking. Comparison of results before and after SF showed that interval training in the alternating mode of intense running and walking prevents an increase in EMG-cost of locomotion during SF and provides more efficient preservation of the neuromuscular functions after SF. The study of EMG characteristics of locomotion in ground-based model experiments with DI, HUBR and HDBR showed that being in these conditions was accompanied by the development of pronounced changes in EMG-A walking after experimental exposure. Any form of hypokinesia (HDBR or HUBR) affects the intermuscular coordination of not only gravity-dependent muscles, but also flexors of the ankle and knee joints. Significant changes in the values of joint angles during first peak phase indicated a decrease contractile properties of leg muscles and increase the "physiological cost" of walking. The EMG-max of the legs muscles during running with 70% BWS decreased compared with running at 100% BWS. For TA, Sol and BF, the reduction was 12%, with no change in GM. In VL and RF, the EMG-max decreased by 36% and 49% respectively. The registration of the EMG during the bicycle ergometric test allowed to make a conclusion about of leg muscle fatigue during the test. The results of the spectral analysis of EMG in all studies performed confirmed changes of EMG shape in the double step cycle, EMG-max and EMG-S.
CONCLUSION: The use of electromyographic analysis in a complex of highly informative technical means makes it possible to more effectively and qualitatively assess changes in the functional state of the MSS in various conditions of activity.

ACUTE EFFECTS OF DIFFERENT EXERCISE MODALITIES ON ANKLE FORCE SENSE IN YOUNG AND OLD ADULTS

SMAJLA, D., GARCÍA-RAMOS, A., TOMAŽIN, K., STROJNIK, V.

UNIVERSITY OF LJUBLJANA

INTRODUCTION: Ankle force sense is important component for maintaining balance during functional activities such as standing, walking, and running. Due to declines in the somatosensory system with ageing, ankle force control could be even more important for older adults. Performing different exercise modalities may acutely alter ankle force sense. The purpose of this study was to determine how different exercise modalities acutely influence ankle force sense in young and older adults.
METHODS: In total, 17 students of Faculty of Sports (23,5±1,9 years) and 15 older adults (67,1±1,8 years), volunteered the study. All participants were physically active people. Before measurements, they performed a familiarization protocol. After that, each of them visited the laboratory 4 times. Each visit contained measurements before and after intervention protocol. Between measurements, subjects performed randomly selected intervention protocols (static stretching, one-leg balance task, concentric contractions, and rest-control). Inter-

vention protocols were designed to target the ankle joint. In static stretching, they performed 6 static stretches (40 s) for each muscle (soleus, gastrocnemius and tibialis anterior). Concentric contractions were performed for ankle plantarflexion and dorsiflexion (30% RM, 25-30 rep.), while balance task contained one leg stance on Airex mat (4x4x20 s).
Force sense test was performed unilaterally at 10% and 30% of the MVC. MVC was measured 15 min before force sense measurement to avoid potentiation. During the force sense test, participants were asked to perform 5 s long isometric contractions in plantar and dorsal direction. First repetition at each force level was performed with visual information, while second was performed without visual information.
Absolute errors of force sense test were calculated for each target force and each direction. Relative absolute error was calculated (%AE=AE/target force, PF10%, PF30%, DF10%, DF30%, PF-AVG, DF-AVG, PF-DF-AVG) to match younger and old adults. The normal distribution assumption (Shapiro-Wilk test) and homogeneity of variances (Mauchly's sphericity test) were confirmed ($p>0.05$). A mixed model analysis of variance (ANOVA) with Bonferoni post hoc corrections was applied on each dependent variable. In case of ANOVA significance post hoc tests were calculated to confirm differences occurred between groups and interventions.
RESULTS: The time × exercise interaction was significant for DF 10%, PF-AVG, DF-AVG, PF-DF-AVG. Stretching had significant negative influence on force sense acuity in both groups ($p<0.05$), while concentric contractions reduced ankle force sense acuity only in older group ($p<0.05$). Balance task didn't induce any significant changes.
CONCLUSION: The main outcomes of the study revealed similar negative influence of static stretching on ankle force sense in both groups, while concentric contractions affected only older group. This should be considered when different consecutive exercise modalities are performed.

LEARNING ADVANTAGES OF AN EXTERNAL RELATIVE TO AN INTERNAL FOCUS INSTRUCTIONS IN CHILDREN WITH HIGH AND LOW LEVELS OF MOTOR IMAGERY ABILITY

ABDOLLAHIPOUR, R.1, BAHMANI, M.2, BABAK, M.2, LAND, W.M.3

1: PALACKÝ UNIVERSITY OLOMOUC, OLOMOUC, CZECH REPUBLIC, 2: KHARAZMI UNIVERSITY, TEHRAN, IRAN, 3: UNIVERSITY OF TEXAS AT SAN ANTONIO, SAN ANTONIO, USA

INTRODUCTION: Experimental studies have shown the beneficial effects of an external relative to an internal focus of attention for performance and learning of different types of motor tasks and in different populations (Wulf, 2013). Nonetheless, research has yet to examine whether this finding holds true for individuals with different levels of motor imagery ability. Research has demonstrated quicker motor skill acquisition in high ability relative to low ability imagers (Goss et al., 1986), which may impact the effectiveness of attentional focus instructions (Kuhn et al., 2017; Lebon et al., 2012). The purpose of the present study was to examine the effects of internal versus external focus instructions on learning of a motor task in children with high or low levels of motor imagery ability.
METHODS: Motor imagery ability was determined by the movement imagery questionnaire – children (MIQ-C). One-hundred and ninety-one subjects (M = 10.13., SD = .65 years) completed the MIQ-C. From this initial pool, only fifty-two children (M = 10.15, SD = .74 years) with 1 SD above (high) or below (low) the average motor imagery scores were recruited for inclusion in the study. Children with high or low levels of motor imagery ability were pseudo-randomly assigned to either internal or external focus groups. The participants in each group were asked to perform 60 trials of an overhand throwing task with their non-dominant hand under either internal (i.e., focus on your throwing arm) or external (i.e., focus on the ball) focus instructions on day 1. A retention test without providing any attentional focus instructions was conducted on day 2.
RESULTS: The results from the manipulation check revealed high adherence to the respective attentional focus instructions for each group. Results indicated that the external focus group was significantly more accurate in their tosses than the internal focus group in both practice ($p = .007$) and retention ($p = .002$), regardless of motor imagery ability. Also, children with a high level of motor imagery ability performed better than the children with a low level of motor imagery ability during retention ($p = .023$), regardless of attentional focus instructions.
CONCLUSION: These findings suggest that an external, relative to internal focus instructions, facilitates motor performance and learning in children independent of imagery ability. As such, imagery ability does not moderate the benefit of an external focus (Wulf, & Lewthwaite, 2016).

AGE AS A MODULATOR OF PHYSICAL EXERCISE EFFECTS ON LEARNING A PERCEPTUAL-MOTOR TASK

FERRER-URIS, B., BUSQUETS, A., ANGULO-BARROSO, R.

INSTITUT NACIONAL DEDUCACIÓ FÍSICA DE CATALUNYA

INTRODUCTION: Acute physical exercise enhances cognitive learning, improving both phases, adaptation and consolidation, of the learning process 1. Recently, an intense but short acute exercise bout (iE) has been observed to also stimulate motor learning in adults 2 and children 3, especially during consolidation. However, whether age could modulate the iE benefits on motor learning is not known. This study's aims were to examine adult versus children differences in: (1) their rotational visuomotor adaptation task (rVMA) baseline performance, (2) their performance during the learning of the rVMA, (3) the effect of the iE on their rVMA learning process, and (4) the effect of iE and rVMA presentation order on their learning.
METHODS: Twenty-nine adults (21.2±1.9 years) and 33 children (9.0±0.9 years) participated in the study. Participants in each age cohort were randomly divided into 3 groups: exercise before learning, exercise after learning, and only learning. All participants engaged in 5 rVMA practice sets: a baseline set without rotation (BA); an adaptation set (AD) where the visual perception of the task on the screen presented a 60º rotation with respect to the hand movement; and three 60º rotated retention sets (RTs) at 1 hour, 24 hours and 7 days after AD. For each trial, the initial directional error at 80ms after the movement onset was measured. Error values for AD and RTs were normalized based on the individual performance during BA. Group x Age ANOVAs were used to analyze the performance during BA and AD sets. The effect of exercise during RTs was analyzed using a RM-ANOVA (Set x Group x Age).

RESULTS: Adults presented lower error values compared to children during BA (p<0.001) and AD (p<0.001). The iE did not enhance AD neither in children nor in adults for any group condition (p=0.228). Children and adult errors were different during RTs when exercise was not implemented (p=0.006). However, during RTs, iE enhanced motor performance (p=0.010), especially in children. In addition, the iE effect was greater when exercise was performed before (d=0.879) than after (d=0.607) the rVMA compared to not exercising, especially in children.
CONCLUSION: It seems that acute physical exercise enhanced motor consolidation in adults and children. These improvements seemed to be stronger in children, reducing the initial relative performance gap when compared to adult participants. Furthermore, the relative performance differences between control adults and children were further narrowed when exercise was presented before the motor learning task. In contrast, intense exercise had a null effect on motor adaptation for adults or children. These results may have implications for exercise based learning interventions.

CROSS-ACTIVATION LEVELS OF QUADRICEPS MUSCLE DURING UNILATERAL CONCENTRIC AND ECCENTRIC KNEE ISOKINETIC CONTRACTIONS

ERASLAN, L., DEMIRCI, S., ULUSOY, B., YILDIZ, T., HARPUT, G., BAYRAKCI TUNAY, V.
HACETTEPE UNIVERSITY, DEPARTMENT OF PHYSIOTHERAPY AND REHABILITATION.

INTRODUCTION: Unilateral strength training can increase strength not only in the trained muscle but also in the homologous muscle of the contralateral limb [1]. Furthermore, forceful unilateral contraction of the limb did indeed produce cross-activation of contralateral limb was shown in upper limb [2]. However, cross-activation level of contralateral limb during varying contraction types (concentric or eccentric) is still missing. The primary aim of this study was to investigate the cross-activation level of the quadriceps muscle during unilateral concentric and eccentric knee extension isokinetic contractions.
METHODS: 43 healthy individuals randomly divided into two groups. Group 1 (n=22) was performed unilateral concentric knee extension contractions. (mean age: 22.6±1.2 yrs.; BMI: 22.5±2.74 kg/m2), while Group 2 (n=21) (mean age: 22.3±1 yrs.; BMI: 23.2±2.8 kg/m2) performing eccentric knee extension exercise bouts, using an isokinetic dynamometer at 60°/s angular velocity. Prior to procedure, subjects' non-dominant limb was fixed using a non-elastic strap at 90° knee flexion, and subjects were instructed to keep their contralateral limb as released as possible during testing. Then, group 1 was instructed to exert 1 set of 10 repetitions of maximal concentric while Group 2 performed 1 set of 10 repetitions of maximal eccentric efforts on their dominant limb through the range of motion from 10° to 90° (0°= full knee extension). While the groups were performing concentric or eccentric exercise bouts, the electromyography (EMG) activation of the vastus medialis (VM), vastus lateralis (VL) and rectus femoris (RF) muscles was recorded from an unexercised contralateral limb by using a surface EMG. Maximum voluntary isometric contraction was used to normalize EMG activation of the quadriceps muscle. Independent samples-t test was used for statistical analysis.
RESULTS: There was significant difference between groups in VM, RF, and VL activation levels of non-dominant limb during dominant limb isokinetic contractions (p<0.05). When compared to Group 1, cross-activation levels of VM ((Group 1= 9.4±3.8%); (Group 2= 33.8±7.7%); p=0.002), RF ((Group 1= 7.4±2%); (Group 2= 17.5±4.8%); p=0.023), and VL ((Group 1= 10.3±6.7%); (Group 2= 37.5±10.3%); p=0.005) muscles were greater in group 2 when compared to group 1 during dominant limb isokinetic contraction.
CONCLUSION: The results of this study showed that during eccentric quadriceps muscle contractions, there was a greater VM, RF, and VL cross-activation levels than the concentric contractions. The activation levels on the untrained limb were very closed the EMG activation threshold for muscle strengthening during eccentric contractions. These findings may support the eccentric cross-education provides a greater strength gain than the concentric ones in untrained limb.

BILATERAL CHARACTERISTICS IN STRAIN OF ILIOTIBIAL BAND AND LOWER EXTREMITIES ALIGNMENT IN MIDDLE-DISTANCE RUNNERS

KIM, D.1, MIYOKAWA, S.2, FUKUDA, T.2, TAKEMURA, M.2
UNIVERSITY OF TSUKUBA

INTRODUCTION: Running-related injuries occurred on the same side of the body. Indeed, bilateral imbalances in strength, alignment, or gait mechanics induce soft and bone tissue to increase stress (1). Throughout a track and field competition, middle-distance (MD) athletes run counterclockwisely on a track. This rule seems to become more vulnerable on the left lower limb. Iliotibial Band Syndrome (ITBS) is well-known as one of the running related injuries (2). Recent studies suggested that abnormal increase of compression force between the iliotibial band (ITB) and lateral femoral epicondyle causes irritation and inflammation to tissues under the ITB, and excessive strain of the ITB increases the compression force (3). Also, lower extremities alignment developing the ITBS. The purpose of this study was to examine the difference of the strain and the alignment in lower extremities ITB between the right and left side in MD runners
METHODS: Seven healthy male distance runners volunteered in this study (Year: 21.2±0.9). We measured lower extremities' alignment and the strain of the ITB bilaterally. Q-angle, Leg heel angle (LHA), pelvic width, arch height, and hip external/internal rotation range of motion (ROM) were accessed. The strain of the ITB was measured using real-time tissue elastography (HI VISION Preirus; Hitachi Medical, Ltd., Japan) in 3 positions (Standing; S, side-lying neutral; N, side lying with knee flexion; KF). Independent t-test was used to examine the difference of between the right and the left side. To determine the relationship of the strain of ITB and alignments, Pearson's correlation coefficient was used.
RESULTS: Comparing between the right and left side, the strain of the ITB on the left side showed significantly greater than that of the right side in N position (p=0.019). The left side of hip internal rotation ROM was greater than the right side (p=0.007). The only left side showed a significant positive correlation between the strain of the ITB and the alignment in the same side (N position and Q-angle (r=0.774, p=0.041), KF and LHA (r=0.764, p=0.046)).
CONCLUSION: The strain of the ITB and the ROM in hip internal rotation in the left side were greater than those on the right side. In a previous study, injured runners had greater hip internal rotation range of motion in comparison with uninjured side of uninjured runners

(4). Running around the field counter-clockwisely may overload on either lower extremity, therefore track & field runners should run clockwisely. We also found that a significant correlation of ITB stain and alignment has shown to indicate the left side, but not the right side, suggesting that a malalignment occurring in the lift side related to one of injury risk factors.

EFFECTS OF PROGRESSIVE RESISTANCE TRAINING ON MUSCLE FUNCTIONS, BODY COMPOSITION, GROWTH FACTORS, AND PRO-INFLAMMATORY CYTOKINE IN HEALTHY ELDERS

TSAI, S.H., SUN, W.H., LIN, C.T., CHANG, H.C., LIU, H.W.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Aging is associated with problems such as loss of muscle mass, obesity, and chronic inflammation. These problems could increase the risks of chronic diseases, falls and mortality. Previous studies have shown that resistance trainings can increase muscle mass and improve physical performance. However, whether progressive resistance training has beneficial effects on body composition, growth factors, and pro-inflammatory cytokine is unclear. Therefore, the purpose of this research was to investigate the effects of a 12-week progressive resistance training on muscle functions, body composition and blood parameters in healthy elders.
METHODS: Eight healthy elders (aged 67.6±2.5yrs, heights 156±6.5cm, and body weights 56.4±7.5 kg) participated in the 12-week progressive resistance exercise program (3 times/week; three sets, 50%–70% of 1RM). Muscle functions, body composition and blood parameters were measured before and after training. The progressive resistance training program consisted of major muscle groups twice a week and minor muscle groups once a week. At least one day off between each training session. The intensity, repetitions and the rest time between sets were adjusted along with the period. Chest press 1RM was measured on the third week and the last week of the training program.
RESULTS: After the 12-week intervention, muscle functions including chest press 1RM and hand grip strength (+21kg and +3.3kg, respectively) were significantly improved when compared with the baseline ($p<0.05$). In comparison, neither body composition (body fat and muscle mass) nor blood parameters (insulin, IL6, IGF-1 and TG) were significantly different after the intervention.
CONCLUSION: The results of this study suggest that the 12-week progressive resistance training improves muscle functions, but does not affect body composition and blood parameters in healthy elders.

CORRELATION BETWEEN AEROBIC CAPACITY AND BALANCE IN BLACK AFRICAN WOMEN FROM A LOW-RESOURCED COMMUNITY IN SOUTH AFRICA

TAMULEVICIUS, N.1, OVIEDO, G.R.2,3, PHIDZA, M.3, CAMERON, M.4, MOSS, S.J.3
1: THE UNIVERSITY OF TAMPA, TAMPA, FLORIDA, USA, 2: UNIVERSITY RAMON LLULL, BARCELONA, SPAIN, 3: NORTH-WEST UNIVERSITY, POTCHEFSTROOM, SOUTH AFRICA, 4: UNIVERSITY OF SOUTHERN QUEENSLAND, AUSTRALIA

INTRODUCTION: Physical activity (PA) and Aerobic Capacity (AC) are essential components in the prevention of illness and improvement of health (1,2). Balance improvement is associated with decreased risk and fear of falling and improvement in quality of life (3,4). Furthermore, balance exercises have shown to improve AC in clinical populations such as people with osteoarthritis (5). It is unclear whether there is a correlation between AC and dynamic and static balance (DB; SB) in black women from a low-recourced community in South Africa. The aim of this study was to assess the correlation of the aerobic capacity (VO2Peak) and balance in this population.
METHODS: A total of 89 sedentary black women (age=55±11.4y, BMI=31±7.6) participated in the "B-Healthy" project. AC was assessed using the metabolic step test (Metalyzer 3B, Cortex, Leipzig, Germany); dynamic balance was assessed using the timed "Up and Go" test (TUG), the single leg stand test (SLST) was used to assess the ability to stand successfully on a single leg and a balance platform (HUMAC Pressure Platform; Stoughton, MA, USA) was used to assess postural sway of the center of pressure (COP). Pearsons r correlation was used to evaluate the associations between VO2Peak, DB, SB and COP displacements.
RESULTS: Absolute and relative VO2Peak (absolute VO2Peak=1.56±0.35 L/min and relative VO2Peak=20.99±5 ml/kg/min) significantly correlated with DB (r=-0.363; r=-0.415; all $p<0.05$) and SB (right leg: r=0.275; r=273; all $p<0.05$; left leg: r=0.284 and r=0.294; all $p<0.05$). No significant correlation were reported between absolute or relative VO2Peak and the COP displacements (r=-0.074 and r=-0.195; all $p>0.05$).
CONCLUSION: Our findings indicate that higher fitness levels in sedentary women is associated with better dynamic and static balance. Future PA interventions in similar populations should include a combination of aerobic and balance exercises.

EXERCISE INTENSITY AND ENERGY EXPENDITURE OF THE ELDERLY DURING A PETANQUE GAME

CHEN, H.W.1, CHEN, H.Y.2, PENG, H.T.1

CHINESE CULTURE UNIVERSITY, TAIWAN

INTRODUCTION: According to the definition of the World Health Organization, the proportion of the elderly population in Taiwan has exceeded 14% in 2018, and it has become an "aged society". It not only represents the result of demographic changes, but also accompanies medical care issues, and even affects the economy of the whole society. Functions of physiological and musculoskeletal system of the elderly declines with aging making inconvenience of daily life and risk of falling. For the elderly, exercises can maintain physiological functions and balance and slow down the aging process. Petanque is an exercise which needs coordinated movement and stratagem, and is suitable for the elderly (Chen, 2008). The purpose of this study was to explore the exercise intensity and energy expenditure of the elderly when playing Petanque to provide information for the public as a basis for sports.
METHODS: Twenty elderly people (68.27±4.16 years old, 163.72±7.63 cm, 64.55±10.47 kg) voluntarily participated the study. They were suitable for exercises with doctors' permission, have more than half a year of Petanque experiences and played Petanque at least three days a week. The signed informed consent was obtain from them before the experiment. ActiGraph physical activity devices (GT9X, ActiGraph, Florida, US) were worn on the wrist of a non-dominant hand by subjects during a three-on-three Petanque game held for an hour. They were not allowed to sit down during the game. Walking step, exercise intensity, and energy expenditure were calculated by an ActiLife software (ActiLife 6.11.5, ActiGraph, Florida, US) . Statistical analysis was performed using a SPSS 23.0 statistical software. All values were expressed as mean and standard deviation.
RESULTS: During the one-hour Petanque game, the average walking step was 1364.77±384.09 steps, and the average energy expenditure was 117.46±39.14 kcal. The exercise intensity was only 1.91±0.39 METs. It was lower than walking (3.23±1.04 METs, 3.2km/hr) (Ho, 2017), Yuanji dance (3.46 METs) (Chung, Wu & Lin, 2005), and Taiji quan (4.04 METs) (Brown, Mucci, Hetzler & Knowlton, 1989). An average of 74.82% of the one-hour Petanque game was low-intensity exercise and there was no period of high-intensity exercise.
CONCLUSION: This study explored that the three-on-three game of Petanque for one hour was just a low-intensity exercise. It could be practiced for longer time compared with other sports to encourage the elderly to think and socialize with people during the Petanque game.

EFFECTS OF A HEALTH PROMOTION PROGRAM FOR OLDER ADULTS IN THE HANDGRIP STRENGTH TEST COMPARED TO THE GENERAL POPULATION

RÍO-DE FRUTOS, X.1,2, GONZÁLEZ-PÉREZ, A.2, LARRINAGA-UNDABARRENA, A.1,2, COCA, A.1

1: UNIVERSITY OF DEUSTO, 2:PHYSICAL ACTIVITY AND HEALTH DEPARTMENT OF MUGIKON

INTRODUCTION: The strength work currently represents the most recommended primary therapeutic strategy to prevent and reverse the decline of muscle mass, strength, and functional deterioration associated with age (Morley et al., 2014). The aim of this study is to compare handgrip strength test (HST) data from active older adults engaged in a health improvement program, with normative values of the general population in the same age ranges (Dodds et al., 2014).
METHODS: 1,869 subjects from the health program for older adults of the Bilbao City Council were evaluated with the HST measured with a dynamometer. Average values of the HST were obtained in 5 years age ranges. From the 1,869 subjects, 87.5% were women and 12.5% were men. 7.86% had < 70 years, 18.78% of 70-74 years, 30.18% of 75-79 years, 31.57% of 80-84 years and 11.61% = 85 years. The mean body mass index (BMI) was 28.48 (4.17) for women and 28.07 (3.43) for men.
RESULTS: Sample (n) and population (N) averages were obtained in the different age ranges (55-59 = 1, 60-64 = 2, 65-69 = 3, 70-74 = 4, 75-79 = 5, 80-84 = 6, 85-89 = 7, 90-94 = 8) and sex (W = women and M = men). The men age ranges 1, 2 and 8 were eliminated since there was only one subject in the group. The means were 1 = n (W:24.7) and N (W:27.5); 2 = n (W:23.5) and N (W:26.5); 3 = n (W:22.4; M:37.4) and N (W:25.3; M:42.3); 4 = n (W:21.7; M:34.6) and N (W:23.5; M:39.1); 5 = n (W:20.1; M:32.7) and N (W:21.4; M:35.6); 6 = n (W:19.3; M:31.9) and N (W:19.1; M:32.2); 7 = n (W:17.9; M:29.0) and N (W:16.6; M:28.5); and 8 = n (W:17.4) and N (W:14.2). The Cohens d effect size as the standardized mean difference between n and N using the standard deviation of N due to the large sample size was calculated. The results were as follows: 1 = W (-0.44); 2 = W (-0.48); 3 = (W:-0.49; M:-0.53); 4 = (W:-0.32; M:-0.55); 5 = (W:-0.24; M:-0.38); 6 = (W:0.03; M:-0.04); 7 = (W:0.28; M: 0.07); and 8 = (W:0.72).
CONCLUSION: Physical activity as part of a health promotion program seems to be effective in obtaining better values in the HST as we grow older compared to the general population, especially in women. These findings suggest that the cutting values to detect the sarcopenia could be delayed and even avoided reaching them.

EIGHT-WEEK OF NEUROMUSCULAR ELECTRICAL STIMULATION TRAINING IMPROVES MUSCLE STRENGTH AND REDOX HOMEOSTASIS IN OLDER MALE INDIVIDUALS

JANDOVA, T.1, BONDI, D.1, DI FILLIPPO, E.S.1, MARRONE, M.1, VERRATTI, V.1, MANCINELLI, R.1, NARICI, M.V.2, FULLE, S.1, PIETRANGELO, T.1

1UNIVERSITY OF G. DANNUNZIO CHIETI AND PESCARA, 2ISTITUTO DI FISIOLOGIA UNIVERSITÀ DI PADOVA, ITALY

INTRODUCTION: Sarcopenia is associated with both strength losses, affecting in particular the quadriceps muscle group [1], and with impaired regenerative capacity of muscles, mostly as a result of increased production of superoxide anions ($O_2^{\bullet-}$) [2]. In this study, we investigated whether 8-wk neuromuscular electrical stimulation (NMES) training of the quadriceps could reverse/mitigate the loss of strength that is associated with sarcopenia and improve muscle redox homeostasis.
METHODS: 20 healthy older males (10 control and 10 trained, aged 65≥years) were recruited for this study. Volunteers trained 3 times/wk for 8 weeks using a NMES device (Genesy 1200 Pro; Globus) for 18 mins in total with 40 passive isometric bilateral contractions set to a maximum-tolerable intensity corresponding to the individual's pain threshold. Pre- and Post- maximum voluntary isometric contraction (MVIC) was assessed by dynamometry and redox status was analysed using fibre fragments obtained through needle biopsy [3] from vastus lateralis by 1) spectrophotometric nitro blue tetrazolium chloride assay for production of superoxide anion ($O_2^{\bullet-}$); by 2) antioxidant

enzyme assays for analysis of superoxide enzyme (SOD) and catalase (C) and by western blotting for the expression of superoxide enzyme 1 (cytosolic) and 2 (mitochondrial) (SOD1, SOD2). Mean values +/-SD were analyzed using repeated-measures ANOVA (MVIC) and paired t-test (redox analyses - trained group).
RESULTS: NMES training significantly increased MVIC by 4.5% (p=0.009). Intracellular O2•- levels (pre-post) did not change. No significant differences were also observed in pre-post SOD and SOD1, however, there was an observed tendency for a decrease in the expression of SOD2 albeit not significant (p=0.09) after NMES. C activity decreased significantly by 40% (p=0.0005) post NMES.
CONCLUSION: The present results support the use of NMES for combating sarcopenia in the elderly as it promotes muscle strength gains. Moreover, observed significant reduction in catalase activity along with the non-significant tendency for a decrease in the expression of SOD2 suggests improved redox homeostasis of the muscle most likely as a result of changes in satellite-cell niche induced by NMES training.

EFFECTS OF SHORT TERM KETTLEBELL EXERCISE ON THE MUSCLE OF LOWER LIMB AND WALKING FUNCTIONS OF ELDERLY WOMEN.

GI DUCK, P., SEONG HYEON, P., TAE DONG, K., SEONG DEOK, Y., DONG HUN, S.
KYUNGPOOK NATIONAL UNIVERSITY, KEIMYUNG COLLEGE UNIVERSITY.

INTRODUCTION: The purpose of this study was to find out about the effects of short-term Kettlebell exercise on the lower body strength and walking functions of the elderly in order to prevent injuries such as physical activity of the elderly due to rapid aging society.
METHODS: The study was conducted 3 times a week for 6 weeks on local elderly women aged 65 or older. Kettlebell weights ranging from 4 to 8 kg were used for Kettlebell deadlifts as well as Kettlebell double arm swings, which are appropriate weights for female beginners. It is important to note that all participants were under minimal physical strain and if at any point the exercise had caused them too much pain, it was stopped immediately. The same number of sets (a total of five sets) was set for each exercise. For the lower body strength test of the participant, the lower core function test (measurement of standing on the chair) was performed. The OptoGait consists of two 1m long receive bars and a webcam (Logitech Webcam Pro 9000), each bar has 96 light-emitting diodes (Light Emitting Diode): While the subject walks between two parallel bars, the two-foot support, the Gait cycle, the Live unit, and the Walk speed.
RESULTS: The results of the application of the Kettlebell movement are as follows. The test result increased from the previous 11.90 (rep) of the athletic group to 15.10 (rep). The walk-through test did not produce any statistically significant differences in all measurement categories, but the numerical difference was insignificant in the group of movements.
CONCLUSION: The conclusions suggest that short-term kettle-bell motion is an effective exercise for women of the elderly, and that for the walking function it is necessary to verify more clearly the effects through additional re-measurements.

THE VARIATION IN PERCEPTION OF FATIGUE IN ELDERLY

SAITO, Y.1, KAKIHANA, W.2
1> KANAZAWA SEIRYO UNIVERSITY, 2> ISHIKAWA PREFECTURAL NURSING UNIVERSITY

INTRODUCTION: A symptom-limited exercise test is widely used for the purpose of customizing exercise program. However, the age-related decline of physiological functions may widen the gap between subjective fatigue and physiological fatigue especially in elderly. The purpose of the present study was to investigate the variation in perception of fatigue in 70s-elederly.
METHODS: Thirty one 70s-elderly, who had never experience exercise test before, underwent the incremental cycling test until reaching to Borg scale subjective rating of 17, "Very hard." The exercise began with a 4-minute warm-up at 20 W at 60 rpm followed by 1-W incremental loading every 6 seconds. Verbal encouragements were given to the subjects during the test. Brachial systolic blood pressure and heart rate (HR) were continuously monitored throughout the test with an automatic indirect manometer. From the product of these parameters, we calculated the double product breaking point (DPBP) according to Tanaka et al. [1]. Ventilatory threshold (VT) was also calculated from VO2 and VCO2 by the V-slope method[2]. Nine subjects who could not continue the test until the end point were excluded from the analysis. In the present study, the ratio of peak HR observed to age-predicted maximal HR was defined as the index of physiological fatigue. Remaining 22 subjects (73.4±0.5 years, means±SE) were divided into the fatigue group (n=11) and the less fatigue group (n=11) based on the index data for the later analysis.
RESULTS: No differences were observed in age and age-predicted maximal HR between the groups. However, peak HR observed during the test was higher in the fatigue group than in the less fatigue group（$p<0.05$）. Therefore, the fatigue index was higher in the fatigue group than in the less fatigue group（$p<0.05$）. However, there were no differences in the exercise time, DPBP, peak VO2 and VT between the groups.
CONCLUSION: Both groups did not show any differences in the exercise performance and the endurance parameters. However, the less fatigue group achieved the similar results as the fatigue group by lower HR. The former group might quit the test on the stop although they had enough energy to continue the test. Our data suggested that the ability to perceive fatigue might differ substantially in 70s-elderly.

PLASMA NOREPINEPHRINE LEVEL AND LIFESTYLE HABITS IN KOREAN ELDERLY PEOPLE WITH ORTHOSTATIC HYPOTENSION

KIM, N.

KEIMYUNG UNIVERSITY COLLEGE OF NURSING

INTRODUCTION: Orthostatic hypotension (OH) is manifested as a result of autonomic nervous system dysfunction. However, few studies have examined the physiological parameters and lifestyle habits related to OH. This study aimed to identify the differences of plasma Norepinephrine (NE) level and lifestyle habits (e.g. physical activity and sleep quality) between Korean elderly with and without OH.
METHODS: In a cross-sectional study, 114 elderly people aged > 65 were recruited in a South Korean city. The convenience sampling methods were employed, and data were collected using (1) participants' blood samples for plasma NE level, and (2) questionnaires to assess lifestyle habits (i.e. Korean version of Physical Activity Scale for the Elderly (K-PASE) and Pittsburge Sleep Qualty Index (PSQI). Using SPSS 21.0, our data were analyzed by descriptive analysis, t-tests, and Pearson's correlation tests.
RESULTS: The plasma NE level was significantly higher in the OH group than in the non-OH group (t=-2.298, p=.023). Regarding lifestyle habits, the OH group performed significantly less physical activity compared to the non-OH group (t=2.735, p=.007). Moreover, the sleep quality of the OH group was significantly poorer compared with the non-OH group (t=-5.390, p<.001). Higher plasma NE level was associated with less physical activity (r=-.155, p=.023) as well as poor sleep quality (r=.172, p=.011).
CONCLUSION: Our study showed that the pathophysiology of OH in the elderly population may involve a high plasma NE and poor lifestyle habits. These findings provide further understanding of the OH phenomena and highlight the need for interventions including the control of plasma NE along with the personalized educations for physical exercises and good sleep patterns.

THE EFFECTS OF UNSTEADY SLOPE TREADMILL WALKING ON PHYSIOLOGICAL RESPONSES DURING UNSTEADY WORKLOAD EXERCISE IN THE ELDERLY

NISHIMURA, K., TAMARI, Y., NAGASAKI, K.

HIROSHIMA INSTITUTE OF TECHNOLOGY

INTRODUCTION: We hypothesized that adaptability to slope changes would be lower in elderly people compared to younger people. The present study aimed to verify these hypotheses to compare the amplitude and the phase lags in heart rate (HR) and oxygen intake during unsteady slope treadmill walking at the same relative walking speed in the young and elderly as well as to clarify the influence of aging on the adaptability for unsteady slope treadmill walking.
METHODS: Twenty-three elderly (68±4 years) and 14 young (21±1 years) individuals volunteered to participate in the study; they provided written informed consent. Before the experiment, each subject performed a graded treadmill exercise test for calculating their peak oxygen intake (0° slope). All subjects performed a treadmill walking exercise for 32 min. The walking speed was set at 25% of the peak oxygen intake. The exercise tests had two parts: a calibration test (steady-state workload exercise) for 12 min and an unsteady workload exercise test for 20 min. The steady-state workload exercise consisted of 3-4 min bouts of walking exercise at 0°, 8°, and 4° slopes. The unsteady workload exercise test consisted of five periods of exercise with gradual increases and decreases in the workload with the slope ranging from 0°-8°. During one period, a slope of 4° was increased gradually by 1° every 15 seconds; similarly, a slope of 8° was gradually reduced by 1° every 15 seconds until 0° was reached. The participants were instructed to perform a total of 5 periods, at a rate of 4 minutes per period. During the exercise test, HR and oxygen intake were measured. The HR and oxygen intake maximal values, minimal values, amplitude, and phase lag (response to maximal/minimal workload) during unsteady-workload exercise were calculated.
RESULTS: At rest, there were no significant differences in HR between the two groups. However, the ln HF, an index of cardiac parasympathetic nervous modulation, and the oxygen intake were significantly lower in the elderly group. The blood pressure was significantly higher in the elderly group. During exercise, HR at 0° was not significantly different between the two groups. However, HR at 8° and 4° were significantly lower in the elderly group. Oxygen intake was significantly lower in the elderly group at 0°, 8°, and 4°. Both the HR phase lags and the oxygen intake phase lags were significantly slower in the elderly group. The amplitude in HR and oxygen intake were also significantly lower in the elderly group.
CONCLUSION: It is known that the cardiac parasympathetic nervous system attenuates with aging. Therefore, the delay in the phase lags of the HR was caused by attenuation of the cardiac parasympathetic nervous system in the elderly participants. The response in oxygen intake delayed with aging. Thus, the delay in the phase lags in the oxygen intake was mainly due to the delay in response speed caused by aging. In conclusion, the human adaptability to unsteady slope exercise decreases with age.

THE EFFECT OF HIGH INTENSITY INTERVAL TRAINING (HIIT) ON IL-6, HOMOCYSTEINE, AND C-REACTIVE PROTEIN IN MASTERS ATHLETES AND SEDENTARY OLDER MALES

HAYES, L.D., HERBERT, P., SCULTHORPE, N., GRACE, F.M.

UNIVERSITY OF CUMBRIA

INTRODUCTION: Low-grade chronic inflammation increases with age and is exacerbated by physical inactivity. Yet, little experimental evidence exists concerning the influence of lifelong exercise training, and high intensity interval training (HIIT) on proinflammatory cytokines in older males. Therefore, this study investigated whether masters athletes exhibited improved inflammatory markers (interleukin [IL]-6, homocysteine, and C-reactive protein [CRP]) compared to sedentary older males. A secondary aim was to investigate whether 6 weeks HIIT preceded by 6 weeks aerobic preconditioning would affect these parameters.
METHODS: Twenty-two males (62 ± 2 years, with a stature of 175 ± 6 cm, body mass of 91 ± 16 kg, and peak oxygen uptake of 28 ± 6 ml/kg/min) comprised the sedentary group and 17 males (60 ± 5 years, with a stature of 173 ± 6 cm, body mass of 78 ± 12 kg, and peak oxygen uptake of 39 ± 6 ml/kg/min) were enrolled as masters athletes. Participants were tested at three time points (1: Baseline, 2: Following 150 min/week moderate intensity exercise (sedentary group) or maintaining habitual training (masters athletes), and 3: Following six weeks HIIT). HIIT involved 6 x 30 s sprints at 40% peak power output, once every five days). Serum concentrations of IL-6, homocysteine, and CRP were measured by electrochemiluminescent immunoassay.
RESULTS: IL-6, and CRP were lower in masters athletes than the sedentary group(all $P<0.05$), but homocysteine was not different ($P>0.05$). HIIT did not alter IL-6, or CRP in masters athletes(all $P>0.05$). However, homocysteine was greater post-HIIT compared to enrollment

(P=0.023, Cohen's d=0.83). Both preconditioning (P=0.001, Cohen's d=0.34), and HIIT (P=0.001, Cohen's d=0.48) reduced the sedentary groups IL-6 compared to baseline. Homocysteine and CRP were both unaltered in the sedentary group (P>0.05).
CONCLUSION: Results of this study indicate that lifelong exercise results in a reduced inflammatory profile in older males. Moreover, moderate exercise intensity and HIIT results in lower IL-6 in previously sedentary older individuals.

PERIPHERAL TISSUE ADAPTATIONS TO HIGH INTENSITY INTERMITTENT VS. MODERATE CONTINUOUS AEROBIC TRAINING IN SPONTANEOUSLY HYPERTENSIVE RATS

MAURIÈGE, P.1,2, JOANISSE, D.R.1,2, LACAILLE, M.2, KRZESIAK, A.3,4, COGNARD, C.4, BOSQUET, L.3, DELPECH, N.3

INTRODUCTION: Hypertension (HT) is a major risk factor for cardiovascular disease. Although most professional societies promote moderate intensity continuous training (MICT), high intensity intermittent training (HIIT) is suggested to provide greater benefits in reducing pathophysiological aspects of HT (1). However, the choice of a training program remains controversial (2,3). To our knowledge, few data are available on the peripheral tissue-specific effects of chronic exercise in spontaneously hypertensive rats (SHRs), and no study has compared yet the impact of HIIT and MICT at the adipose tissue (AT) and skeletal muscle (SM) levels. The aim of this preliminary study was to compare in male SHRs the effects of HIIT and MICT on retroperitoneal AT (RPAT) and extensor digitorum longus (EDL) muscle. Although both regimens are expected to have beneficial effects on health, we hypothesized that HIIT would lead to greater changes in the expression of factors involved in angiogenesis, fibrosis and extracellular matrix (ECM) remodeling in AT and SM, as well as in blood pressure (BP) regulation.
METHODS: 8-wk-old male SHRs divided into 3 groups of 5-6 animals: Untrained (UT), MICT or HIIT. Rats were trained for 8 wks, 5 d/wk, sessions consisting of 36 min. of running at 70% of Vmax (MICT) or 6 sets of alternating 3 min. sequences at 90% and 50% Vmax (HIIT). Gene expression was assessed by RT-qPCR using L27 as a housekeeping gene (4) from AT and SM samples recovered following training. Selected genes were PGC1-•, HIF-1•, VEGF-• and leptin for angiogenesis; TGF•-1 for fibrosis; metalloproteases (MMP-2/-9) and their respective inhibitors (TIMP-1/-2) for ECM remodeling and angiotensinogen, a specific-AT marker for BP.
RESULTS: Both training modalities limited rat body mass increases and decreased mean BP similarly, compared to UT (0.01 CONCLUSION: The reduced TIMP-2 expression in EDL in response to training attested of some ECM remodeling. The importance of this change remained mitigated, considering the unchanged MMP-2/TIMP-2 ratio. The lack of other changes in gene expression in both EDL and RPAT could be due to the low statistical power and might suggest that exercise interventions were insufficient to elicit adaptive responses in the examined tissues. Further studies in the subcutaneous inguinal AT and the soleus SM are in progress.

THE ASSOCIATION OF ACTN3 R577X POLYMORPHISM WITH ELITE JAPANESE ATHLETE STATUS BY VARIOUS SPORT EVENTS

AKAZAWA, N., OHIWA, N., FUKU, N., KUMAGAI, H., SHIMIZU, K., SUZUKI, Y.

JAPAN INSTITUTE OF SPORTS SCIENCES, JUNTENDO UNIVERSITY

INTRODUCTION: The alpha-actinin-3, located in skeletal muscle Z-line of fast-twitch fibers, regulate muscle function. A common null polymorphism R577X in the alpha-actinin-3 gene (ACTN3) results in its complete absence in fast-twitch muscle. The ACTN3 R577X polymorphism is associated with sprint/power performance in both European (Yang et al. 2003) and Asian athletes (Kikuchi et al. 2016). However, little is known the impact of the ACTN3 R577X genotype on various sports events other than sprint/power-oriented sports. The aim of the present study was to examine the association between the ACTN3 R577X polymorphism and elite Japanese athlete status by various sport event such as sprint/power, martial arts, ball game, racket game, and endurance sports.
METHODS: Subjects consisted of 907 elite Japanese athletes who were all of international level and 649 Japanese controls who were part of previous study (Mikami et al. 2014). We analyzed the genotype frequency of the ACTN3 R577X polymorphism among category of sports in sprint/power (n=138), martial arts (n=102), ball game (n=421), racket game (n=83), and endurance athletes (n=163) by using the TaqMan SNP genotyping assay.
RESULTS: There was a trends of the ACTN3 R577X genotype frequency between different sports type of athletes and control ($P < 0.05$). Sprint/power athletes showed a higher frequency of R-dominant genotype (RR+RX) than control (OR = 1.62, 95%CI 1.01-2.58). Significant higher frequency of RR+RX genotype in sprint/power athlete was observed compared to racket game and endurance athlete (OR = 2.62, 95%CI 1.09-3.89, OR = 1.89, 95%CI 1.09-3.26, respectively).
CONCLUSION: The ACTN3 R577X genotype frequencies are associated with sport event in elite Japanese athlete especially in sprint/power sport, which is demonstrated high frequency of RR+RX genotype.

EFFECTS OF COMBINED TRAINING ON THE EXPRESSION OF GENES RELATED TO BROWNING AND AUTOPHAGY IN SUBCUTANEOUS ADIPOSE TISSUE OF INDIVIDUALS WITH OVERWEIGHT AND TYPE 2 DIABETICS

BONFANTE, I.L.P., MATEUS, K.C.S., DUFT, R.G., DE-LIMA-JÚNIOR, J.C., TROMBETA, J.C.S., FINARDI, E.A.R., LIMA, J.A.B., BRUNELLI, D.T., MORARI, J., CHACON-MIKAHIL, M.P.T., VELLOSO, L.A., CAVAGLIERI, C.R.

UNIVERSITY OF CAMPINAS

INTRODUCTION: Physical training has shown an influence on browning of adipose tissue in animals studies, being regulated by the autophagy process (1,2). The browning and autophagy are related to metabolic improvment and could be used to prevent and treat

some diseases as type 2 diabetes (T2DM) and obesity (1). However, humans studies have shown contradictory results about training and browning process (1). Moreover, the relationship between training, browning, autophagy and glycemic improvement is unknown, even more in a overweight type 2 diabetics population. Thus, this study aimed to evaluate the combined training (CT) effects on glycemic levels and expression of genes related to browning and autophagy in subcutaneous adipose tissue of overweight T2DM individuals.
METHODS: Subcutaneous adipose tissue biopses (waist) and blood samples were obtained pre and post experimental period in both sexes middle-aged overweight T2DM people. The subjects were randomly assigned in combined training group (CTG: n=17; age= 51.10 ± 3.94 yrs; BMI= 29.56 ±3.56 kg/m²) and control group (CG: n=17; age: 52.41± 4.44 yrs; BMI= 29.36 ± 3.32 kg/m²). The training protocol was composed of resistance exercises (30-35 min, 1 to 1.15 min interval), followed by aerobic exercises (35 min in 50-70% of the VO2max) in the same session, performed 3 times weekly, for 16 weeks. Glucose levels were assessed by the GOD-Trinder method and the gene expressions were evaluated by Real-time reverse polymerase reaction by TaqMan system. The probe contained in the target primers related browning, autophagy and the reference gene was the FAM probe. The ANOVA two-way followed Tukey post hoc test were carried out in statistical analysis.
RESULTS: The CTG showed a decrease in glucose levels (p= 0.04) while CG showed an increase tendecy (p= 0.07). In browning genes, TMEM26 increased (p= 0.03) in CTG, as well as CD137 gene that showed an increase effect of time (p= 0.04). In CG a decrease in effect of time was observed for EPSTI1 (p= 0.03) and to increase FNDC5 (p= 0.04). For autophagy genes, the CTG showed decrease in ATG4B (p< 0.01) and a tend to decrease ULK1 (p= 0.06). Differently, the CG presented increase in ATG4B (p= 0.01) and increase tendecy in ULK1 and LC3 (both with p= 0.06).
CONCLUSION: The CT improved glycemic control, and this occurs due to the increase in browning genes and decreasing in autophagy genes. In CG, some genes expression results showed an opposite pattern of observed in CTG, which is accompanied by a tendecy of worse glycemic control. These results give evidence that in humans, training and glycemic levels are related to some markers of browning and autophagy process

IMPACT OF PARTICIPATING TO A 330 KM LONG ULTRA-TRAIL VERSUS A 67 KM SHORT ULTRA-TRAIL ON MUSCULAR AND CARDIAC GENETIC REGULATION BY MICRORNAS.

LE GOFF, C.1, MARGUERIT, K.1, KAUX, J.F.1, CROISILLE, P.2, VIALLON, M.2, MILLET, G.P.3, CAVALIER, E.1, LADANG, A.1

INTRODUCTION: Even though endurance exercise has always shown beneficial action on cardiovascular diseases, the impact of an ultra-endurance experience on the human body has not been studied enough yet. Indeed, the consequences of such effort could represent a major issue to the organism and particularly to the myocardial muscle, could lead to sudden cardiac death when experienced too many times - a phenomenon which is more and more linked to the athletic world. The main objective of this study was to measure the impact of high level physical activity on the expression of different microRNAs such as specific to muscular and cardiac suffering (miR-1, miR 133a and miR 208b), specific to muscular suffering (miR 133b, miR 206, miR 499a and miR 499b) specific to cardiac suffering (miR 208a) and specific to fibrosis (miR 21 and miR 29b).
METHODS: The study was conducted on two different trails participants: the "Tor des Géants" (TDG), 330 km long and the "Ultra Tour de Liège" (UTL), 67km long. Blood samples were collected at different timings. Timing of sampling were respectively: 4 days before starting (t0), after completing 148 km (t2), finish line (t3) and 3 days after the end of the race for the TDG (t4) , and for the UTL : just before the starting (t0), at the finish line(t2) : and 3 hours after finishing (t3). There was a number of 12 TDG studied volunteers and 10 from the UTL. MicroRNAs were extracted by using miRneasy® Serum/Plasma kit and qRT-PCR has been employed to measure their expression.
RESULTS: Only miR-1, miR-133a, miR-133b, miR-206 and miR-499a showed significant variation in their expression during both races. The variation was found to be linked to the exhaustion during the race. From these data, four out of the five miRNAs showed a higher expression level during the shorter trail (UTL). No correlation was found between miR-208a and frequently used cardiac biomarkers (hs-TnT, sST2 and NT-proBNP). No significant variation was found in fibrosis specific microRNAs (miR-21 and miR-29b).
CONCLUSION: From the amount of microRNAs tested, the expression of five of them increased significantly during both the races, which showed myocardial and muscular cellular suffering. Moreover, the levels of miRNA never came back to the baseline during recovery times. However, the fibrotic miRNA did not show any significant increase during in any race, suggesting there was no permanent damage of the heart, but this point needs further investigations.

EVALUATION OF EXERCISE-INDUCED MUSCLE DAMAGE USING URINARY TITIN N-TERMINAL FRAGMENT AT REPEATED BOUT EFFECT

YAMAGUCHI, S., SUZUKI, K., KANDA, K., OKADA, J.
WASEDA UNIVERSITY

INTRODUCTION: Recently, urinary titin N-terminal fragment (TF) was newly considered as the biomarker for evaluating exercise-induced muscle damage (EIMD). Because of the non-invasion of TF on sampling EIMD, it is an excellent biomarker that can dramatically lower the burden on subjects. It has already understood that TF is as sensitive as CK in previous study (1), however, it is remained unknown whether TF is possible to detect the characteristics of EIMD or not. EIMD has a characteristic that subsequent symptom is lighter then initial symptom, which is called "repeated bout effect (RBE)" (2). It was cleared that CK shows a low value with RBE, but we do not know response of TF yet. Therefore, this study aimed to clarify whether TF is a biomarker effective biomarker in detecting repeated bout effect, which is a well-known characteristic of EIMD.
METHODS: Eight healthy young men performed 30 maximal eccentric contractions on elbow flexor on day 1 on first week (Bout1), then performed the same exercise on day 1 of third week (Bout2). The muscle soreness (SOR), range of motion (ROM), maximal voluntary isometric contraction (MVIC), blood and urine samples were collected immediately before, immediately after, 24h, 48h, 72h, 96h, 120h and 144h after each exercise session. Changes in dependent variables were compared between Bout1 and Bout2 using two-way ANOVA.

RESULTS: SOR, STR, ROM and CIR displayed that Bout2 was significantly lower than Bout1 (P <0.05). It was considered that RBE was shown in Bout2. Urinary TF with RBE showed a significantly low value than the initial urinary TF (P < 0.05).
CONCLUSION: We found that TF was able to be a biomarker that can accurately reflect RBE. In the past, while the characteristics of TF remained unknow, it was not clear whether TF has the validity of evaluating EIMD. Therefore, researcher could not measure EIMD using TF alone. However, because of the high correlation between TF and CK which was found in previous study, and present study found that TF could reflect the characteristics of RBE, it can be considerd that TF has almost the same sensitivity and detection effectivity with CK. TF might be able to evaluate EIMD alone in the future.

THE EFFECT OF SWIM EXERCISE ON THE DEXAMETHASONE-INDUCED DECREASE IN SKELETAL MUSCLE MASS AND MITOCHONDRIAL ENERGY METABOLISM IN RATS

FLIS, D.J., CZYRKO, E., RODZIEWICZ, E., JOST, Z., KACZOR, J.J., ZIOLKOWSKI, W.
UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Muscle atrophy results from several pathologic conditions such as diabetes, cancer and chronic obstructive pulmonary disease. Furthermore, administration of synthesized glucocorticoid such as dexamethasone (DEX) also induces a decrease in muscle mass. There are plenty of data indicated that muscle atrophy is related to mitochondrial dysfunction. Interestingly, nutrients, drugs and other factors which may improve mitochondrial function, like physical training might be beneficial in the prevention of muscle atrophy. Therefore, the aim of the study is to investigate the effect of DEX treatment and swimming on the mass of skeletal muscle rich in type I and II muscle fibres and mitochondrial energy metabolism.
METHODS: Male Wistar rats were divided into four groups: non-exercise, saline treatment (S), non-exercise, DEX treatment (D), exercise, saline treatment (E), and exercise, DEX treatment (ED). The rats were injected with DEX for 9 days. Since the 6th day of treatment, the animals in the E group were trained for 4 days to reduce the stress of swimming. Each day during the preparatory procedure, the rats swam for 30 min in water at 35°C. On the 10th day, rats underwent long-lasting swimming. The rats swam for 3 hours and were burdened with an additional 3% of their body weight. After the cessation of exercise, soleus (SOL, rich in type I muscle fibres) and extensor digitorum longus (EDL, rich in type II muscle fibres) muscles were immediately removed, weighed and prepared for further measurement. In muscles homogenates, the activities of citrate synthase (CS) and cytochrome c oxidase (COX) were measured.
RESULTS: The muscle mass in both SOL and EDL muscles decreased after DEX treatment (-7% and -14% D vs. S group, respectively). In EDL muscle, these changes were associated with the reduction of CS activity (-22% D vs. S group). DEX treatment did not influence on CS activity in SOL muscle. The activity of COX was not changed in both SOL and EDL muscles after DEX treatment. The swim exercise procedure in the ED group alleviated the negative effects of DEX. The applied exercise protocol caused inhibition of muscle mass reduction in both types of muscles (+8 % ED vs. D group for SOL and EDL). This change was associated with an increased in the CS activity (+22% ED vs. D group) only in EDL muscle.
CONCLUSION: Our findings show that DEX treatment caused a decrease in muscle mass in both muscles. However, the higher destructive alteration was observed in EDL than in SOL muscles. The applied exercise protocol has a protective effect in the prevention of sarcopenia. It is very likely that this positive change is associated with maintaining energy metabolism.

THE IMPACT OF EXERCISE MODE AND INTENSITY ON EXERCISE INDUCED GASTROINTESTINAL DAMAGE

EDWARDS, K., DOWLING, C., MUSGRAVE, H., CHERRY, J., REYES, J., KITIC, C.
UNIVERSITY OF TASMANIA

INTRODUCTION: Exercise increases gastrointestinal (GI) damage and it is assumed that mechanical stress (intra-abdominal pressure and movement of organs) induced by running contributes to greater intestinal damage than that caused by cycling but there is little evidence to support this. Exercise intensity is also known to disrupt the gastrointestinal tract, but data is scarce on the trajectory of intestinal damage with increasing intensity. Two studies were undertaken to 1) determine if running was associated with greater intestinal damage than cycling when exercising at the same relative intensity, and 2) quantify intestinal damage with increasing exercise intensity.
METHODS: Following a VO2max test (cycling) participants completed either one running and one cycling trial (45 min at 70% F˙O2max, n = 7) (study 1) or three 60 min cycling trials at different intensities (40%, 60% and 80% 7˙O2max; n=6) (21°C, 40% RH) (study 2). Oxygen uptake was measured every 5 minutes during exercise and running speed or bike power output was adjusted if necessary to ensure e˙O2 remained consistent. Venous blood samples were collected pre- and immediately post- exercise to measure intestinal damage via intestinal fatty acid binding protein (I-FABP). Rating of perceived exertion (RPE), rectal temperature, thermal sensation (TSS), heart rate (HR) and gastrointestinal symptoms were recorded during each trial.
RESULTS: In study 1 the magnitude of change in I-FABP pre- to post-exercise was significantly greater with cycling (65±56% d=1.07) compared to running (28±35%, d=0.65), with a moderate effect between modes (d=0.79; p = 0.049). Average RPE and HR were significantly lower during running than cycling (both p<0.0001). There was no significant difference in TSS (p=0.16) or rectal temperature (p=0.34) between modes. In study 2 the magnitude of change in plasma I-FABP was significantly greater at 80% VO2max than 40% VO2max (p<0.01). Exercise at 80% VO2max was associated with the highest GI symptom frequency score (30 ± 3) followed by exercise at 60% VO2max (6 ± 2) and 40% VO2max (4 ± 1). Average HR and RPE increased with increasing exercise intensity (both p<0.0001).
CONCLUSION: Contrary to conventional thinking, running was not associated with greater intestinal damage compared to cycling when exercising at the same relative intensity. The greater increase in damage following cycling may be attributable to the higher heart rate and RPE, indicating a greater physiological demand when cycling at the same relative a˙O2 compared to running. In addition, increasing exercise intensity induced greater intestinal damage than low intensity exercise. Further investigation is required to determine a threshold intensity at which markers of damage are increased.

F-MARC: THE BEDROCK OF THE CARDIOVASCULAR SCREENING OF HIGHLY TRAINED FOOTBALL PLAYERS VERSUS CLASSIC PRE-PARTICIPATION EVALUATION

STOIAN, I.M., IONESCU, A.M., STOIAN, I.

** PROF. C.C. ILIESCU EMERGENCY CARDIOVASCULAR DISEASES INSTITUTE, BUCHAREST, ROMANIA ** NATIONAL INSTITUTE OF SPORTS MEDICINE, BUCHAREST, ROMANIA*

INTRODUCTION: Football is the most popular sport with professional and recreational players and possible unknown cardiac diseases with high risk of sudden cardiac death SCD (1,5). In 2006, FIFA implemented a mandatory, complex assessment Pre-Participation Evaluation for Cardiovascular Diseases (PPE.CV) to detect cardiac pathologies. In 2009, The International Olympic Committee (IOC) Consensus Statement for health evaluation of elite athletes recommended a classic clinical evaluation and 12 lead electrocardiography (ECG) as athletes' check- ups. The study/aim is to compare the results of the PPE.CV policy for professional football players, according to the FIFA (F-Marc) program comparing to the IOC health evaluation.
METHODS: 2016-2018: 320 highly trained professional players (National Team/Clubs).
Study Group: 211 athletes (ath.);100% M, 17-37 yo. 178 (84.4%) Caucasians; 33 (15.6%) Africans.Prior primary care medicine (history; physical exam) done in sports clubs.
PPE.CV during off - season, yearly, and before major competitions according to: IOC PPE.CV (2): Recommended protocol comprising physical exam, personal symptoms / family history (FH), ECG . (4)
F - Marc (FIFA) PPE.CV (1) In the Cardiology Institute, to the Football Teams requests, as a double-checking evaluation: Mandatory protocol, self imposed: comprising physical exam, personal symptoms/ FH, ECG and echocardiography (ECHO). (3)
RESULTS: Height 174±2 cm; weight78 ± 1kg; BSA1.94 m2. Blood pressure 125 ±5 mmHg.
IOC and F-Marc 211 ath. clinical exams and ECG: 195 (92.4%) normal clinical exams and ECG; 16 (7.6%) isolated borderline ECG changes associated to normal clinical exams.
F-Marc ECHO (mandatory): 211 ath: 200 (94.7%) normal; 11 (5.3%) abnormal: 3, hypertrophic cardiomiopathy (HCM); 2 right ventricular dilatation,1 abnormal origin coronary artery,1 dilated cardiomiopathy, 3 stenotic bicuspid aortic valve,1 mitral prolapse. Decesed, one HCM African player ,disobeing the sport interdiction.
CONCLUSION: F-MARC, a mandatory complex PPE.CV program, identified potential lethal cardiac diseases in asymptomatic players. The recommended (clinical exam, ECG) IOC PPE.CV was an insufficient tool for cardiac diseases diagnosis.

COMPARISON OF CAROTID INTIMA-MEDIA THICKNESS OF LONG-DISTANCE RUNNERS WITH OR WITHOUT EXERCISE-INDUCED HYPERTENSION

KIM, Y.J., KWON, I.S., CHANG, H.

SUNGSHIN UNIVERSITY, KOREAN NATIONAL SPORT UNIVERSITY, SEOUL WOMEN'S UNIVERSITY

INTRODUCTION: Exercise-induced hypertension (EIH) increases the prevalence of hypertension during stabilized periods in the future and is a risk factor for cardiac and cerebrovascular diseases as well, but it has never been studied yet for long-distance runners. The purpose of this study was to evaluate the risk of EIH by measuring the carotid intima-media thickness (CIMT) of long-distance runners with EIH.
METHODS: The subjects of this study were amateur marathoners and ultra-marathoners who were middle-aged men with ages of ≥40 to <60 (51.1±4.8), and they usually participate in sports twice a week or more and have more than three years of athletic experience. Graded exercise test (GXT) and CIMT were measured for all the test subjects. The groups are composed of normal group (NG, n=17) whose stable systolic and diastolic blood pressure is <140/90mmHg and systolic blood pressure during maximal exercise is <210mmHg, EIH group (EIHG, n=39) whose stable systolic and diastolic blood pressure is <140/90mmHg and systolic blood pressure during maximal exercise is ≥210mmHg, and complex group (CG, n=10) whose stable systolic and diastolic blood pressure is ≥140/90mmHg and systolic blood pressure during maximal exercise is ≥210mmHg.
RESULTS: There was no statistically significant difference in the age, height, weight, BMI, and athletic career among the subject groups. For CIMTmax(mm), NG, EIHG and CG showed 0.66±0.14, 0.76±0.14, 0.87±0.15, respectively, and CG was substantially higher than NG ($p<.01$). For CIMTmean(mm), NG, EIHG and CG were 0.53±0.12, 0.62±0.12, 0.72±0.13, respectively, where both EIHG and CG showed significantly higher values than NG ($p<.05$ and $p<.01$, respectively).
CONCLUSION: CIMTmean of long-distance runners with EIH was identified to be significantly thicker than NG as well as CG, which suggests that GXT is required to detect EIH and carotid thickness should be measured to prevent cardiovascular diseases.

AUTONOMIC NERVOUS SYSTEM RESPONSE OF TEAM SPORT AND ENDURANCE TRAINED ATHLETES TO THE 30-15 INTERMITTENT FITNESS TEST

HOOS, O.1, KAUFMANN, S.1,2, GRONWALD, T.3, BENEKE, R.2

1 JULIUS-MAXIMILIANS-UNIVERSITY WUERZBURG, 2 PHILIPPS-UNIVERSITY MARBURG, 3 MSH MEDICAL SCHOOL HAMBURG

INTRODUCTION: The aim of the study was to evaluate differences in vagal modulation and non-linear dynamics of cardiac autonomic activity in team sport (TSA) and endurance trained athletes (ETA) in response to an all-out intermittent fitness test (IFT).
METHODS: n=11 competitive team sport athletes (TSA; age: 23.1±3.5yrs, height: 185±6cm, weight: 81.7±10.0kg) and n=8 endurance trained athletes (ETA; age: 26.0±3.6yrs, height: 177±6cm, weight: 66.9±5.6kg) performed an all-out IFT (1), while data on running speed

(RSpeak), oxygen consumption (VO2peak) and blood lactate (BLCpeak) were assessed. Besides HR, linear (SDNN, lnRMSSD) and non-linear (alpha1) measures of 5min-HRV were analyzed during three test conditions: rest (RE; reference point), the last 5min of IFT (EX) and after 10min of recovery (REC). Differences between variables were tested by two-way ANOVA (group x test condition), effect sizes were denoted as Cohen´s d.
RESULTS: Compared to TSA, ETA reached higher RSpeak (19.3±0.6km/h vs. 18.5±1.3km/h, p=0.07, d=0.87) and VO2peak (68.7±3.4ml/kg/min vs. 62.0±5.9ml/kg/min, p=0.007, d=1.27) but similar HRpeak (190±9bpm vs. 192±10bpm, p=0.57, d=0.208) and BLCpeak (10.0±3.2mmol/l vs. 10.4±1.7mmol/l, p=0.79, d=0.25). For all HRV-measures, medium to large effects were present for test condition (p<0.001, d>3.99), group (0.001-2.79) in REC compared to RE, alpha1 was higher in RE (0.001 CONCLUSION: Compared to TSA, ETA showed stronger vagal activity during rest with more complex dynamics, as well as a faster vagal reactivation and a stronger correlated reorganization of cardiac autonomic activity during recovery (2, 3). In this context, non-linear HRV may add information on complex regulation of cardiac autonomic activity during and after high intensity (intermittent) exercise.

INFLUENCE OF HIGH TEMPERATURE ENVIRONMENT ON CIRCULATORY DYNAMICS OF BRAIN AND ACTIVE MUSCLE DURING ENDURANCE EXERCISE.

SUGANE, H., CHAEN, Y., HASEGAWA, H.
GRADUATE SCHOOL OF INTEGRATED ARTS AND SCIENCES

INTRODUCTION: Exercise in the high-temperature environment increased body temperature. Exercise-induced hyperthermia is thought to lead to fatigue from peripheral and central factors. Body temperature rises during exercise increase skin blood flow increases due to heat dissipation. However, an increase in skin blood flow inhibit cerebral blood flow and muscle blood flow, it may degrade endurance performance. Therefore, this study investigated the influence of heat environment on circulatory dynamics of brain and active muscle during endurance exercise.
METHODS: Six male long-distance runners performed a familiarization session and two experimental trials. They performed 40 min of semi-recumbent cycling at 60% of peak oxygen uptake in hot (35°C; HOT) and thermoneutral environments (22°C; CON). They were able to drink 2 g/kg of water three times every ten minutes. Rectal (Tre) and skin temperatures (chest, left upper arm, thigh, and lower leg) (Tsk), heart rate (HR), skin blood flow (SBF), middle cerebral arterial blood flow velocity (MCA Vmean), muscle blood flow, and muscle oxygen saturation at the thigh were measured.
RESULTS: Rectal (Tre) and skin temperatures (chest, left upper arm, thigh, and lower leg) (Tsk), heart rate (HR), skin blood flow (SBF), middle cerebral arterial blood flow velocity (MCA Vmean), muscle blood flow, and muscle oxygen saturation at the thigh were measured. Tre in the HOT (38.78±0.25°C) was a significantly higher ($p < 0.05$) than that of CON (37.83±0.19°C). Tsk was significantly higher ($p < 0.05$) than CON (34.51±0.54°C) at HOT (37.42±0.37°C). HR in the HOT (172±12bpm) was significantly higher ($p < 0.05$) than that of CON (140±11bpm). HR in the HOT continued to increase to the end of the exercise, whereas in CON, it was a plateau from 20 minutes of exercise to the end. SBF increased with exercise in both conditions. SBF in the HOT (25.8±6.5mL/min/100g) was significantly higher ($p < 0.05$) than that of CON (18.4±1.9 mL/min/100g). MCA Vmean decreased by 21% in HOT from baseline to the end of exercise (59.82±8.8, 47.47±8.3cm/sec), but that of CON (58.77±4.6, 67.38±2.5cm/sec) increased by about 15%. Muscle blood flow and muscle oxygen saturation varied with exercise, but no significant difference was observed between the conditions.
CONCLUSION: These results suggest that distribution of blood flow to the skin may occur due to body temperature regulation in the high-temperature environment and cerebral blood flow may decrease but muscle blood flow is not affected.

ARTERIAL STIFFNESS IN YOUNG MALE ATHLETES OF VARIOUS SPORTS

YOSHIOKA, M., CHOI, Y., TOCHIGI, Y., SATO, T., TANAHASHI, K., PARK, J., MOMMA, R., MAEDA, S.
TSUKUBA UNIVERCITY

INTRODUCTION: Arterial stiffness is strongly influenced by exercise training. Previous studies showed that arterial stiffness in endurance athletes (i.e., long-distance runners) is low, whereas arterial stiffness in strength athletes (i.e., throwers or weightlifters) is high. The adaptation of the arterial stiffness may be different depending on the type of athletic training. However, there are many sports that cannot be classified as endurance or strength training type. The aim of this study was to compare arterial stiffness among athletes who perform various sports
METHODS: The total of 83 male athletes belonging to the collegiate sports teams (15 long-distance runners, 11 soccer players, 10 handball players, 28 kendo players, and 19 tennis players) and 7 healthy sedentary individuals (control group) were participated in this study. The subjects were divided into 4 groups based on the sports type characteristic: endurance athletes (long-distance runners), mixed-trained athletes with high endurance capacity (MTH; soccer players and handball players), mixed-trained athletes with low endurance capacity (MTL; kendo players and tennis players), and control group (healthy sedentary individuals). Carotid-femoral pulse wave velocity (cfPWV), an index of central arterial stiffness, was measured.
RESULTS: cfPWV, an index of central arterial stiffness, showed significantly lower in MTH group compared with control group and MTL group ($P<0.05$). Also, cfPWV showed significantly lower in endurance athletes group compared with control group ($P<0.05$). Systolic blood pressure showed significantly lower in endurance athletes group compared with MTL group ($P<0.05$).
CONCLUSION: The present study showed that cfPWV varies depending on the competitive characteristics in mixed trained athletes. We suggest that the competitive characteristics of athletes influence the adaptation of arterial stiffness.

ACUTE EFFECTS OF HIGH-INTENSITY INTERVAL EXERCISE COMPARED WITH MODERATE-INTENSITY CONTINUOUS EXERCISE ON ARTERIAL STIFFNESS IN HEALTHY YOUNG ADULTS

LEE, R., SEONG, C., KIM, M., HWANG, M.
INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Aerobic exercise is one of the exercise mode frequently employed to prevent cardiovascular disease. Even in healthy young adults, stiffened arteries are associated with increased cardiovascular disease risk. Compared to vulnerable populations such as older adults and chronic disease patients, effects of exercise intensity on arterial stiffness have been rarely investigated in young adults.

The purpose of this study was to investigate the acute effects of high-intensity interval exercise (HIIE) compared with moderate-intensity continuous exercise (MICE) on central artery stiffness in young adults.
METHODS: In a randomized crossover design, nine young adults performed both HIIE (10 minutes warm up at 70% of HRpeak, 4 sets of 4 minutes at 90% of HRpeak and 3 minutes at 70% of HRpeak interval exercise, 2 minutes cool-down at 70% of HRpeak) and MICE (47 minutes continuous exercise at 70% of HRpeak) with 7 to 11 days interval. To assess central artery stiffness, both aortic pulse wave velocity (aortic PWV) and augmentation index (AIx) were measured before and immediately after the exercises, at 30 minutes, 60 minutes, 120 minutes, and 24 hours after the exercises.
RESULTS: There was a statistically significant difference between two exercise intensities in the changes of AIx after exercise (p=0.007). AIx in HIIE was significantly lower than that in MICE immediately after the exercise (5±4% vs. 13±2%, p=0.031). AIx was significantly decreased at 120 minutes after HIIE (8±3% vs. -6±3%, p=0.015) and at 60 minutes (10±3% vs. -3±2%, p=0.009) and 120 minutes after MICE (10±3% vs. -4±3%, p=0.004). However aortic PWV was significantly increased immediately after HIIE (5.5±0.2m/s vs. 6.7±0.4m/s, p=0.006). In healthy young adults without overt clinical disease, positive effects of acute aerobic exercise on arterial stiffness were not maintained until 24 hours.
CONCLUSION: In conclusion, acute HIIE has a superior effect on AIx changes immediately after the exercise bout compared to MICE. However, acute effects of both HIIE and MICE on arterial stiffness are not maintained to the next day in healthy young adults.

EFFECTS OF INGESTING OXYGENATED WATER ON HEART RATE AND BLOOD LACTATE DURING SIMULATED GAMES IN TAEKWONDO ATHLETES

CHUNG, Y.K., WU, Y.N., WANG, S.C., HE, C.S.

NATIONAL CHUNG CHENG UNIVERSITY

INTRODUCTION: It has been demonstrated that ingestion of oxygenated water could improve performance of endurance exercise (1). Recently, the study showed that O4 oxygenated water ingestion resulted in enhanced post-exercise lactate clearance following a 5000m time-trial in trained distance runners (2). The post-exercise recovery was enhanced via increased lactate clearance. Taekwondo athletes required to compete in several combats during a single day. Such repeated exposure to combat dramatically altered the physiological requirements (3). Furthermore, the post-exercise recovery between combats has become even more important since the modification of Taekwondo rules in 2017. Therefore, the aim of the study was to investigates the effects of ingesting oxygenated water on heart rate and blood lactate during two simulated games in Taekwondo athletes.
METHODS: Eight elite Taekwondo athletes from National Chung Cheng University participated in the study. In the counterbalanced and double-blind design, all participants were randomly given with O4 oxygenated water (experimental group) or placebo (control group). The simulated games were held in accordance with the 2017 Taekwondo rules. The interval between the two games during a single day were 90 minutes. Participants ingested a series of 4 × 15mL volumes of either O4 oxygenated water or placebo before and during the games. The heart rate and blood lactate concentration were measured before and after the games. Two competition days were separated by one week. Data was analyzed by repeated measures two way ANOVA. The significant level is $\alpha = 0.05$.
RESULTS: There was a significant time effect ($p < 0.05$) in blood lactate during two games in a day (Combat1-pre: 2.0 ± 0.8, Post-1min: 12.1 ± 5.3, Post-5min: 8.7 ± 2.7, Post-10min: 7.0 ± 3.0, Post-90min: 2.8±0.8; Combat2-pre: 2.8 ± 0.8, Post-1min: 14.8 ± 4.0, Post-5min: 9.1 ± 2.7, Post-10min: 7.4 ± 2.5, Post-90min: 4.7 ± 2.1; mmol/L). The blood lactate concentration was significantly elevated in combat 2 compared with combats 1. However, there was no interaction effect in heart rate and blood lactate between the experimental group and the control group during the simulated games.
CONCLUSION: The study showed that repeated exposure to taekwondo combat was associated with increased blood lactate responses. Furthermore, it seems that ingesting O4 oxygenated water had on effects on the heart rate and blood lactate during two simulated Taekwondo games. Further research is warranted in order to clarify the effects of O4 oxygenated water on the different types of exercise.

EFFECT OF HIGH INTENSITY INTERVAL TRAINING (HIIT) ON PERFORMANCE AND VASCULAR FUNCTION IN ELITE TRIATHLETES

HAYATE, N.1, HIROKATSU, T.2,3,4, SEIJI, M.5, TAKESHI, O.2

(1) (2) RYUTSU KEIZAI UNIVERSITY, (3) NTT EAST, (4) NTT WEST, (5) UNIVERSITY OF TSUKUBA

INTRODUCTION: High intensity interval training (HIIT) has become popular as a training protocol to improve endurance performance. Regarding to triathlon, previous studies conducted performance tests simulating the sprint distance (swim 750m, bike 20km, run 5km) and demonstrated that HIIT improves athletic performance in non-elite triathletes. However, effects of HIIT has not yet been explored in elite triathletes and in distance of the Olympic game (1.5km, 40km and 10km, respectively) and official time trial of Japan Triathlon Union (JTU; swim 400m, run 5km) except for 5-km run. This study investigated the effects of HIIT on performance (run 5km, 10km; swim 400m) and vascular function in university elite triathletes.
METHODS: Subjects were elite-level triathletes belonging to a university triathlon team (4 men and 1 woman). The HIIT-based running program (100m [120-130% maximal oxygen uptake] × 20-35, 400m [105-110%] × 3-10, 120sec [100-105%] × 0-7, 30sec [all out] × 0-6) included 3-4 sessions per week for 5 weeks according to the previous study (García-Pinillos et al., 2017). They were asked to maintain their swimming and cycling routines. Time trials (5 and 10-km run and 400-m swim), Wingate test, and assessment of vascular function were performed before and after the training period.
RESULTS: Running and swimming time improved after the 5-week HIIT program (5-km run, effect size [ES] = 0.50; 10-km run, ES = 0.85; swim, ES = 0.75). Particularly, personal best time was achieved in 5-km run (n = 1) and swim (n = 3). Peak and mean power of Wingate test were greater after the training period compared to before the intervention (ES = 6.50 and 5.74, respectively), suggesting that the HIIT program increased anaerobic capacity. The HIIT program increased leg blood flow and vascular conductance at rest and decreased resting vascular resistance relative to before the training period. In addition, pulse wave velocity, an index of arterial stiffness, was lower after the intervention period compared to before the period. It is possible that the HIIT program increased aerobic capacity via an improvement in peripheral blood circulation and a decrease in left ventricular afterload.
CONCLUSION: These results suggest that HIIT improves performance of elite triathletes in the Olympic distance and JTU official time trial.

ASSOCIATION BETWEEN PHYSICAL FITNESS AND CARDIOVASCULAR RESPONSES TO ACUTE STRESS IN MILITARY FIREFIGHTERS

SPERETTA, G.F., MENDES, H.A., CANTO, N.E., LIMA, L.R.A.

FEDERAL UNIVERSITY OF SANTA CATARINA

INTRODUCTION: It is well known that the military firefighters are constant exposed to acute stress situations, however the cardiovascular responses to these circumstances are not completely understood. Moreover, it is not clear whether the physical fitness levels influence the cardiovascular responses in these professionals. Thus, the aim of the present study was to evaluate the cardiovascular responses to a mental stress test and evaluate a possible correlation between cardiovascular parameters and physical fitness in military firefighters.
METHODS: Male members of the Military Fire Brigade of the State of Santa Catarina in Florianopolis, Brazil, with a median age of 35.5 (31.3; 47) years old performed anthropometric evaluation and maximum incremental test in a treadmill. Acute mental stress was induced using a 3-minute Stroop color–word test. The pulsatile blood pressure (BP) and heart rate (HR) were measured before, during and after Stroop test using Finomiter. The cardiac interval was also used to evaluate the autonomic modulation through HR variability.
RESULTS: The results demonstrated a median body weight of 27.8 (25; 29.8 kg/m²), abdominal circumference of 94.5 (90.5; 97 cm), and body fat of 22.2 (20; 25.5%). Our data also showed increased systolic BP (SBP) 136 (130; 147) according to guidelines values. The mental stress produced increases in SBP (Δ = 24 mmHg,) diastolic BP (DBP; Δ = 13 mmHg) and HR (Δ = 19mmHg). Additionally, the acute stress promoted increases in the low frequency of the cardiac interval, indicating a higher sympathetic modulation to he heart. We found negative correlation between VO2 peak and SBP of recovery, and final velocity (km/h) in the incremental test and the HR of recovery.
CONCLUSION: These results demonstrate that there is an association between physical fitness and the SBP and HR of recovery after an exposure to acute stress in military firefighters.

EFFECTS OF INCREASED CALF VENOUS COMPLIANCE WITH ENDURANCE TRAINING ON CIRCULATORY RESPONSES TO ACUTE EXERCISE

IIMURA, Y., MAEDA, K., OUE, A.

TOYO UNIVERSITY

INTRODUCTION: Endurance exercise training is thought to increase calf venous compliance (CVCPL) (Monahan et al. 2001), and increased CVCPL might induce enhanced venous capacitance and venous return (Hayata et al. 2006). Accordingly, it is expected that the increase in CVCPL with exercise training causes increased stroke volume (SV) and decreased heart rate (HR) during exercise after training compared with before training. Thus, the purpose of this study was to investigate the effect of increased CVCPL with endurance training on circulatory responses to acute exercise.
METHODS: Sixteen young participants (Age: 20.9 ± 0.2 yr) were divided into a training group (n = 8) and control group (n = 8). The training program consisted of cycling exercises in alternating 2-min intervals at 40% maximal oxygen uptake (VO2max) and 80% VO2max for 40-60 min/day, 3 days/week for 8 weeks. CVCPL at rest, VO2max and circulatory responses to exercise were measured before (Pre) and after (Post) 8 weeks. CVCPL was evaluated from the change in calf volume by venous occlusion plethysmography during the deflation protocol (Halliwill et al. 1999). In addition, participants performed a cycling exercise at low (65 ± 4 W) and moderate (105 ± 6 W) workload for 5 min, respectively. The same absolute workloads were used in both Pre and Post. HR, SV, cardiac output (CO), and systolic (SBP), diastolic (DBP), and mean (MAP) blood pressure were measured during exercise.
RESULTS: In the training group, CVCPL and VO2max were increased after training ($P < 0.05$). During exercise at both low and moderate intensity, HR was lower in Post than Pre ($P < 0.05$), although CO and SV were similar between Pre and Post. DBP and MAP during exercise at both intensities also did not differ between Pre and Post, while SBP during exercise at only moderate intensity was lower in Post than Pre ($P < 0.05$). Increase in CVCPL with exercise training showed no correlation with the changes in HR, SV, CO, and BP during exercise from Pre to Post.
CONCLUSION: SV during exercise did not change after training despite the increase in CVCPL with training. The increase in CVCPL might be too small to cause a change in circulatory responses to exercise. These results suggest that increased CVCPL with endurance training for 8 weeks might not contribute to adaptive circulatory responses to acute exercise.

THE EFFECTS OF EXERCISE HABITS AND SEX ON IMMUNE RESPONSE IN DIFFERENT EXERCISE INTENSITIES

KUMAZAWA, Y., SATO, K.

KOBE UNIVERSITY

INTRODUCTION: Although athletes need to maintain best conditions for playing higher performance, intensive exercise cause immunosuppression, and it results in deterioration of the condition and their performance. In fact, upper respiratory tract infection is one of the diseases with the highest incidence for athletes and reduced the performance. One of the mechanisms of upper respiratory tract infection is continues intensive exercise cause decreases in cytokines such as interferon-gamma (IFN-γ), consequently decreases in Natural killer Cell Activity (NKCA). A previous study reported high intensity exercise suppressed NKCA counts after exercise (1). However, it is not

clearly revealed that the effect of acute exercise on immune functions in different exercise habits or sex. Therefore, the aim of this study was to verify the effects of the different exercise intensities on NKCA and IFN-γ for taking exercise habits and sex into consideration.
METHODS: The subjects were randomly divided into four groups, which consisted of male athletes, male non-athletes, female athletes and female non-athletes (n = 7 each groups). Subjects conducted aerobic exercise with cycle ergometer for 15 min at 70% peak oxygen uptake (VO2peak: moderate intensity), and 90% VO2peak until exhaustion (high intensity). The intervals in exercise session were 10 min according to previous study (2). The blood samples were collected from fingertips before and after each exercise session, 30 min and 1 h after exercise.
RESULTS: In male athletes, the rate of change (%) for NKCA at 1 h post exercise was higher than any other time point. On the other hand, %IFN-γ at 30 min and 1 h post exercise were significantly lower than that after moderate intensity exercise ($P < 0.05$). In female athletes, %NKCA at 30 min and 1 h post exercise were higher than that after moderate intensity exercise. However, %IFN-γ 30 min post exercise was lower and it returned to baseline level at 1 h post exercise. In female non-athletes, %NKCA after high intensity exercise was lower than that after moderate intensity exercise. %NKCA at 1 h post exercise was higher than that after high intensity exercise, but no statistically significance were investigated. Moreover, %IFN-γ at 1 h post exercise was significantly higher than that after high intensity exercise and 30 min post exercise ($P < 0.05$).
CONCLUSION: In conclusion, different responses were seen both %NKCA and %IFN-γ in different exercise intensities. Moreover, %NKCA and %IFN-γ were affected by exercise intensities, exercise habits and sex. Therefore, athletes should take exercise intensities into consideration for training to avoid suppression of immune system as well as deterioration of the condition and their performance.

FACTORS AFFECTING PERFORMANCE ON AN ARMY URBAN OPERATION CASUALTY EVACUATION FOR MALE AND FEMALE SOLDIERS

REILLY, T.

CANADIAN ARMED FORCES

INTRODUCTION: Casualty evacuation in an urban operation (UO) is a core competency all Canadian Army members could be expected to perform. A predictor test was develop to assess one's ability to complete the UO and is called FORCE Combat (FC). This test constitutes the sole Canadian Army physical fitness individual battle task standard for land operations. This study was conducted to determine what physical and physiological characteristics contribute to the performance of a casualty evacuation in an urban operation and its predictive test, FORCE Combat and describe the metabolic demand of the UO in female soldiers.
METHODS: Seventeen military members (9 M and 8 F) completed a loaded walking maximal aerobic test, the UO and FC. Heart rate reserve (HRR) and completion time were used as efficiency/performance measures. Oxygen consumption (VO2) was directly measured for UO on five female participants with a portable indirect calorimetry system, and analysed using descriptive statistics. Stepwise multiple regression analysis were used to determine the contribution of the non-modifiable (age, sex, height) and modifiable characteristics (lean body mass to dead mass ratio (LBM:DM), VO2max corrected for load (L.VO2max), peak force (PF) measured on an isometric mid-thigh pull (IMTP) and medicine ball chest throw distance (Dist) on to the performance of each exercise.
RESULTS: LBM:DM and PF were the only factors included in the stepwise regression model for UO, predicting 75% of UO performance ($p<0.01$). For FC, L.VO2max only was included in the stepwise regression model predicting 57% of FC performance ($p<0.01$). Sex, age and height were not included in the regression model. The average metabolic cost of UO was 21.4 mL of O2*kg-1*min-1 in female soldiers while wearing PPE
CONCLUSION: These results identify the important contributors to the performance on an urban operation casualty evacuation in both males and females. Specifically, this study showed that modifiable factors such as body composition, PF on IMTP and L.VO2max are key contributors to performance of UO and FORCE Combat. In addition, to our knowledge, this is the first study to report of direct measure of metabolic demand on an UO in female soldiers. Future investigations should determine the influence of environmental factors such as ambient temperature or altitude on the performance of a casualty evacuation in an urban operation.

RELATIONSHIP BETWEEN PHYSICAL ACTIVITY AND MUSCULOSKELETAL DISORDERS IN MEN AND WOMEN 19-64 YEARS OLD

MOKHLESABADIFARAHANI, A.

PAYAME NOOR UNIVERSITY

INTRODUCTION: Research on health and physical activity has focused on physiological problems and diseases, such as cardiovascular disease. Focusing on these diseases can lead to loss of common musculoskeletal disorders (Bergman, S., 2007). Musculoskeletal disorders can affect the movement system, which reduces performance, pain, injuries and consequently life quality reduction over time(Barrett et al., 2016). Aim of this study was to investigate the relationship between physical activity levels in different domains (occupation, domestic, leisure time and transportation) and musculoskeletal disorders among men and women aged between 19 and 64 years in Tehran.
METHODS: Data from a cross-sectional survey were analysed. From a statistical population of 6234, a sample of 540 was selected by cluster random sampling. Physical activity levels data in the domains of occupation, domestic, transportation and leisure time with International Physical Activity Questionnaire (IPAQ) and musculoskeletal disorders (MSDs) data were collected by Nordic Musculoskeletal Disorders Questionnaire. Chi-square and Pearson tests were used to determine the relationship between variables in SPSS software version 22.
RESULTS: There is a significant difference ($P=0.003$) between the physical activity of men 1571 (SD ±2640) MET-min/week and women 792 (SD ±1415) MET-min/week.Total physical activity in men (occupation, leisure time, transportation) 3582 MET-min/Week was higher in men than women 910 Met-min/week. But the physical activity at domestic in women 2973 Met-min/week was more than men. There was a significant relationship between physical activity of leisure time at all levels and reduction of musculoskeletal disorders ($P = 0.009$). There was also a reverse relationship between total physical activity at domestic and hip disorders ($r = -0.238$).
CONCLUSION: Results showed that physical activity in leisure time can significantly reduce musculoskeletal disorders. Physical activity in other areas does not seem to be sufficient to result in positive physical and physiological adaptations. Physical activity at leisure time may increase the musculoskeletal health of the individuals and may reduce the damage caused by sedentary behaviours.

IMPACT OF DIFFERENT MODES OF EXERCISE IN FITNESS LEVELS AND BODY COMPOSITION IN WELLNESS EXERCISE POPULATION.

AYUSO CHICO, M., SÁNCHEZ-LORENTE, I.M., ITURRIAGA, T., LÓPEZ-FERNÁNDEZ, J., FERNÁNDEZ-ELÍAS, V.E., JIMÉNEZ, A.
UNIVERSIDAD REY JUAN CARLOS, MADRID

INTRODUCTION: Body composition and VO2peak are the most used indicators of health and wellness in individuals. Further, they are key variables studied during exercise program interventions in both general and clinic population. However, it remains unclear how these variables are affected when people exercise in their own or under a soft supervision in sports facilities and leisure centres. Thus, the purpose of this study was to compare the relationship between body composition and VO2peak with the free-chosen exercise performed by low-active individuals
METHODS: A total of 201 participants (133 men, age 36.7 ± 9.6 yo; 68 women, age 36.7 ± 11.8 yo) were classified according to their chose in four different exercise conditions: weight training (WT), workout classes (WC), running (RN), recreational sport (RS) or sedentary behaviour (not meeting PA guidelines; SED). Body composition, VO2peak and lower body strength were assessed.
RESULTS: In men, % of fat mass was significantly lower in RG than in SED (p=0.001) and WT (p= 0.001). In women, % of fat mass was significantly lower in RT than in SED (p=0.004). VO2peak in men was significantly lower in SED than SF (p=0.031), WC (p=0.002), RN (p=0.000) and RS (p=0.033) and it was significantly higher in RG than in WT (p=0.001), WC (p=0.008) RN (p=0.017). In women VO2max was significantly lower in SG than WT (p=0.003), GE (p=0.015), RT (p=0.001) and it was significantly higher in RN than in WT (p=0.007), WC (0.000) and RS (p=0.003). Lower body strength in men and women was significantly lower in SED than WT (p=0.013for men; p=0.001 for women), WC (p=0.000; p=0.003) and RS (p=0.004; p=0.001).
CONCLUSION: People who engaged in exercise showed better fitness level and body composition compared to sedentary individuals regardless of the type of exercise performed. However, people who engaged exercise through recreational sports have similar body composition and fitness than sedentary counterparts. Thus, it seems that supervised exercise, even in a mild way, results in better fitness than unsupervised exercise.

ASSOCIATION LIVING ARRANGEMENT WITH PHYSICAL ACTIVITY LEVELS AMONG YOUTH IN SHANGHAI, CHINA

CAO, Z.B., FAN, X., ZHU, Z., ZHUANG, J., LIU, Y., TANG, Y., CHEN, P.J.
SHANGHAI UNIVERSITY OF SPORT; #SHANGHAI JIAO TONG UNIVERSITY

INTRODUCTION: It is well established that parents can support or hinder their children`s physical activity (PA) in direct and indirect ways. We aimed to investigate the associations between living arrangement and the PA levels of youth aged 9–19 years while accounting for age, sex, and socioeconomic status in Shanghai, China.
METHODS: Participants included a sample of 13,237 primary (9–11-year-olds), 11,157 junior middle (12–14-year-olds), and 8,819 junior high school students (15–19-year-olds) in Shanghai, China, who took part in the 2014 Physical Activity and Fitness in Shanghai China—The Youth Study. Participants' moderate-to-vigorous PA (MVPA) levels, information about living arrangement, and guardians' sociodemographic factors were collected via questionnaires.
RESULTS: Only 17.8% of school-aged youths in Shanghai met MVPA recommendations, with significantly more boys (20.6%) meeting recommendations than girls (p<.001). Youths living in rural areas showed an overall significantly higher percentage of meeting MVPA recommendations (20.3%) than those living in urban areas (p< .001). Youths who lived with single parents showed an overall significantly lower percentage of meeting MVPA recommendations (15.3%) than those living with their grandparent(s) or with both parents (p< .001). Children who live with their grandparent(s) were less likely to meet MVPA recommendations than those who lived with both parents (boys: adjusted odds ratio (aOR) = 0.72, 95% confidence interval (CI) = 0.61–0.84; girls: aOR = 0.84, 95%CI = 0.72–0.98).
CONCLUSION: Type of living arrangement was associated with the PA of youth in Shanghai, with no significant gender difference. Youth aged 9–19 years who lived with single parents had the lowest percentage of meeting MVPA recommendations. The probability of achieving 60 min/day MVPA recommendations was significantly lower among 9-11-year-old children living with their grandparent(s) than children living with both parents; however, no such difference was observed among adolescents. Our findings suggest that living arrangement may be an important consideration for promotion of PA among youth in China.

THE EFFECT OF AGE, TRAINING STATUS, GENDER AND GENES ON MAXIMAL STRENGTH TRAINING ADAPTABILITY

GOLEVA-FJELLET, S., KITTILSEN, H.T., SÆBØ, M., BRATLAND-SANDA, S., STØA, E.M., NICOLAISEN, I., HELGERUD, J., WANG, E., FREBERG, B.I., STØREN, Ø.
UNIVERSITY OF SOUTH-EASTERN NORWAY

INTRODUCTION: Maximal strength training (MST) yield effective improvements in muscle strength. Strength training is a known factor to counteract the decline in muscle strength and mass observed with aging. Thus, it is also a good strategy for maintaining good physical function and decrease risk of falls in an ageing population. However, the impact of age on MST adaptations is not fully understood. The susceptibility for age-related declines in muscle mass and strength, as well as the adaptability to strength training, is influenced by genes. Relatively high, but variable, heritability estimates have been reported for various muscle strength phenotypes. The main goal of the study was to determine the effects of age, training status, gender and genetic variants on MST adaptability.
METHODS: Seventy-six subjects (33 males and 43 females), ages ranging from 20 to 82 years, with a training status typical for their age group were recruited. Participants were divided into five age-based groups. Of these, 49 completed the study (body weight (BW) 76.3 ± 12.2 kg, age 45.3 ± 16.0 years), while 27 did not (BW 78.1 ± 14.9 kg, age 41.0 ± 14.7 years). The participants followed supervised MST 4 · 4 repetitions maximum (RM), three times a week for 8 weeks. Maximal strength (1RM), BW and BMI were measured pre- and post-intervention. To evaluate baseline training status, 1 RM was corrected for age, gender and BW (1RM corrected). Following widely investigated polymorphisms were genotyped: ACE I/D, ACTN3 R577X, PPARGC1A Gly482Ser, LEP rs2167270 and LEPR rs1137101. The effect of I/D, R577X and Gly482Ser were investigated in relation to pre- and post-intervention 1RM (corrected) and Δ1RM (%). In addition, relationships between rs2167270, rs1137101, and BW and BMI were analyzed.

RESULTS: Overall, the MST intervention improved 1 RM by 24.2 ±14,0%. No significant differences in improvements were found between the different age groups or between genders. Participants with the ACTN3 XX genotype exhibited lower gains in 1RM compared to the R allele carriers (18.7 ± 6.7 vs 25.8 ± 15.2 kg, P= 0.031). In addition, PPARGC1A T allele carriers had higher baseline 1RM (corrected) compared to the CC genotype (20.7 ± 4.4 vs 17.48 ± 4.4; P=0.027). C allele carriers, on the other hand, demonstrated larger gains in 1RM (%) compared to the homozygotes for the minor T allele.
CONCLUSION: In healthy individuals with an average muscle strength, the training response was not affected by gender, age or baseline training status in a short-term training intervention. These findings imply that individuals, independently of age, have a great potential for muscular strength improvements and that MST may be used as an excellent strategy for healthy aging. Although the present study found significant associations between two of the single nucleotide polymorphisms and baseline 1RM and/or gains in 1RM, they likely play only a minor role in the adaptability to MST in the general population.

A GENDER COMPARISON OF MUSCULOSKELETAL DISORDERS, PAIN AND FORWARD HEAD POSTURE AMONG OFFICE WORKERS

DEPRELI, O., ANGIN, E.

EASTERN MEDITERRANEAN UNIVERSITY

INTRODUCTION: Office workers are forming a very important part of the risk group for musculoskeletal disorders (MSD) as they are working at a desk and sitting for a long time in a chair in workplaces. While they are many risk factors that play a role in development of MSD, gender is one of the individual risk factors that can be effect MSD, pain and posture. The purpose of this study to compare MSD, pain and forward head posture among male and female office workers.
METHODS: As a result of power analysis, 180 office workers were included in this study. The Nordic musculoskeletal questionnaire that referring the symptoms in parts of the body and visual analogue scale were used to study the prevalence of MSD, pain intensity respectively. Forward head posture (FHP) was assessed with photography method and the craniovertebral (CV) angle that was formed by the horizontal line through C7 and the line connecting C7 with tragus was measured.
RESULTS: A total of 180 individuals who were 58.9% female and 41.1% male participated in the study. No significant differences were found with regard to the comparison of age and working years ($p > 0.05$) while height, weight and body mass index (BMI) of them has been found to be statistically significantly ($p<0.05$). Female office workers had statistically significant musculoskeletal symptoms during the past 12 months, most commonly in the neck (50.9 %), shoulder (38.7%), wrists (33%), upper back (55.7%), and hips (17%). Comprasion of pain intensity and CV degree also has been found statistically significant ($p<0.05$).
CONCLUSION: Biological differences between genders such as body size, muscular capacity, hormonal conditions, and work-life balance explain a lot of the differences in MSD prevalence amongst males and females. Higher MSD, pain intensity and FHP prevalence by females is due to higher exposure to physical and psychosocial conditions. Additionally, because of non-adjustable workstations and lack of individual assessment of them, effective preventive interventions designing can be effective in reducing the risk of MSD, pain intensity and FHP.

PREVALENCE OF CHRONIC ANKLE INSTABILITY AND HISTORY OF ANKLE SPRAIN IN MALE AND FEMALE COLLEGIATE ATHLETES

KOUMURA, T.1, KUNUGI, S.2, MASUNARI, A.3, MIYAKAWA, S.2, MUKAI, N.2

UNIV. OF TSUKUBA

INTRODUCTION: Ankle sprains are among the most common musculoskeletal injuries1), and many individuals with ankle sprains develop chronic ankle instability (CAI). Some studies report that demonstrated a higher incidence of ankle sprain in females compared with males2). However, the difference in the prevalence of CAI between male and female has not been investigated. The purpose of this study was to investigate the prevalence of CAI and history of ankle sprain in male and female collegiate athletes, and each sport.
METHODS: A total of 354 collegiate athletes in this cross-sectional questionnaire study. The participants were 261 males (Age:20.0±1.2, Height:173.9±6.2cm, Weight:74.0±11.2kg) and 93 females (Age:19.9±1.3, Height:163.7±6.9cm, Weight:57.9±7.1kg). Sport including football, rugby football, handball, lacrosse (males only), football, basketball, handball, lacrosse (females only). We asked to all participants about their history of ankle sprain. The participants who had a history of ankle sprain answered the questionnaire based on the international ankle consortium criteria. This analysis was used to compare the Chi-squared test between male and female with history of ankle sprains and CAI, and each sport with ankle sprain history and prevalence of CAI. The statistical significance level was set at $p<0.05$.
RESULTS: There was no a statistically significant difference between male and female with ankle sprain history. The prevalence of CAI on the female (48.0%) was significantly higher than that on the male (31.7%) with CAI. ($p=0.039$) There was no a statistically significant difference between each sport with ankle sprain history and prevalence of CAI.
CONCLUSION: The prevalence of CAI on the female collegiate athletes was significantly higher than that on the male collegiate athletes with CAI. Some studies reported that general joint laxity in female is higher than male, correlative in severity of ankle sprain and general joint laxity. and, severity of initial sprain predicted re-sprain3). Therefore, we found that the prevalence of CAI in female collegiate athletes is higher than male collegiate athletes.

EXPLORING THE EFFECTIVENESS FOR CARDIO TRAINING WHILE OPERATING OUTDOOR FITNESS EQUIPMENT

CHANG, K.T., CHOW, H.W., YANG, C.C.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: A growing body of literature addresses the importance of upgrading open green spaces or parks to promote physical activities to reach a broader, more sustainable base of citizens. Recently, many parks worldwide have installed outdoor fitness equipment (OFE) in order to attract more citizens to visit them and to engage in physical activities. Despite the popularity of OFE, very little research has investigated the effectiveness of using the equipment. Especially, the effectiveness for cardio training of using OFE remains

unclear. Earlier studies showed that OFE users do not use the equipment long enough to achieve physical activity recommendations. Thus, the benefits of OFE alone in achieving a higher level of physical activity to improve health remains questionable. Therefore, this study aims to examine the intensities in terms of heart rate while operating OFE for an extended time.
METHODS: As the air walker and ski machine are the most popular endurance training OFE for developing cardiovascular function, we recruited five males and five females to perform 30-minutes workout on each device with a set tempo of 100 bpm. The participants wore POLAR H10 heart rate strap on their chest to monitor their heart rate for every second.
RESULTS: The mean age of the participants was 22.7(range:18-27) years. Most of the participants have regular physical activity except for one female who has sedentary lifestyles. Overall, the average heart rate for air walker was 96.50±15.27 bpm (range: 63-141), and the ski machine was 94.85±15.83 bpm (range: 58-138). While performing OFE, only one sedentary female reach 60 % -70% of her maximum heart rate (HRmax). Other nine participants, while operating the air walker, about 23.6 % of their time fell in 50-60% HRmax, 70.4% of the time in 40-50% HRmax, and 5.2% of the time in 30-40% HRmax. For ski machine, about 27.3 % of their time fell in 50-60% HRmax, 60.6% of the time in 40-50% HRmax, and 11.9% of the time in 30-40% HRmax.
CONCLUSION: Heart rate is an important indicator to monitor cardio endurance training as it can objectively reflect the physiology response for a training intensity. This study has shown that even using OFE for an extended time for cardio endurance training, the participants' heart rates remain under very light intensities across the whole workout based on heart rate training guide. Despite the rapid worldwide expansion of parks with OFE, a relatively small body of literature has examined the effectiveness of using OFE. This study's findings have significant contribution in terms of providing objective and solid assessment of training effectiveness based on heart rate for using OFE.

IS-PM02 Eccentric cycling: Basics and clinical applications [Clinical track]

ACUTE PHYSIOLOGICAL RESPONSES TO ECCENTRIC CYCLING

DUFOUR, S.P.
UNIVERSITY OF STRASBOURG

Eccentric (ECC) muscle work (i.e braking muscle actions) can be generated using various forms of exercise among which ECC cycling currently emerges as particularly promising in the fields of health and sport performance (1). Despite widespread belief, ECC cycling can be performed, up to very high intensity, without inducing muscle damage, especially if the subjects are regularly and progressively exposed to ECC cycling. This presentation highlights some of the specific mechanical, cardio-respiratory, vascular, and neuromuscular responses to acute ECC cycling. Mechanical analyses demonstrate that the major extensor and/or flexor muscles of the lower limbs can be targeted during ECC cycling and that much higher pedal torque and power output can be achieved in ECC vs. more conventional concentric cycling. In an integrative view of exercise physiology, attenuated metabolic, pulmonary, cardiovascular and neuromuscular responses have been consistently observed in ECC vs. concentric cycling performed at similar power output (i.e. similar mechanical power). Alternatively, comparing ECC with concentric cycling at similar metabolic power (i.e. similar oxygen uptake), requires much greater power output to be achieved and maintained in ECC cycling. In this particular condition, higher neuromuscular activation, heart rate and cardiac output have been identified in ECC cycling, together with greater breathing rate and lower tidal volume. These specific cardiovascular and ventilation responses to ECC cycling should be emphasized as they have practical consequences for the management of training load in ECC cycling programs (2). To further our understanding of the physiology of ECC muscle work, recent data were collected during incremental ECC knee extensor exercises, with particular emphasis on the parameters of lower limb oxygen delivery and utilisation. These data gathered during invasive experiments in exercising humans in vivo extend and complete the data collected during ECC cycling, confirming that much greater mechanical power can be achieved with ECC muscle actions albeit at very low metabolic cost. Of interest, leg blood flow was similar in ECC vs. concentric knee extensor exercises at similar metabolic power. This last result questions the origin of the specific cardiovascular responses observed at the systemic level during ECC cycling. Overall, the combination of high mechanical load and low metabolic cost makes ECC cycling an interesting exercise modality, especially emerging for clinical populations with limited cardiorespiratory function and locomotor ability (3). The specific physiology of ECC cycling definitively warrants further attention to design and optimize future ECC cycling training programs.

ECCENTRIC CYCLING: BASICS AND CLINICAL APPLICATIONS

NOSAKA, K.
EDITH COWAN UNIVERSITY

It is well documented that exercise is medicine, and is effective for treating and preventing many of psychiatric, neurological, metabolic, cardiovascular and pulmonary diseases, musculoskeletal disorders, and cancer [1]. However, it is not necessarily clear what kind of exercise is the best or is more effective than others. It is possible that "eccentric cycling" is one of the best modalities for the diseases mentioned above.
In fact, effects of "eccentric cycling" or "eccentric stepping" training on patients with type 2 diabetes mellitus, chronic obstructive pulmonary disease, chronic heart failure, obesity, cancer, and knee and/or hip joint disorders have been reported. However, the number of studies in which effects of eccentric cycling or stepping exercise on clinical populations were investigated, is still small, although the exercise modality was introduced more than 20 years ago. Currently, several different kinds of eccentric ergometers are on the market, but all of them are expensive to be installed in exercise clinics and gyms.
The first use of eccentric cycling/stepping in clinical condition goes back to early 2000, and the group by LaStayo et al. published interesting papers. In the study published in 2003 [2], they investigated the effects of a high-force eccentric ergometer training (ECC) in compari-

son to a traditional weight training (TRAD) on muscle fiber cross-sectional area and strength, balance, stair descending abilities, and fall risk in older adults (70-93 y) with cardiopulmonary rehabilitation. They reported that a significant increase in muscle fiber cross-sectional area was found for both groups (ECC=60%, TRAD=41%), but only the ECC group showed increases in strength (60%), balance (7%), and stair descent (21%) abilities.
Using eccentric cycling/stepping, it is possible to provide strong mechanical stimulus to skeletal muscles with relatively low metabolic demand and reduced cardiorespiratory stress. Our recent study showed that eccentric cycling stimulated the brain better than concentric cycling. These characteristics are ideal for clinical populations and individuals with limited exercise capacity. There are many options for the eccentric cycling/stepping protocols by modulating the intensity, volume, cadence, exercise time (continuous vs intermittent), frequency, saddle position, and others (e.g., environmental factors). However, these have not been explored enough yet, so more studies are required to establish eccentric cycling/stepping exercise protocols suitable for different conditions.
This presentation will review the studies in which eccentric cycling/stepping was used for treatment and rehabilitation of clinical or older individuals, discuss potential advantages and disadvantages of eccentric cycling/stepping in exercise medicine interventions, and clarify the future research directions.

ECCENTRIC CYCLING IN CHRONIC HEART FAILURE

GREEN, D.J.

THE UNIVERSITY OF WESTERN AUSTRALIA

In Australia alone, 300,000 patients live with HF and 30,000 are diagnosed each year (annual cost >~$1billion).1 In contrast with other cardiovascular diseases, HF death and hospitalisation has steadily risen across the last decade. Although impaired cardiac function initiates HF, the cause of exercise intolerance is often lies in skeletal muscle.2 Improving exercise capacity (VO2peak) is linked to clinical outcomes: every 6% increase in VO2peak is associated with 5% lower risk of mortality. Exercise training treats the multiple systemic and peripheral effects of HF3 and is strongly advocated in clinical guidelines (Class I Level A). However, exercise prescription is highly challenging, since impaired functional capacity limits the ability to prescribe exercise at an intensity high enough to induce clinical benefit. Over the past 2 decades, our group has pioneered novel approaches to personalised exercise training in HF,4-9 focused on identifying and treating peripheral limitations. These approaches have been adopted into clinical practice worldwide. Based on our recent studies regarding its unique energetic, biomechanical and muscular ultra-structural effects2, 10-15 we propose that eccentric exercise, where muscles produce force whilst lengthening, may prove effective for HF patients. Our recent study of the acute effects of eccentric versus concentric cycling indicates that some differences exist in terms of the impact on artery function and current studies are addressing the cerebrovascular impacts of eccentric cycling.

OP-PM18 Health and fitness: Ageing I

INTERVENTIONS TO IMPROVE AND SUSTAIN PHYSICAL FUNCTIONING, COGNITION AND PSYCHOSOCIAL WELLBEING FOR NURSING HOME RESIDENTS WHO ARE UNABLE TO WALK

CORDES, T.1, SCHOENE, D.2, WOLLESEN, B.1

1: UNIVERSITY OF HAMBURG, 2: FRIEDRICH-ALEXANDER UNIVERSITY ERLANGEN-NÜRNBERG

INTRODUCTION: Nursing home residents are often characterized by multimorbidity and low levels of mobility (1). Despite these health-related problems, they still have resources, which should be promoted to improve physical functioning, cognition and psychosocial wellbeing. However, most interventions in nursing homes are aimed at residents who are still able to walk (2). Hence, the aim of this systematic review is to summarize the current evidence on seated exercise interventions for nursing home residents.
METHODS: Five electronic databases were searched (Medline, Embase, Cinahl, Cochrane Central, and PsycInfo). Studies were eligible if: i) they were conducted in nursing home residents, ii) participants were above the (mean) age of 65 years, iii) they included one treatment arm with seated exercise only and, iv) the measured outcomes were related to physical and/or cognitive functioning and/or wellbeing. The quality assessment was done with the Downs and Black checklist.
RESULTS: Nine studies met the inclusion criteria. Different types of interventions were identified: six studies with multicomponent functional strength, flexibility and coordination training, two studies with moderate yoga, qigong or breathing exercises, one study with toe and ankle training. Studies also differed in sample size, training duration and intensity. Eight of nine interventions improved relevant outcomes. One large RCT investigating habitual physical activity found no differences between intervention and control group following a functional strength program. Only few studies point out suggestions for seated only interventions and the amount of participants who were unable to walk remained unclear.
CONCLUSION: The results provide limited evidence and indicate that seated exercise programs may improve physical or cognitive function and/or wellbeing in nursing home residents. For beneficial effects, interventions should include moderate or higher intensities with multicomponent functional exercises and motivational equipment. Further research is needed, to provide specific recommendations on how interventions should be structured, especially for nursing home residents who are unable to walk.

NOVEL MAT EXERGAMING TO IMPROVE PHYSICAL PERFORMANCES, COGNITIVE FUNCTION, DUAL-TASK WALKING, AND FALL RISK IN COMMUNITY-DWELLING OLDER ADULTS

SONG, C.

NATIONAL TAIPEI UNIVERSITY OF NURSING AND HEALTH SCIENCES

INTRODUCTION: Physical exercise and cognitive training have been previously demonstrated to improve physical functioning and reduce falls for older adults. The purposes of this study were to utilize an interactive exergame mat system to develop a novel cognitive-physical training program, and to explore the training effects on physical performance, cognitive function, dual-task walking (DTW), and fall risk compared to control.
METHODS: This was a quasi-experimental, non-randomized controlled intervention study in community-dwelling older adults. The exercise group (n=56, age: 70.7±4.6 years) received ladder-, 3-by-3 grid-, and circle-type of mat exergame with simultaneous cognitive-physical training (EMAT) while the control group (n=54, age: 72.0±5.7 years) underwent a multicomponent exercise intervention focused on physical and cognitive training. Two-hour training session per week over 3 months was applied. Functional fitness, MoCA, DTW with counting and carrying a tray with water, and fall risk questionnaire (FRQ) were assessed before and after interventions.
RESULTS: EMAT enhanced functional fitness, increased MoCA score, improved DTW, and decreased FRQ score (all $P<0.05$). EMAT showed a significant advantage compared to control in lower-extremity strength and flexibility, dynamic balance and agility, and FRQ score (all $P<0.05$).
CONCLUSION: The current study provides the evidence of a novel mat exergaming program on physical and cognitive performances. EMAT could also effectively reduce fall risks and increase the dual-task ability, walking while concurrently performing cognitive and/or motor interference tasks, which is important in fall prevention for older adults.

CLUSTER ANALYSIS OF MOTOR AND COGNITIVE SKILLS OF INSTITUTIONALIZED INDIVIDULAS WITH DEMENTA: 4 PHENOTYPES FOR DEVELOPING INDIVIDUALIZED PHYSICAL ACTIVITY PROGRAMS

BARISCH-FRITZ, B., BEZOLD, J., TRAUTWEIN, S., SCHARPF, A., WOLL, A.

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: The number of individuals with dementia (IWD) increases to approximately 152 million in 2050 (Patterson et al., 2018). The decline of cognitive and motor skills in IWD eventually leads to permanent care. Almost three-quarters of residents in care facilities have dementia. Considering all medical and care aspects, the burden of health system is enormous. Thus, all treatments that can delay disease progression are valuable to consider. Physical activity (PA) is promising, but clear evidence is still not given (Blankevoort et al., 2010). One explanation is the multifaceted variation possibilities of PA. To the best of our knowledge, there are no individualized PA programs based on different preconditions of IWD, following the example of individualized medicine. This study identifies different phenotypes of IWD based on their motor and cognitive skills to develop individualized PA programs.
METHODS: Data was collected within a multicentre randomized controlled trial (Trautwein et al., 2017). We included IWD (>65 years) with primary dementia of mild and moderate state, living in care facilities. Cognitive skills were examined by Mini Mental State Examination (MMSE, global cognition); motor skills by Frailty and Injuries: Cooperative Studies of Intervention Techniques (FICSIT, balance), 6m Walk Test (WT, gait speed), modified 30-Second Chair-Stand Test (CST, lower limb function), and Timed Up&Go Test (TUG, mobility). Suitability of variables was tested by distributions, correlations and outlier identification. After z-transformation of all variables, we performed a hierarchical cluster analysis with Ward's method and tested the group differences by one-factorial ANOVA with Scheffe-Post-Hoc-Test.
RESULTS: Baseline data of 238 IWD (age 86±6 years, MMSE 17±4) were used. Based on MMSE, FICSIT, WT, and CST (TUG was excluded due to high correlations) four phenotyps were identified. Variables of cluster 1 (n=87; MMSE 13±2; FICSIT 2±1; WT 10±3sec; CTS 7±3), cluster 2 (n=11; MMSE 15±6; FICSIT 0.5±0.5; WT 22±4sec; CTS 4±2), cluster 3 (n=86; MMSE 20±3; FICSIT 3±1; WT 9±3sec; CTS 10±3), and cluster 4 (n=54; MMSE 19±3; FICSIT 1±1; WT 12±2sec; CTS 5±2) differ statistically significant.
CONCLUSION: Following the example of individualized medicine, the four identified phenotypes illustrate the necessity of individualized PA programs with different priorities. These findings need to be evaluated: First, by cluster analysis within different samples of IWD, possibly with different cognitive and motor variables, and second by evaluation of the effectiveness of individualized PA programs based on phenotypes. Nevertheless, this new concept can contribute to increase evidence of PA in IWD and thus, might offer new possibilities for the implementation of PA in care facilities.

THE EFFECTS OF A MULTIMODAL EXERCISE PROGRAM PLUS BRAIN GAMES APPS IN COGNITIVE PARAMETERS OF NURSING HOME RESIDENTS

RAIMUNDO, A., FERREIRA, S., LEITE, N., SOARES, G., MARMELEIRA, J.

DEPARTAMENTO DE DESPORTO E SAÚDE, ESCOLA DE CIÊNCIAS E TECNOLOGIA, UNIVERSIDADE DE ÉVORA, PORTUGAL;

INTRODUCTION: The aging process leads to inevitable life changes and is characterized by a progressive loss of psychological and physiological functions (1). Often, these changes lead to institutionalization, where cognition and physical fitness tends to decline (2). Some studies have shown that multimodal exercise programs can have a broad impact in older adults, improving a number of cognitive and physical functions, including executive functioning, speed of behavior and balance (3). Also, in recent years there has been a growing interest in the use of digital technological devices for promoting specific competencies in the elderly. Moreover, to the best of our knowledge, few studies on the effects of multimodal exercise interventions have focused on nursing home residents. Therefore, the main objective of this pilot study is to examine the effects of an intervention designed for nursing home residents that include both a multimodal exercise component and a videogame component (brain games apps).
METHODS: Twelve older women and men were selected by convenience among a nursing home residence. During the first 4 weeks (control period), the participants continued with their normal daily life activities. After the control period, the group engaged in an intervention program for 6 weeks. The intervention program consisted of a multimodal exercise program (2 times per week) plus selected brain games played on a tablet computer (2 times per week). The 4 exercise sessions per week were alternated between multimodal exercise program and brain games performed on the tablet computer.

Assessment of cognition was collected: prior to the control period (T0), after the control period (T1), and at the end of the intervention (T2). The 8 ft up-and-go test of the senior fitness test (4) was performed with and without a cognitive dual task (counting backward from 30). This type of assessment has been shown to be reliable and valid to establish the fall risk of healthy elderly people (5). A clinical psychologist administered the Mini-Mental State Examination (MMS) as well as the Montreal Cognitive Assessment (MOCA) questionnaire to analyze the effects of the program on immediate and short-term memory.
RESULTS: The intervention did not affect the ability to perform the 8 ft up-and-go test under single- and dual-task conditions (p=0.250 and p=0.375 respectively). Regarding immediate and short-term memory ability (measured by questions from the MMS and MOCA questionnaires), we found an improvement in one of the items related to short-term memory on MOCA. In this case, an increase in memory capacity was observed between T0 and T2 (p=0.033).
CONCLUSION: In this pilot study, we found a few positive changes in related cognitive variables as the result of the planned intervention. Nevertheless, the gains observed in short-term memory are encouraging. It is important that future studies test the effectiveness of engaging older adults in similar interventions using a large sample and a longer duration.

EFFECTS OF GROUP-BASED EXERCISE PROGRAM ON COGNITIVE FUNCTION, BIOMARKER AND SENIOR FUNCTIONAL FITNESS IN OLDER ADULTS AT DIFFERENT LEVELS OF COGNITIVE IMPAIRMENT

HO, T.H., LO, M.S., LIN, L.L., YANG, N.H., CHOU, J.W.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Insulin growth factor-1(IGF-1) has been shown to have potent effects on cellular neuroplasticity of central nervous system development and maturation. The Senior Functional Fitness Test (SFFT), which evaluates the functional fitness performance, the physiological capacity to perform normal everyday activities safely and independently of older adults. The purpose of this study is to explore the effects of functional physical fitness and cognitive performance (biomarker : IGF-1) after a group exercise program intervention with different level of cognitive impairment in Community-dwelling Older Adults.
METHODS: 43 participant 60 to 80 years old were divided into mild cognitive impairment (MCI, n=21) group and serious cognitive impairment (SCI, n=22) group using the Saint Louis University Mental Status (SLUMS) questionnaire. All the subjects performed a group-based exercise program. Group-based exercise program performed twice-weekly multicomponent exercise training for 1.5hours led by a certified fitness instructor for 12 weeks. The primary outcomes were SLUMS score, serum levels of IGF-1 and the performance of SFFT before and after all training. SFFT was used to measure upper muscle strength (30-second arm curl and grip), lower muscle strength (30-second chair-to-stand), aerobic endurance (two-minute step), agility and dynamic balance (eight-foot up-and-go). A paired samples t-test was used to compare the functional fitness, biochemical indicator, and cognitive performance.
RESULTS: After the 12-week exercise intervention, the cognitive ability for MCI(+8.8%) and SCI(+19.9%) had both increased significantly($p < .05$), and the change of SCI had increased significantly than MCI ($p < .05$). There was no significant change in serum levels of IGF-1 between groups at both pre- and post-study. In lower limb strength, MCI(+14.8%) and SCI(+12.8%) had increased significantly($p < .05$). In upper strength (grip), MCI(+15.7%) and SCI(+16.3%) had increased significantly($p < .05$) . MCI(-15.3%) and SCI(-9.2%) had improved significantly in agility and dynamic balance ($p < .05$). Although both MCI and SCI increased lower/upper strength and dynamic balance, there was still no significant different change between the two groups. In aerobic endurance, MCI(+14.6%) and SCI (+40.1%) had significantly improved($p < .05$), and SCI had a growing trend towards higher ($p = .07$).
CONCLUSION: This study suggests the impact of a structured twice-weekly group-based multicomponent exercise program may benefit the functional fitness and the cognitive except biomarker IGF-1in older adults with middle or serious cognitive impairment Probably, there was not high enough intensity to stimulate the thresholding, due to no significant change in the biomarker. According to this study, a group-based exercise program can slow down the fading of the cognitive performance, improving Senior Functional Fitness in the elderly with moderate to serious cognitive impairment in the community.

FEASIBILITY STUDY OF PROLONGED STATIC AND DYNAMIC STANDING AS COMPARED TO SITTING IN OLDER ADULTS WITH TYPE 2 DIABETES MELLITUS

MARUSIC, U., MULLER, M., ALEXANDER, N., BOHNEN, N.

SCIENCE AND RESEARCH CENTRE KOPER

INTRODUCTION: Physical inactivity is prevalent in older adults and poses a risk factor for the development of type 2 diabetes mellitus (T2DM). The aim of this pilot study was to examine the feasibility and possible clinical effects of two forms of non-exercise physical activity intervention using a standing desk in older adults with T2DM.
METHODS: Twelve older adult patients with T2DM were tested in the semi-randomized crossover design, in which baseline 180-minute sitting was compared to either 240-min static or dynamic standing to increase overall movement. Oxygen uptake, cognitive performance, as well as sessions and breaks duration, overall movement activity, and musculoskeletal discomfort was monitored during all three sessions.
RESULTS: All participants were able to complete all sessions, representing feasibility of prolonged-term standing paradigm in older patients with T2DM. Oxygen uptake and overall movements were progressively increased from sitting, static and dynamic standing, respectively ($p<0.001$). The duration of breaks during dynamic standing was shorter as compare to static standing ($p=0.024$) as well as total musculoskeletal discomfort and legs swelling was higher in static standing as compared to sitting or dynamic standing ($p=0.043$) . Finally, no negative impact on cognition was observed in both standing conditions.
CONCLUSION: Standing as a non-exercise physical intervention is feasible in older adults with T2DM and may have clinical benefits. Standing with cued movements seem especially beneficial and might represent a novel non-behavior-invasive intervention concept, that targets sedentariness and can be easily and safely integrated into daily routines.

OP-PM19 Nutrition: Ergogenic aids I

ISOLATED EVALUATION OF DIFFERENT SPORTS DRINKS COMPONENTS ON ENDURANCE PERFORMANCE AND SUBSTRATE OXIDATION IN CYCLING

HOTTENROTT, L., ZELLER, S., MÖHLE, M., FERRAUTI, A.

FACULTY OF SPORT SCIENCE RUHR UNIVERSITY BOCHUM

INTRODUCTION: The composition and ingredients of sports drinks consumed in endurance sports are very different and not every sports drink achieves the desired outcome.
The variety in sources and concentrations of carbohydrates and other added ergogenic substances like nitric oxide (NO) forming substances (beetroot, arginine and L-citrulline) and their isolated effect on endurance performance have not been sufficiently investigated. Numerous studies looking at performance enhancing effects following the intake of dietary nitrate have found inconclusive results (1).
Aim of the study was to evaluate sports drink on endurance performance, rated perceived exertion (RPE) as well as carbohydrate (CHO) and fat metabolism. Individual substances of the performance drink mix, isolated in three different drinks and a placebo drink were tested.
METHODS: 12 healthy and well-trained male endurance athletes (cyclists, triathletes) of age 33,6 ± 8,3 years and with a body mass index of 24,1 ± 2,7 kg/m² participated in the study in an experimental crossover design. The intervention included a warm up period of 30 min cycling at 50% of the previously determined peak oxygen uptake (VO2peak) followed by 40 min cycling at 80% (VO2peak) with a subsequent increase of power every minute by 10 watts until exhaustion. In a double-blinded and randomized protocol, four different drinks (A=placebo, B=dextrose, C=B plus nitrate booster and D=C + arginine and L-citrullin) were added to 300 ml water and ingested 60 min and 30 min before each cycling test. Maximal performance at exhaustion, respiratory gases exchange, HR, RPE, lactate and glucose concentration every 10 minutes, pre and post as well as body weight and urine pH pre and post, were measured.
RESULTS: There were no differences in maximal performance (p=0.818), peak oxygen uptake (p=0.670), maximum lactate concentration (p=0.746) and maximum heart rate (p=0.950) between the four treatments. During the 40-minute cycling at 80% VO2peak no statistical significant differences in lactate and glucose concentration, heart rate, respiratory gas exchange parameters were found. Significant differences ($p<0.001$) for blood glucose concentration were found at rest and in the warm up phase between placebo and the three treatments ($\eta 2=0.54$; large effect). The pre-post comparison showed significant differences (p=0.02) in the urine pH values between the CHO drinks and the placebo ($\eta 2=0.11$; medium effect).
CONCLUSION: There was no meaningful effect of different sports drinks components on performance and substrate oxidation during a 40-minute cycling at 80% VO2peak with subsequent increase of power until exhaustion.
Reasons for the lack of effects can include exercise duration and intensity as well as frequency of ingestion and composition of the sports drinks.

CHRONIC LOW DOSE CAFFEINE INGESTION AND SELF-PACED HIGH INTENSITY TRAINING

SALAM, H., HOPKER, J., MARCORA, S.

UNIVERSITY OF SULAYMANIYAH

INTRODUCTION: Many athletes use caffeine before and during competitions however, the chronic use of caffeine during training is not well understood. Therefore, the aim of this study was to investigate the acute effects of caffeine on high intensity interval training (HIIT) and how these were affected by chronic caffeine intake.
METHODS: Using a randomized, counterbalanced and double-blinded placebo-controlled design, twenty recreational male endurance athletes (age 33 ± 9 yrs; άO2peak 55.3 ± 8.9 ml.kg-1.min-1) ingested either caffeine (3 mg.kg-1 body mass), or a placebo 1 hour before a HIIT session. HIIT consisted of 4 x 4 min bouts (RPE 16, 17, 18, and 19) of exercise, with 3 min active recovery between each. Power output, HR and blood lactate were recorded throughout each HIIT session. Subsequently, participants were randomly allocated to either ingest caffeine (3 mg.kg-1 body mass) or placebo capsules three times a week, 1 hour before regular training sessions. After 4 weeks of chronic supplementation, all participants performed a follow-up HIIT assessment using the same study design as outlined above.
RESULTS: During HIIT sessions, caffeine increased power output, HR and blood lactate at both the baseline and follow-up assessments ($P<0.05$). After 4 weeks of caffeine or placebo ingestion, there were no differences between groups in their power output, HR or blood lactate responses during HIIT following acute caffeine or placebo ingestion ($P>0.05$).
CONCLUSION: Caffeine ingestion 1 hour prior to HIIT acutely increases power output, HR, and blood lactate for exercise at the same RPE. The frequent ingestion of caffeine during training does not reduce its ability to enhance power output for the same level of effort during HIIT.

KETONE ESTER SUPPLEMENTATION BLUNTS OVERREACHING SYMPTOMS AND STIMULATES PERFORMANCE DURING ENDURANCE TRAINING OVERLOAD

POFFÉ, C., RAMAEKERS, M., VAN THIENEN, R., HESPEL, P.

KU LEUVEN

INTRODUCTION: Overload training is a prerequisite for sustained performance gain. However, when accompanied by inadequate recovery, a maladaptive catabolic state develops, causing performance decrements for weeks (overreaching) up to months (overtraining). As previous studies have shown that blood ketones can diminish training- or fasting-induced catabolic events (1), we hypothesized that oral ketone intake can inhibit endurance training-induced overreaching.
METHODS: Fit male subjects participated in two daily cycling sessions (3 weeks, 6 days per week) while receiving either a ketone ester drink (KE, n=9) or a control drink (CON, n=9) following each session. Blood samples and biopsies from m. vastus lateralis were obtained before, during, and after the training period.
RESULTS: Sustainable training load in week 3, as well as thirty min time-trial performance at the end of a 2h training session, were 15% higher in KE than in CON (both $p<0.05$). KE markedly inhibited the training-induced increase in nocturnal adrenaline ($p<0.01$) and nora-

drenaline (p<0.01) excretion, as well as the decrease in resting (CON: -6 ± 2bpm; KE: +2 ± 3bpm, p<0.05), submaximal (CON: -15 ± 3bpm; KE: -7 ± 2bpm, p<0.05) and maximal (CON: -17 ± 2bpm; KE: -10 ± 2bpm, p<0.01) heart rate. Energy balance during the training period spontaneously turned negative in CON (-510 kcal/d), but not in KE (+47 kcal/d). The training consistently increased GDF15, but ~2-fold more in CON than in KE (p<0.05). In addition, delta GDF15 correlated with the training-induced drop in maximal heart rate (r=0.60, p<0.001) and decrease in osteocalcin (r=0.61, p<0.01). Other measurements such as blood ACTH, cortisol, IL-6, leptin, ghrelin, and lymphocyte count, and muscle glycogen content, did not differentiate KE from CON.
CONCLUSION: These findings indicate that KE inhibits the development of overreaching symptoms during a period of strenuous endurance training. In addition, we identify GDF15 as a potential marker of overreaching.

TART CHERRY JUICE HAS NO EFFECT ON MUSCLE FUNCTION LOSS OR MUSCLE SORENESS FOLLOWING A SOCCER MATCH IN PROFESSIONAL PLAYERS

CLIFFORD, T., ABBOTT, W., BRASHILL, C., BRETT, A.
NEWCASTLE UNIVERSITY

INTRODUCTION: Functional manifestations of exercise induced muscle damage (EIMD) include muscle soreness and loss of muscle function, symptoms which can persist for several days following strenuous exercise. Studies suggests that Montmorency tart cherry juice (TCJ), which is rich in antioxidant and anti-inflammatory compounds, can attenuate EIMD and hasten the recovery of muscle function, presumably due to a reduction in the acute inflammatory response associated with muscle damaging exercise. Nonetheless, studies conducted to date have been performed in controlled laboratory environments and with untrained volunteers, questioning the transferability of these findings to professional athletes. Thus, the aim of this study was to investigate the effects of TCJ on recovery from a soccer match in professional players.
METHODS: This study employed a double blind, placebo controlled, crossover design. Ten professional soccer players from the reserve team of an English Premier League Club (age, 19 yrs; height, 1.8±0.5 m; mass, 76.9±1.2 kg) consumed 2 x 30 ml servings of TCJ or an isocaloric cherry flavoured control drink (CON) before and after a 90 min match, and 12 and 36 h following the match. Muscle function (countermovement jump height: CMJ, reactive strength index: RSI) and subjective muscle soreness (MS), were measured pre, 12, 36 and 60 h following each match.
RESULTS: GPS data indicated that distance covered in each match was not different (TCJ, 10.6 km; CON, 10.1 km; P=0.158). CMJ performance was similarly reduced in the days after the match following TCJ and CON supplementation, with the greatest loss occurring at 12 h post-match (-5.9±3.4% vs. -6.0±3.4% of baseline values, respectively; P=0.808; ηp2=0.031). CMJ was reduced by ~3% 60 h post, but no differences were observed between groups (P>0.05). Decrements in RSI were also greatest at 12 h post-match (TCJ, -10.1±8.4% vs. CON,-14.0±4.8% of baseline values) but no group differences were observed at any time point (P=0.562; ηp2=0.065). MS increased 12-60 h post-match in both groups, peaking at 12 h post (TCJ, 119±14; CON, 118±22 mm) but no group differences were observed (P=0.706; ηp2=0.050).
CONCLUSION: This is the first study to assess the effects of TCJ on recovery in professional athletes. The primary findings of this study were that tart cherry juice did not attenuate markers of EIMD and hasten recovery following a soccer match in professional players. These findings are in contrast to a number of studies purporting the benefits of TCJ supplementation on EIMD in sub-elite and untrained athletes. These findings suggest that TCJ is not an effective recovery aid when 1) an ecologically valid model of inducing muscle damage is performed, 2) there are no dietary restrictions and, 3) participants are elite, professional players, and therefore the magnitude of muscle damage is relatively mild. These findings question the use of TCJ as a recovery aid in professional soccer players.

CHINESE HERBAL DECOCTION (DANGGUI BUXUE TANG) SUPPLEMENTATION AUGMENTS PHYSICAL PERFORMANCE AND FACILITATES PHYSIOLOGICAL ADAPTATIONS IN SWIMMING RATS

CHANG, C.W, HSU, M.C, WU, Y.T.
KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: In the sports field, scientists have been fascinated with the investigation of the benefits and safety of medicinal herbal supplements. One of the popular Danggui (DG) formulae, Danggui Buxue Tang (DBT), has been suggested to have outstanding performance-enhancing effects. However, its action in terms of biochemical regulation is not yet well understood. The objective of this work was to understand whether DBT can improve physical capacity and alter energy expenditure under exercise training.
METHODS: Forty rats were assigned to four groups: sedentary (SE), exercise training (ET), ET supplemented with 0.3 g/kg rat/d DG extract, and ET supplemented with 1.8 g/kg rat/d DBT extract. During the twenty-one-day treatment period, the exercised groups were subjected to a protocol of swimming training with a gradually increased load. Physical performance evaluation was assessed using the forelimb grip strength test and an exhaustive swimming test. Muscle glycogen contents and exercise-related biochemical parameters were analysed.
RESULTS: Both herbal supplementations remarkably elevated physical performance (approximately 50% and 80% improvement for DG and DBT, respectively, compared with SE). In particular, grip strength in DBT-treated rats was even significantly better than that in the rats treated with DG ($p < 0.05$). DBT also preserved muscle glycogen storage with exercise training. Regarding the regulation of fuel usage, DBT had a positive impact alongside ET on reducing anaerobic glycolysis via decreased serum lactate and lactic dehydrogenase levels.
CONCLUSION: Our results suggest that the increase in exercise capacity after DBT supplementation may be attributed to its effects on metabolic adaptations in response to high-intensity exercise. Furthermore, in combination with exercise training, DBT provides a better ergogenic effect than DG alone.

THE EFFECT OF DIFFERENT KIND OF EXERCISE ON THE LNCRNA GENE EXPRESSION

DROZDOVSKA, S., POLISHCHUK, A., HRUBYAK, L., DOLZHENKO, M., DOSENKO, V.

NATIONAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORT OF UKRAINE,SHUPYK NATIONAL MEDICAL ACADEMY OF POSTGRADUATE EDUCATION, BOGOMOLETS PHYSIOLOGY INSTITUTE, NATIONAL ACADEMY OF SCIENCE, KYIV, UKRAINE

INTRODUCTION: Recently a new group of RNA has been found, termed long noncoding RNA (lncRNA), which relates to wide range of biological pathways in response to exercise (1). Gene expression of lncRNAs can serve as the potential informative detector of the adaptation process to exercise (2). However, no study has been conducted on the overall expression patterns of lncRNAs during exercise.
METHODS: During the course of the study a total of 53 highly qualified endurance athletes (swimming, rowing, long distance running) were enrolled. A total of 30 subjects not involved in sport activities were recruited in the sedentary group. LIPCAR, NRON, MIAT, MHRT lncRNAs were extracted from blood. lncRNAs gene expression was studied using the method of Real-time PCR.
RESULTS: LIPCAR lncRNA expression decreased by 2.07 times ($p < 0.05$) after high intensity exercise, and by 17.5% after moderate intensity exercise. In untrained subjects the expression increased by 2.48 times. NRON expression increases after a high intensity exercise by 7 times ($p < 0,05$) and decreases after a moderate intensity exercise. The expression of MHRT, MIAT lncRNAs increases both after high intensity exercise (by 4.26 times, and 6.4, $p < 0.05$ respectively), and moderate intensity exercise.
CONCLUSION: LncRNAs expression respond differently to exercise of different duration and intensity. After high intensity exercise LIPCAR expression significantly decreases, while NRON, MHRT, MIAT significantly increases. After moderate intensity exercise, the expression of NRON, MIAT, decreases slightly, while MHRT increases. Adaptation to exercises of varying intensity results in a different expression of non-coding RNA. Long-term adaptation to long distance running leads to increased expression of NRON, MHRT, MIAT and decrease LIPCAR level.

MICRORNA RESPONSES TO ACUTE RESISTANCE EXERCISE PROTOCOLS: A PILOT STUDY

WOOD, N., PETERS, R., BALCHIN, C., PRICE, O.J., CAMPBELL, M.D., JOHNSON, D.L., STAVROPOULOS-KALINOGLOU, A.

1,4LEEDS BECKETT UNIVERSITY, 2,3UNIVERISTY OF LEEDS

INTRODUCTION: MicroRNAs (miRNAs) are non-coding RNAs that have an important role in regulating gene expression. Although circulating miRNAs are considered good markers of response to acute resistance training (RT) (1), change in expression according to the applied stimulus (e.g. high-intensity low-volume vs. low-intensity high-volume) has yet to be investigated. The aim of this study was therefore to evaluate the impact of RT protocols on circulating miRNA levels. We selected miRNA 29a, 128a, 486 as they have been previously shown to be implicated in skeletal muscle regeneration and structural adaptation (i.e. hypertrophy) (2).
METHODS: Following local research ethics approval and written informed consent ten healthy recreationally active males (accustomed to resistance exercise) (age = 24 ± 3 years; BMI = 25.5 ± 2.8) were enrolled into the study. Participants attended the laboratory on three occasions separated by a period of 3-7 days. During visit 1, baseline maximal strength (1-RM) was determined via a 10 sub-maximal repetition protocol (3). Subsequently, in randomised order (i.e. visit 2 and 3) participants completed 3 sets of seated leg-press to volitional exhaustion at a workload equivalent to 30% or 70% 1-RM. Venous blood samples were obtained pre and 10-min post exercise. Real-time polymerase chain reactions (RT-PCR), using Qiagen RT-PCR kits and protocols were conducted to quantify the change in selected miRNA (29a, 128a, 486) levels between RT protocols. Log2 fold expression for each miRNA was calculated from the RT-PCR data.
RESULTS: Baseline 1-RM did not correlate with changes to miRNA levels (70%: 29a R=-0.207, 128a R=-0.006, 486 R=0.311, 30%: 29a R=-0.268, 128a R=0.092, 486 R=0.384) and no significant difference was observed in miRNA expression between RT protocols ($P<0.05$) (miRNA 29a P=0.230; 128a P=0.178; 486 P=0.379). Importantly, however, a trend in data was observed to suggest circulating levels of all miRNAs were lower following high-intensity low-volume RT (29a mean=-1.843, 128a mean=-1.508, 486 mean=-2.231) in comparison to low-intensity high-volume RT (29a mean=0.148, 128a mean=0.296, 486 mean=-0.433).
CONCLUSION: For the first time, our findings indicate that high-intensity low-volume RT induces a greater reduction in miRNA levels in comparison to low-intensity high-volume RT. The absence of statistical significance between protocols may be related to the low sample size of our population and/or acute study design. Further research is required to confirm our findings, determine if other miRNAs may be affected by RT and what the longer-term adaptations to different RT protocols may be.

MOLECULAR ANALYSIS AND SPORT PERFORMANCE IN ÉLITE RUGBY UNION PLAYERS

PASQUALETTI, M., CANU, G., MINAZZATO, L., URBANI, A., MORDENTE, A., GALVANI, C.

UNIVERSITÀ CATTOLICA DEL SACRO CUORE

INTRODUCTION: The field of sports genetics has demonstrated a rapid expansion in recent years, with an increasing need to have a simultaneous analysis of genomic and phenotypic (performance) data (1). The aim of this study was to identify genetic correlations with rugby-specific physiological and anthropometric variables.
METHODS: 27 élite rugby union players (22.6±2.9 y; 93.6±16.1 kg; 180.9±7.2 m) were divided according to playing position: forwards and backs. Genomic DNA was extracted from whole EDTA blood samples. Genotyping was performed by PCR allele-specific, PCR-RFLP method and direct Sanger sequencing for ACE I/D polymorphism, ACTN3 R577X and MCT1 A1470T variants, respectively. Lean body mass (skinfolds measurement, LMI), muscular power (counter movement jump, CMJ), agility (5-0-5 agility test, AT), speed (20m sprint test, ST), maximal aerobic power (Yo-Yo intermittent recovery test level 1, V'O2max) and repeated sprint ability (20s cycle 12x20m, RSA) were evaluated. The distribution of genotypes was determined by chi-square and the unpaired t-test was used to compare forwards and backs; levels of significance were set at $p<.05$.

RESULTS: According to anthropometric characteristics forwards are substantially heavier and markedly taller than backs, LMI resulting lower for the backs than for the forwards (weight: 106.7±10.1, 81.5±9.6 kg; height: 184.8±5.5, 177.4±6.9 cm; LMI: 45.8±4.8, 57.8±4.8 kg/mm; p<.01). According to physical characteristics backs generally produce a superior vertical jump performance, are faster during the agility and sprint test, have superior V'O2max (expressed relative to body mass) values and a lower total sprint time compared with the forwards (CMJ: 41.3±5.9, 36.0±6.3 cm; AT: 2.2±0.1, 2.4±0.2 s; ST: 3.0±0.1, 3.2±0.2 s; V'O2max: 51.1±3.2, 46.1±3.2 mlO2/kg/min; RSA: 38.2±0.9, 42.0±2.4 s; p<.05). Genotypes and allele frequencies were comparable between groups in both absolute and relative terms (ACE: X^2=1.362, df=2, p=ns; ACTN3: X^2=2.085, df=2, p=ns; MCT1: X^2=1.057, df=2, p=ns).
CONCLUSION: Our data confirm the pronounced differences in the anthropometric and physical characteristics of the forwards and backs (2), and a non-significant difference in the ACE, and ACTN3 genotype in the proportions and allele frequencies between the two groups of players (3,4). Moreover, the information obtained from this study has found no significant differences in the distribution of the MCT1 genotype between forwards and backs.

ACTN3 GENOTYPES AND ITS RELATIONSHIP WITH MUSCLE MASS AND FUNCTION OF KOSOVAN ADULTS

BOSHNJAKU, A., KRASNIQI, E., TSCHAN, H., WESSNER, B.
UNIVERSITY OF VIENNA

INTRODUCTION: The ACTN3 gene in humans encodes the muscle protein α-actinin 3, whereby a common null polymorphism (rs1815739) results in the replacement of an arginine (R) with a premature stop codon (X) at the amino acid at position 577 [1]. It has been shown that humans homozygotic for the XX genotype were at a significantly higher risk of sarcopenia and osteoporosis than RR homozygotes [2]. Therefore, the aim of this study was to determine the relationship between ACTN3 genotypes, muscle mass and function in Kosovan men and women.
METHODS: In this cross sectional study, genomic DNA was extracted from saliva samples of 300 participants living in Prishtina (Kosovo) (M: 47.2%, F: 52.8%) aged 66.1 ± 9.8 years. ACTN3 genotypes were assessed on a QuantStudio 7 Flex Real-Time PCR System using commercially available primers and probes. Anthropometric data (weight, BMI, body composition), physical performance (handgrip strength, 30-s chair stand test and gait speed) and isokinetic peak torque of knee extensors were determined at 60°/s (Biodex). Differences between genotype groups (RR, RX, XX) were analyzed by one-way ANOVA.
RESULTS: The study population was characterized by a BMI of 29.3±4.7 kg/m² (f: 30.6±4.7 kg/m², m: 27.9±4.3 kg/m², p<0.001), muscle mass of 26.9±5.4 kg (f: 23.5±3.2 kg, m: 30.8±5.4 kg, p<0.001), a handgrip strength of 30.8±9.6 kg (f: 25.4±5.9 kg, m: 36.9±9.2 kg, p<0.001), a 30-s chairstand test of 11.7±3.1 reps (f: 11.3±3.2 reps, m: 12.0±3.0 reps, p=0.049), a gait speed of 1.52±0.34 m/s (f: 1.45±0.30 m/s, m: 1.60±0.37 m/s, p<0.001), and a isokinetic peak torque (knee extensors) of 74.6±39.2 Nm (f: 58.9±27.6 Nm, m: 92.2±42.7 Nm, p<0.008). The quality of 282 samples (94.0%) was high enough to perform genotyping. The ACTN3 genotype distribution in the remaining samples was RR=41.5%, RX=53.9%, XX=4.6% which was in Hardy-Weinberg equilibrium. However, no significant differences were found between the genotype groups in all measured parameters when tested in the whole population or separated by gender (p>0.05).
CONCLUSION: Our data suggest that muscle mass, strength and function are not related to ACTN3 genotype in Kosovan older adults. Interestingly, the percentage of participants carrying the XX genotype (4.2%) was considerably lower compared to the worldwide average (18%) [1]. As the level of overweight and obesity in this population was high (M: 76.7%, F: 87.2%), this could have masked the outcome measures [3]. However, we hypothesize that during ageing environmental factors might become more important than genetics to determine physical fitness.

ASSOCIATION BETWEEN RAAS GENE POLYMORPHISM AND ELITE LONG-DISTANCE RUNNERS PERFORMANCE

YANG, X., HU, Y., LI, Y., GONG, L., MEI, T.
BEIJING SPORT UNIVERSITY

INTRODUCTION: The renin–angiotensin–aldosterone system (RAAS) played an important role in blood pressure(BP) regulation. Several researches had indicated the association between RAAS polymorphisms and the hypertension[1-3], and between BP and exercise[4]. Due to the important role of RAAS in aerobic capacity, the purpose of this study was to explore the association between RAAS gene polymorphisms and elite long-distance runners' performance, and the mechanism of how the polymorphism worked.
METHODS: (1) Analyzed 16 SNPs between elite long-distance runners and control subjects by MALDI-TOF-MS. RAAS SNPs were AGT rs5049/rs2148582/rs5051, REN rs5707/rs11240688/rs2887284, ACE rs4344/rs4363/rs4343, ACE2 rs2074192, AGTR1 rs5182, AGTR2 rs1403543, CYP11B1 rs6410/rs6387, and CYP11B2 rs1799998/ rs3802230. (2) Analyzed the association between 16 SNPs and cardio-pulmonary function data of 79 female long-distance runners.(3) PcDNA3.1-AGTR1 -T and pcDNA3.1-AGTR1-C plasmid were constructed, and the plasmids were transfected into mammalian 293T cells. AGTR1 mRNA levels were detected by RT-PCR.
RESULTS: (1) Genotype frequencies of AGTR1 rs5182 were significant different between the long-distance runners and control subjects, International-level runners and control subjects, 5km runners and control subjects, 10km runners and control subjects, male runners and male controls(p<0.05). No significant differences were found in other SNPs.
(2) AGT gene rs2148582 and rs5051 were associated with FVC/VC. REN gene rs5707 was associated with VC,FVC andFEV1, while rs11240688 was associated with FVC and FEV1. ACE gene rs4344 and rs4343 each was associated with FEV1. AGTR1 gene rs5182 was associated with MV, meanwhile AGTR2 gene rs1403543 was associated with FVC/VC.(p<0.05)
(3) Transiently transfected pcDNA3.1-AGTR1-T and pcDNA3.1-AGTR1-C plasmids into 293T cells successfully. However, mRNA levels between TT and CC were not significant different (p = 0.991).
CONCLUSION: AGTR1 gene rs5182 could be a genetic marker of elite long-distance runners in Han Population from Northern China, but this polymorphism did not affect AT1R protein function through changing its mRNA level. AGT rs2148582/rs5051, REN rs5707/rs11240688, ACE rs4344/rs4343 ,AGTR1 rs5182, and AGTR2 rs1403543 could be candidate molecular markers to predict cardio-pulmonary function of female long-distance runners in Han Population.

THE EFFECTIVENESS OF BLOOD FLOW RESTRICTION VS. HEAVY LOAD RESISTANCE TRAINING DURING REHABILITATION OF ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION PATIENTS: A UK NHS RANDOMISED CONTROLLED TRIAL.

HUGHES, L., ROSENBLATT, B., HADDAD, F., GISSANE, C., MCCARTHY, D., CLARKE, T., FERRIS, G., DAWES, J., PATON, B., PATTERSON, S.D.

ST. MARY'S UNIVERSITY

INTRODUCTION: Personalised blood flow restriction resistance training (BFRRT) has been proposed as a potential effective and feasible alternative to traditional heavy load resistance training (HLRT) for the rehabilitation of anterior cruciate ligament reconstruction (ACLR) patients.(1,2,) The aim of this study was to compare the effectiveness of BFRRT and standard care HLRT at improving skeletal muscle hypertrophy, strength and physical function in ACLR patients following surgery within the National Health Service (NHS).
METHODS: Twenty eight patients scheduled for unilateral ACLR surgery with hamstring autograft were recruited for this parallel group, two-arm, single assessor blinded randomised controlled clinical trial. Participants were block randomised to either HLRT (n=14) or BFRRT (n=14). Participants completed 8 weeks of biweekly unilateral leg press training on both limbs alongside standard hospital rehabilitation. Interventions were designed consistent with recommended protocols. Scaled maximal isotonic strength (10RM), muscle morphology of the vastus lateralis of the injured limb, self-reported function, Y-balance test performance, knee joint pain and effusion and range of motion (ROM) were assessed at pre-surgery, post-surgery, mid-training and post-training. Knee joint laxity and scaled maximal isokinetic knee extension and flexion strength at 60°/s, 150°/s and 300°/s were measured at pre-surgery and post-training.
RESULTS: Twenty-four participants completed the study and there were no adverse events. Scaled 10RM strength significantly increased in both limbs (40-106% and 33%-104%) with no group differences. Significant increases in knee extension and flexion peak torque were observed at all speeds in the non-injured limb with no group differences. Significantly greater attenuation of knee extensor peak torque loss at 150°/s and 300°/s and knee flexor torque loss at all speeds was observed with BFRRT. No group differences in knee extensor peak torque loss were found at 60°/s. Significant and comparable increases in muscle thickness (5.8-6.7%) and pennation angle (3.4-4.1%) were observed with no group differences. No significant changes in fascicle length were observed. Significantly greater and clinically important increases in several measures of self-reported function (50-218% vs. 35-152%), Y-balance performance (18-59% vs. 18-33%), range of motion (78% vs. 48%), and reductions in knee joint pain (67% vs. 39%) and effusion (6% vs. 2%) were observed with BFRRT compared to HLRT, respectively. No adverse effects on laxity were observed.
CONCLUSION: Personalised BFRRT can improve skeletal muscle hypertrophy and strength to a similar extent as HL-RT with a greater reduction in knee joint pain and effusion, leading to greater overall improvements in physical function. Therefore, BFRRT may be more appropriate for early rehabilitation in ACLR patient populations within the NHS.

LOWER LIMB ANTHROPOMETRICS AND KNEE DYNAMIC VALGUS AS EXPLANATORY FACTORS FOR LANDING KINETICS. A FEMALE SOCCER COHORT STUDY.

BIKANDI, E.1, AMÚ-RUIZ, F.A.2, GÓMEZ, A.3, LEKUE, J.A.1, LARRUSKAIN, J.1, ETXALEKU, S.3, IZQUIERDO, M.4, SETUAIN, I.3,4

ATHLETIC CLUB

INTRODUCTION: Due to the devastating impact of the ACL injury on the athlete´s career, many multifactorial prevention screenings have been widely designed specially in female soccer, in order to reduce injury incidences. Functional, biomechanical and neuromuscular contributors have been described. Pelvic and lower limb anthropometrics in combination with biomechanical variables such as knee valgus kinematics and landing kinetics, are considered as important factors that should be evaluated during any ACL injury risk screening procedure. There is large evidence asserting that women who suffered an ACL injury showed previously larger vertical ground reaction forces during a drop landing. However, the relation of this fact with knee valgus kinematics and anthropometrical variables such as pelvic width and femur length, remains controversial. Thus, the objective of this cross-sectional descriptive study was to analyse if lower limb anthropometrics and knee valgus kinematics could explain landing kinetics as ACL injury risk factor in a female football environment.
METHODS: 64 adolescent female soccer players (age 20,32•4,9) from 4 different football teams completed a pre-season ACL injury prevention screening conformed by functional, biomechanical and performance testing battery. Pelvic width and femur length were measured as anthropometrics gold variables.). Knee valgus kinematics and landing kinetics during a vertical bilateral drop jump landing were registered and extracted. Correlation and significance level between variables interaction were analysed.
RESULTS: No significant p correlation index (<0.4) was observed between all variables. However, there was a little correlation (r=0,303) between the landing peak ground reaction force and knee valgus kinematics, at p = 0,01 significance level, and also with the femur length (r=-0,338). In addition, the linear regression analysis showed that the pelvic width, femur length and knee valgus kinematics explained in 89,1% the landing kinetics results, with a significance level p=<0,05.
CONCLUSION: A considerate significance level between lower limb anthropometrics, knee valgus kinematics and landing kinetics was the main finding at the present study. According with previous research, altered motor control capabilities would cope with aberrant lower limb mechanics in strenuous movement patterns like the drop jump. Due to their unique characteristics, female athletes would have more potential intrinsic risk factors such as pelvic and femur morphology. However, the causal relationship between these variables still remains controversial. Thus, more exhaustive screening methodologies with stronger measurement procedures are needed in order to detect the main contributors for ACL injury mechanics.

ACUTE AND CHRONIC NEUROMUSCULAR ADAPTATIONS TO LOCAL VIBRATION: TOWARD A NEW NEUROMUSCULAR REHABILITATION MODALITY

LAPOLE, T.1, COULONDRE, C.2,3, RUPP, T.2, SOURON, R.1, MILLET, G.Y.1

1UNIV LYON, UJM SAINT-ETIENNE, LABORATOIRE INTERUNIVERSITAIRE DE BIOLOGIE DE LA MOTRICITÉ, EA 7424, F-42023, SAINT-ETIENNE, FRANCE

INTRODUCTION: Muscle disuse (e.g. bed rest, injury) is known to reduce muscle strength through both peripheral and central alterations. While classical countermeasures implying traditional muscular exercise (e.g. strength training) or its alternatives (e.g. neuromuscular electrical stimulation, whole-body vibration) have proven efficacy, they are not appropriate in case of extreme weakness or pain. In this context, the aim of this presentation is to emphasize through our recent works that local vibration (LV) directly applied onto a relaxed muscle or its tendon is a strong stimulus to modulate the central nervous system through the activation of Ia afferents (Souron et al. 2018b) and may be of prime interest in rehabilitation. When LV is acutely applied for 30 min, a decrease in force-generating capacities has been reported, principally triggered by neural alterations (Souron et al. 2017). Thus, LV has the potential to act as a significant neuromuscular workload by inducing some fatigue which, when repeated, trigger long-term neural adaptations leading to improved functional performance (Souron et al. 2018a). As a perspective, we now investigate potential benefits of LV in rehabilitation following reconstruction of the anterior cruciate ligament (ACL). Muscle weakness that may persist several months after surgery is likely the consequence of muscle atrophy and arthrogenic muscle inhibition. Here, we propose to use LV in the early rehabilitation period to reduce surgery-induced arthrogenic muscle inhibition and accelerate neuromuscular recovery.
METHODS: Eight subjects awaiting ACL reconstructive surgery were randomly assigned to an experimental (n=4) or control group (n=4). Both groups followed a standard rehabilitation during 8 weeks after surgery. In addition, the experimental group had LV on the quadriceps of their injured leg thrice per week (1-h session; 100 Hz). Maximal isometric voluntary contraction (MVC) of the knee extensors was recorded before surgery and after the 8-week rehabilitation period in both groups.
RESULTS: At 8 weeks post-surgery, the control group presented a 29±11% decrease in MVC while the decrease was 19±15% in the experimental group.
CONCLUSION: Local vibration applied after reconstruction of the anterior cruciate ligament seems to promote early neuromuscular recovery. These preliminary results need to be confirmed on a larger population.

EFFECTS OF SPORT-SPECIFIC SENSORIMOTOR TRAINING VS HYPERTROPHY TRAINING ON KNEE JOINT MOTOR CONTROL OF ELITE FEMALE HANDBALL PLAYERS IN SPORT-SPECIFIC RISK SITUATIONS

ERDRICH, S.1, KUNI, B.2, WOLF, S.I.3, SIEBOLD, R.4, SCHMITT, H.5, ROTH, K.1

1: HEIDELBERG UNIVERSITY OF SPORT AND SPORT SCIENCE, 2: ORTHO-CENTER KARLSRUHE, 3: UNIVERSITY HOSPITAL HEIDELBERG, 4: ATOS HOSPITAL HEIDELBERG, 5: ATOS HOSPITAL HEIDELBERG

INTRODUCTION: Deficient motor control during landing is considered a risk factor for anterior cruciate ligament (ACL) injury. The aim of this study was to investigate the effects of six-weeks progressive sport-specific sensorimotor training (PSSMT) versus machine-based hypertrophy training (HYPT) on knee biomechanics and electromyographic activity of elite female handball players in sport-specific risk situations. In a sub-hypothesis we examined the correlation between knee kinematics and kinesiophobia.
METHODS: 19 female athletes participated in this study. 6 female sports students were tested twice to determine test-retest-reliability. 13 elite female handball players were assigned via matched randomization to a PSSMT (n=6) or a HYPT group (n=7). Kinematics and kinetics were captured via a VICON motion analysis system (120 Hz) and two Kistler force plates (1080 Hz). Surface EMG was collected bilaterally from the gluteus medius (GluM), vastus medialis (VM), Biceps Femoris (BF) and Gastrocnemius Medialis (GM). Functional dynamic testing included a DJ (30 cm) and the modified "Heidelberg-Jumping-Coordination-Test" (mHJCT, adapted from [1]). The mHJCT is a single leg jumping test with an unanticipated change of direction after hitting an overhead goal (jump-land-side-cut=JL-SC, jump-land-stabilize=JL-Stab, jump-land-cross-cut=JL-CC). All subjects underwent a clinical knee examination and filled in questionnaires concerning self-reported knee function and kinesiophobia. Pre-post changes and group effects were calculated with paired student t-tests and an ANCOVA respectively (alpha=0,05). For our sub-hypothesis a Pearson´s correlation was conducted.
RESULTS: Test-retest-reliability showed variable results. Striking was the throughout excellent reliability for the kinematics of the JL-Stab maneuver for the non-dominant (nd) side (ICC: 0,844-0,948). We found three group effects: PSSMT significantly reduced joint excursion in transverse plane (p=,0.43) for JL-Stab and joint excursion in sagittal plane (p=.011) for JL-SC for the nd side. Latter was involved with an increased BF activity (n.s. group effect). HYPT group showed an increased peak valgus (p=.015) for JL-Stab for the nd limb which was accompanied by a decreased GluM and GM activity. For the sub-hypothesis we found a moderate inverse correlation between higher kinesiophobia and increased peak valgus of the nd side during the DJ (r=.-490, p=.023).
CONCLUSION: PSSMT improved dynamic knee stabilization in transverse plane in unanticipated single leg landings after hitting an overhead goal, whereas HYPT worsened dynamic valgus for the same maneuver. Hypertrophy training without functional input should be considered critically, because it is questionable if the strength transfer is guaranteed in all three planes. Questionnaires of kinesiophobia should be incorporated in ACL injury prevention research; they might have the potential to identify high-risk athletes without expensive equipment.

EFFICACY OF HEAVY SLOW RESISTANCE TRAINING IN MANAGEMENT OF PATELLAR TENDINOPATHY: A SINGLE BLINDED RANDOMIZED CONTROLLED TRIAL

WIESINGER, H.P.1, KÖSTERS, A.1, MÜLLER, E.1, SEYNNES, O.R.2, HERFERT, J.3, HECHT, S.3, NIEBAUER, J.3, RIEDER, F.1,3

1 PARIS-LODRON UNIVERSITY OF SALZBURG, 2 NORWEGIAN SCHOOL OF SPORT SCIENCES, 3 PARACELSUS MEDICAL UNIVERSITY SALZBURG

INTRODUCTION: Heavy slow resistance (HSR) training is currently regarded as the treatment of choice for the conservative treatment of patellar tendinopathy (Malliarias et al. 2013). However, the efficacy of this type of intervention in reducing pain and restoring tendon structure and function has never been assessed against a wait-and-see tendinopathic control group. In this prospective study, we com-

pare the effects of HSR training in patients with patellar tendinopathy to the changes measured without intervention in equally affected controls.
METHODS: Patients with chronic (>3 months), untreated patellar tendinopathy were randomized to 3 months of wait-and-see (WaS; 29±5 yrs; male=12; female=1) or HSR (27±6 yrs; male=11; female=3). Pre- and post-intervention testing comprised evaluations of neovascularization, tendon degeneration (hypo-echoic area and/ or anterior-posterior thickening), pain (VAS), functional limitations (VISA-P), ultrasound-based determination of mechanical and material properties and MRI-based measurement of patellar tendon cross-sectional area in vivo.
RESULTS: At baseline, anthropometric and tendon parameters did not differ between groups. During the course of the study, mean HSR training compliance was 80%. Significant group x time interactions for the VISA-P (p=.005, η^2=.36) and VAS scores (p=.002, η^2=.25) proved clinically improvement for the HSR group only (+24±15pts; -38±26pts). However, training did not affect indicators of tendon degeneration and neovascularization. Similarly, isometric quadriceps strength (+7%; p=.223; η^2=.06), patellar tendon stiffness (-7%; p=.411; η^2=.03) and Young's modulus (-4%; p=.850 η^2<.01) were unaffected by HSR training, although a site-specific decrease in patellar tendon cross-sectional area (medial site: -5%; p=.018; η^2=.21) was observed in this group.
CONCLUSION: The meaningful improvements in patellar tendon pain and function after HSR training were comparable to recent findings (Kongsgaard et al. 2010). Interestingly, the efficacy of HSR on this primary outcome was not reflected in features typically used in the diagnosis of tendinopathy (tendon degeneration and neovascularization) or in measurements of tendon mechanical and material properties. Additionally, the reasons why isometric knee extension torque did not increase with training or the decrease in patellar tendon cross-sectional area remain elusive. In summary, this study confirmed the efficacy of HSR to treat tendinopathy in a design including WaS patients but further research is needed to uncover the mechanisms associated with clinical improvements.

OP-MI06 Health and fitness

BREAKING UP PROLONGED SEDENTARY TIME IN INDIVIDUALS WITH CHRONIC SPINAL CORD INJURY: THE SPINAL CORD INJURY MOVE MORE (SCIMM) STUDY.

BAILEY, D., WITHERS, T.M., GOOSEY-TOLFREY, V.L., LEICHT, C.A., DUNSTAN, D.W., CROFT, L.

UNIVERSITY OF BEDFORDSHIRE

INTRODUCTION: Individuals with a spinal cord injury (SCI) have an increased risk of cardiovascular disease (CVD) as a result of metabolic SCI-related disturbances and high sedentary time. High CVD risk is characterised by a clustering of CVD risk markers including obesity, dyslipidaemia and impaired glucose tolerance. In able-bodied individuals, breaking up prolonged sitting with short, regular bouts of walking can reduce postprandial glucose and triglyceride concentrations. However, the effects of breaking up prolonged sedentary time in individuals with an SCI have not been examined. The primary aim of this study was therefore to evaluate the postprandial glucose response to breaking up sedentary time in this population. Secondary aims were to explore the effects on other CVD risk markers and psychological outcomes.
METHODS: A randomised controlled two-condition crossover design was used. Fourteen participants (six male, eight female) with a chronic SCI below the fifth Thoracic vertebra aged 50.5±8.5 years (DEXA trunk fat 44.3±7.7%) completed the study. Participants completed two, 5.5 h conditions separated by ≥6 days: (1) uninterrupted sedentary time (SED), and (2) sedentary time interrupted with 2 min of moderate-intensity (Rating of Perceived Exertion = 13 [Borg 6-20 scale]) arm-crank activity every 20 min (SED-ACT). Standardised breakfast and lunch meals were provided prior to the start of each condition and at 3 h, respectively. Blood samples were collected regularly to allow calculation of net incremental area under the curve (iAUC) for glucose, insulin and triglycerides. Blood pressure was measured hourly and questionnaires to assess psychological responses were completed at baseline and post-condition. Linear mixed models were used to compare the outcomes between conditions.
RESULTS: Post-lunch glucose iAUC was significantly lower in SED-ACT (mean 112.3; 95% confidence interval 60.4, 164.3 mmol/L·2.5 h) than SED (179.3; 127.4, 231.3 mmol/L·2.5 h, p=0.015) with a large effect size (d=0.66). Post-breakfast (p=0.905) and cumulative 5.5 h (p=0.275) glucose iAUC did not differ between conditions (p=0.905). There were no significant differences in insulin iAUC, triglyceride iAUC, or blood pressure between conditions (p>0.05). There was a trend for positive affect increasing during SED-ACT (p=0.055) with no change in SED and a significant main effect of condition (p=0.008) for mental wellbeing in favour of SED-ACT. Participants also rated the activity breaks during SED-ACT as enjoyable.
CONCLUSION: These findings suggest that breaking up prolonged sedentary time is an enjoyable approach to lowering postprandial glucose concentration and improving mental health in individuals with an SCI. This type of intervention may thus have promise for reducing CVD risk in this sedentary population.

CARDIOVASCULAR RESPONSE TO PEAK VOLUNTARY EXERCISE IN MALES WITH CERVICAL SPINAL CORD INJURY

MACHAC, S., RADVANSKY, J., KOLAR, P., KRIZ, J.

DEPARTMENT OF REHABILITATION AND SPORTS MEDICINE AT 2ND MEDICAL FACULTY, CHARLES UNIVERSITY AND UNIVERSITY HOSPITAL MOTOL

INTRODUCTION: Traumatic damage to the cervical spinal cord is usually associated with a disruption of the autonomic nervous system (ANS) and impaired cardiovascular control both during and following exercise. The magnitude of the cardiovascular dysfunction remains unclear. The aim of the current study was to compare cardiovascular responses to peak voluntary exercise in individuals with tetraplegia and able-bodied participants.
METHODS: A case-control study.

SUBJECTS:
Twenty males with cervical spinal cord injury (SCI) as the Tetra group and 27 able-bodied males as the Control group were included in the study.
OUTCOME MEASURES:
Blood pressure (BP) response one minute after the peak exercise, peak heart rate (HRpeak), and peak oxygen consumption (VO2peak) on an arm crank ergometer were measured. In the second part of the study, 17 individuals of the Control group completed the Tetra groups workload protocol with the same parameters recorded.
RESULTS: There was no increase in BP in response to the exercise in the Tetra group. Able-bodied individuals exhibited significantly increased post-exercise systolic BP after the maximal graded exercise test (123±16%) and after completion of the Tetra groups workload protocol (114±11%) as compared to pre-exercise. The Tetra group VO2peak was 59% and the HRpeak was 73% of the Control group VO2peak and HRpeak, respectively.
CONCLUSION: BP did not increase following maximal arm crank exercise in males with a cervical SCI unlike the increases observed in the Control group. Some males in the Tetra group appeared to be at risk of severe hypotension following high intensity exercise, which can limit the ability to progressive increase and maintain high intensity exercise.

EFFECTIVENESS OF ACTIVE VIDEO GAMES USAGE ON INTELLECTUAL DISABLED CHILDREN'S BODY COMPOSITION, PHYSICAL ACTIVITY LEVEL AND MOTOR ABILITY

WANG, J., LAU, W.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Children with intellectual disabilities (ID) are more vulnerable to obesity when compared to the normal children. Active video games (AVGs) on physical activity (PA) behavior have attracted academic interest since 2000. It has been demonstrated that AVG intervention is compatible with the school setting and behavioral change in health and PA. However, special populations such as ID children and their needs have been neglected in this area. This study aimed to determine the effect of a prescribed AVG intervention on ID children's body composition, PA levels, and motor ability.
METHODS: A standard two-arm parallel, single-blinded cluster trial was conducted in 203 ID students aged 8-18 years from five special schools in Hong Kong. Students with mild intellectual disability categories were assigned into intervention group and control group. The intervention group was provided with AVG (bowling, soccer, boxing, track and field, table tennis, beach volleyball, golf, tennis). The intervention consisted of two 30-min sessions per week, with a total of 12 weeks. The exercise intensity of AVG employed was moderate-vigorous intensity (3-6 METs). The control group continued with usual PA alone and did not receive the AVG intervention.
RESULTS: Significant increases in BMI and body fat percentage were observed at post-test within both groups. The same trend existed for motor skills. Children's BOT-2 score within the intervention group increases from 52.06 (21.80) baseline to 55.27 (16.32) after intervention, while it increased from 58.01 (14.74) at baseline to 60.46 (14.20) at post-test within the control group. However, the intervention effect with adjusted changes in the intervention group relative to the control group was not statistically significant for children's body composition, physical activity levels, and motor skills. Among the children with different age and body weight groups, the adjusted changes were not significant, indicating no intervention effect was detected after the 12-week intervention using AVG.
CONCLUSION: A more in-depth understanding why the AVG intervention towards ID student's body composition, PA and motor skills is ineffective was discussed. These observation and explanation may provide better guidelines for future AVG intervention to the ID children.

THE RELATIONSHIP BETWEEN EXERCISE STARTING TIMING DURING PREGNANCY AND PREVALENCE OF SACROILIAC JOINT PAIN IN POSTPARTUM.

KAWABE, R., MORINO, S., ISHIHARA, M., UMEZAKI, F., HATANAKA, Y., YAMASHITA, M., AOYAMA, T.

KYOTO UNIVERSITY

INTRODUCTION: More than 50% pregnant women experience low back and posterior pelvic pain during pregnancy, and these 45% continue to express these pain in postpartum. And quality of life and activities of daily living are impaired during pregnancy and postpartum. Although there are some studies about the relationship between exercise habits during pregnancy and the pain. there is few report discussing the relation between the start time of exercise. So the purpose of this study is to investigate the relationship between exercise starting timing during pregnancy and prevalence of sacroiliac joint (SIJ) pain in postpartum.
METHODS: In this study, 32 pregnant women (30.7 ± 4.9 years old) who attended the obstetrics and gynecology clinic were participated. The data were collected four times at regular checkups and midwives' health promotion days ; the 24th week of pregnancy, the 30th week, the 36th week, and immediately after birth. The questionnaire including about SIJ pain and exercise habits during pregnancy was obtained at the points. Depending on starting time of exercise, the participants were classified to three groups; a group who underwent exercise continuously from the 24th week of pregnancy until birth (A group) , a group conducted from the 30th week (B group), a group conducted from the 36th week (C group). The ratio of presence / absence of SIJ pain after birth between 3 groups was compared by the Chi-square test. Thereafter, when a significant difference was observed, the Chi-square test with Bonferroni correction was used to compare within each group. The statistical significance level was less than 5%.
RESULTS: There were 10 subjects in A group, 8 subjects in B group, and 11 subjects in C group. Prevalence of SIJ pain after childbirth was 30% in A group, 75% in B group, and 81.8% in C group. The incidence of SIJ pain was significantly different between 3group (p=0.034). Among them, A group was significantly lower than C group (p=0.016). Pregnant women who started exercise early during pregnancy tend to have less SIJ pain.
CONCLUSION: The results showed that the earlier stating of exercise lower the rate of occurrence of SIJ pain. Ligaments of SIJ loose by increasing relaxin values during pregnancy. And heavy load to the pelvis during childbirth causes sacroiliac joint pain. The muscles strengthening may prevent the damage of SIJ. There may be many limitations on current study, but the result of the study may promote the prevention of SIJ pain of pregnant women. Early starting of exercise prevents the SIJ pain after birth.

EFFECTS OF EXERCISE AND EXERCISE COUNSELLING IN HEMODIALYSIS PATIENTS: PRELIMINARY RESULTS

BOGATAJ, S., PAJEK, J., BUTUROVIC PONIKVAR, J., PAJEK, M.

UNIVERSITY MEDICAL CENTRE LJUBLJANA

INTRODUCTION: Exercise has various benefits for hemodialysis (HD) patients. Currently, the most widely used exercise program for HD patients is cycling during dialysis. The aim of this study was to determine the effect of the addition of functional exercise and exercise counselling guided by a kinesiologist to the basic exercise program of cycling during dialysis on HD patients.
METHODS: Twenty-nine HD patients participated in the study. We first tested their physical condition with selected motor tests (T0). The main outcomes of our measurements were: 6-minutes walking test (6MWT), 10 repetitions sit-to-stand test (STS10), handgrip strength test (HG) and sit-and-reach test (SRT). After baseline testing, we carried out randomization and divided patients into two groups - one experimental (EXP) and one active control group (CON). In the first phase, which lasted for 8 weeks, the EXP group attended a guided functional exercise before the dialysis procedure and afterward performed a cycling session during dialysis. The CON group participated in intradialytic cycling equal to cycling program of the EXP group. The intensity of exercise was determined by the Borg scale of perceived exertion. After eight weeks we repeated the baseline tests (T1). In phase 2 (next 8 weeks) EXP group was instructed to exercise at home using the skills mastered during the first phase of the study on non-dialysis days and continued with the program of intradialytic cycling as did the CON group. We provided counselling, monitored and motivated them to exercise in their home environment. Following this phase, the tests were repeated (T2). Analysis of covariance (ANCOVA) was used to examine the differences between the EXP and CON group adjusted for their baseline measurements.
RESULTS: Twenty-seven patients completed a 16-week training. The final analysis revealed that there were statistically significant differences in STS10 between the groups in T1 (p=0,004) and T2 (p=0,046). In 6MWT there were no significant differences between the groups in T1 (p=0,228) and also in T2 (p=0,178) compared to their T0 values. The difference was again detected in T1 (p=0,000) and T2 (p=0,018) between the groups in the HG test. For SRT the difference was found only in T1 (p=0,001) with no difference in T2 (p=0,157).
CONCLUSION: Both types of exercise are effective in improving aerobic endurance and strength of lower limbs. However, we believe that if we want to improve various motor skills, cycling during dialysis alone is not sufficient. Our research showed us that functional training led by a kinesiologist at a dialysis centre is practical, feasible and effective in improving the physical function of HD patients.

EXERCISE-BASED INTERVENTION AS A COMPLEMENTARY TOOL IN THE PROMOTION OF HEALTH OF PRISON INMATES WITH SEVERE MENTAL ILLNESS: A RANDOMIZED CONTROLLED TRIAL FROM THE PSYCHIACTIVE PROJECT

BUENO-ANTEQUERA, J.

PABLO DE OLAVIDE UNIVERSITY

INTRODUCTION: Severe mental illness (SMI) is a leading cause of disability and mortality worldwide, and reducing the associated growing burden represents a global health priority. Evidence has consistently demonstrated that exercise-based interventions are a feasible, effective, and acceptable adjunct to usual care for people with SMI and provide benefits to both mental and physical health outcomes. However, despite the overwhelming burden of SMI in prison environments, which is associated with an increased risk of physical inactivity, somatic disorders, suicide, self-harm, violence, health care expenditures, and premature mortality on release from prison, only 6 exercise-based intervention peer-review studies have been done in this context, and none exclusively in inmates with SMI. Therefore, understanding the feasibility and effects of exercise-based interventions on the health of prison inmates with SMI represents both a challenge and an opportunity for public health and the scientific community. The aim of this randomized controlled trial was to evaluate the feasibility and effects of an exercise-based intervention in prison inmates with SMI.
METHODS: Forty-one men prison inmates with SMI were randomly allocated to intervention group consisted in 3 weekly sessions of group-based aerobic and strength exercises plus usual care (n = 21) or control group who received usual care (n = 20) during 12 weeks. Fitness and anthropometric measures were assessed using field-based tests, handgrip-dynamometry, bioelectrical-impedance, and waist and hip circumferences. Baseline and follow-up assessments, design, implementation, and supervision (face-to-face) of intervention throughout the study period were conducted by two experienced exercise physiologists. Data was assessed using null-hypothesis significance testing with Bonferroni adjustment (significant at $p < 0.004$) and magnitude-based inferences.
RESULTS: There were no adverse events and 10 intervention participants withdrew. The remaining 11 participants attended the 77% of the sessions, of which 9 attended ≥70% and met the compliance demands. In both the intention-to-treat and per-protocol analyses, the intervention provided substantial improvements in cardiorespiratory fitness and several anthropometric measures. The per-protocol analysis also showed substantial benefits in upper-body strength. No significant differences were found for either intention-to-treat or per-protocol. Furthermore, additional analysis showed beneficial effects of exercise participation in handgrip and lower-body strength.
CONCLUSION: The intervention was safe, had a high dropout rate, and seemed to be effective for improving fitness and anthropometric measures in men prison inmates with SMI. The current study could help to raise health professionals awareness of the importance of considering exercise as medicine in prison inmates with SMI and may encourage the scientific community to research the feasibility and benefits of exercise programs in prison environments.

Invited symposia

IS-BN02 Not so simple? Muscle-tendon interaction to amplify or attenuate power in human movement

MUSCULAR ADAPTATION OF ANKLE-FOOT FUNCTION TO PRODUCE ACCELERATIONS IN HUMAN GAIT

FARRIS, D.

UNIVERSITY OF EXETER

Springy muscle-tendon interactions can aid energy savings for human gait (1), but are considered ill-suited to tasks where net positive work must occur (2) such as accelerations. This is despite evidence that muscles with elastic tendons can contribute to significant positive power outputs in other species (3). In several studies examining the role of ankle and foot muscles in contributing to net positive work output, we highlight the importance of these muscles for adapting locomotor function for changes in gait speed.
Examination of lower limb joint mechanics during accelerative walking and running showed a shift in mechanical function at the ankle joint to one resembling a motor, as opposed to its normal spring-like mechanics. Furthermore, it was the only joint that fundamentally

changed in its function in the switch from constant speed to accelerative locomotion. This was unexpected given the architecture of ankle plantar flexor muscles and the underlying muscular mechanism warranted further investigation.
Therefore in a subsequent study of the muscle-tendon interactions underpinning the shift to motor-like behavior, we described a change in muscle-tendon mechanics. This involved muscle fascicles shortening to load tendons early in stance, rather than tendons storing kinetic energy from bodily motion. The release of stored energy in late stance during acceleration thus contributed to the net positive external work required.
More recently, we have implicated intrinsic muscles of the foot in modulating energetic function of the limb. Tasks in which the energetic state of the body must be altered involve adaptation of power flow through the foot. Adaptations in foot function for this purpose are reflected in changes in electromyographic activity of the plantar intrinsic foot muscles. In particular, electromyographic data during walking reveals an increase in activity during accelerative push-off, compared to constant speed walking.
In summary, the potential contribution of distal lower limb muscles to accelerative tasks should not be discounted on the basis of their architecture. With appropriate coordination, such muscles contribute to positive external work in human locomotion.

MUSCLE-TENDON FUNCTION IN ELITE HIGH JUMPERS

ALBRACHT, K.1,3, GOLDMANN, J.P.1,4, HEINRICH, K.1, SANNO, M.1, STÄUDLE, B.1,3, RITZDORF, W.2, BRÜGGEMANN, G.P.1, BRAUNSTEIN, B.1,4

GERMAN SPORT UNIVERSITY (1), IAAF WORLD HIGH JUMP CENTRE (2), UNIVERSITY OF APPLIED SCIENCE AACHEN (3), M@MENTUM (4)

INTRODUCTION
During take-off, the horizontal velocity of the jumper's COM from the run-up must be transformed into vertical velocity (Dapena, 2006). It is assumed, that the optimal run-up velocity depends on each athletes ability to resist buckling of the take-off leg through sufficient muscular strength of the knee extensor muscles (Dapena, 2006). Many studies have demonstrated that the plantar-flexor muscle-tendon units are equally important in producing force and power required for jumping. However, today no information is available about mechanical properties of the plantar-flexor muscle-tendon units of elite high jumpers. To obtain a better understanding of the contribution of the plantar-flexor muscle-tendon units to high-jump performance, we analyzed muscle and tendon properties as well as 3D jump kinetics and kinematics of elite high jumpers.
METHODS
High jumps of seven world-class athletes (personal best 224±6 cm) were captured with 19 infrared-cameras (300 Hz, Vicon, UK). Ground reaction forces of the take-off were recorded with a 3D force-plate. Ankle joint work and power in the sagittal plane were determined with a standard inverse dynamics approach and a full body model (ALASKA, Germany). Additionally, maximal isometric torque for plantar-flexion, fascicle length and tendon length of the gastrocnemius medialis muscle and Achilles tendon stiffness were determined using a combination of dynamometry, ultrasound, and kinematic data.
RESULTS AND DISCUSSION
The average maximum COM height was 2.13 ± 0.05 m with an average run-up velocity of 6.8 ± 0.4 m/s and an average contact time of 185±29 ms. Despite a considerable inter-individual variability of the examined variables, only one significant correlation was found between maximal isometric plantar-flexion torque and run-up velocity ($r=-0.85$, $p=0.01$). This indicates that athletes with a slow run-up velocity have stronger calf muscles relative to body mass. None of the other variables (run-up velocity, energy loss during take-off, net ankle work, peak ankle power) showed a correlation to the properties of the muscle-tendon unit, which could be due to the small number of subjects. However, the analysis of the individual data indicates that jumpers with a fast run-up velocity and a short ground contact have short stiff tendons and long muscle fascicles. These tendon properties are necessary to enable the storage and release of the COMs energy within the constraints of the brief ground contact. The long fascicles, probably enable sufficient force generation at fast shortening velocities during the run-up, which may also explain the negative correlation between muscle strength and run-up velocity. The results of this study indicate that different take-off techniques of elite high jumpers are partly reflected in the triceps surae muscle-tendon properties.

MUSCLE-TENDON FUNCTION DURING A DISSIPATIVE TASK

SEYNNES, O.

NORWEGIAN SCHOOL OF SPORT SCIENCES

In actions requiring rapid deceleration, energy is dissipated via eccentric muscular contractions. In situ studies have shown that tendon elasticity can act as a mechanical buffer by temporarily storing energy and releasing it slowly, lowering muscular stretch velocity and likely reducing probability of muscle damage (2). Although the buffering role of series elastic elements had previously been observed during stair descent (3), this phenomenon was only recently investigated extensively in humans (1, 4).
Collectively, these studies demonstrate that the temporary storage of elastic energy is modulated as a function of the task demand (i.e. body weight, jumping height), preserving muscle fascicular behaviour and, arguably, preventing damage. While these findings appear consistent in the synergist gastrocnemius and soleus muscles, differences were seen within the triceps surae muscles and between plantar flexors and knee extensors, in the way an increased demand for energy dissipation was accommodated.
This presentation will propose an overview of the above studies and present recent observations on the influence of training-induced changes in tendon stiffness upon muscle-tendon behaviour during landing (5).

OP-BN10 Testing and training in swimming I

THE EFFECT OF SWIMMING TRAINING IN SYNCHRONIZED SWIMMERS ABILITIES

LASKI, V.1, CSELKÓ, A.2, WILHELM, M.2

1:UNIVERSITY OF PÉCS, DOCTORAL SCHOOL OF BIOLOGY AND SPORTBIOLOGY, 2:UNIVERSITY OF PÉCS FACULTY OF SCIENCES INSTITUTE OF SPORT SCIENCES AND PHYSICAL EDUCATION

INTRODUCTION: In synchronized swimming high level of technical and conditional abilities are needed, and well planned swim trainings create the basis of it. Based on these the aim of our study was to show that well planned swim trainings are decreasing the effort needed for the proper technical performance of basic elements like vertical, barracuda and to find the components of body composition influencing the elucidation of these technical elements.
METHODS: Elit synchronized swimmers participated in the study. 2 groups N1=18, 15,62±1,16years (Local Group=LG) and the other group was N2=48, 17,44±2,83 (National Group=NG). The training time was 4x3hrs/week. Body composition (Inbody720) and anthropometric parameters were measured four times. Swimming and artistic swimming measurements were quantified twice a year. Muscle force was also measured with dynamometer. After a standard warm up, 4x100 freestyle and 200m medley swimming performance were measured. Blood lactate level (BL) from fingertips and heart rate (HR) were also analyzed in rest and after 1 minute of exercise, respectively. Barracuda, body boost and vertical elements were performed and scored.
RESULTS: Body composition did not change significantly during the studied period (1 year) in the athletes. Lactate levels changed significantly before and after the exercise. We found the highest blood lactate levels one minute after the swimming (12±2,8mmol/l) and synchronized swimming exercises (10,74±2,03mmol/l). We measured no significant differences in lactate level between the two types of exercises. Negative correlation was found between 200m medley swimming time and the score of vertical position (r=-0,6). Negative correlations was found: (i) between the 4x100m freestyle time and vertical score (r= -0.53), (ii) in 200m mixed swimming and vertical position (r= -0.59) (iii) in 4x100m freestyle swimming (r=-0.51) and (iv) in 200m medley swim (r= -0.54).
CONCLUSION: Anthropometric indices (body height, body weight, body fat and lean body mass) were not significantly correlated similarly to Sajber et al (2013). We found higher maximum BL, lower HR compared to the earlier research (Rodriguez et el. 2014). Strong correlation was found between swimming performace, muscle strenght and performance of synchro elements. Based on our results, the swimming efficiency affects the performance of different technical elements.

THE EFFECT OF MUSCLE FATIGUE ON SCAPULAR KINEMATICS AND FUNCTIONALITY IN ADOLESCENT SWIMMERS

UGUR OZYILMAZ, U., TURGUT, E., BAYRAKCI TUNAY, V.

HACETTEPE UNIVERSITY FACULTY OF HEALTH SCIENCES

INTRODUCTION: Swimming is a sport characterized by cyclical and coordinated movements between body segments. Fatigue is very important in swimming performance. The fatigue of a muscle affects the entire swimming pattern and disrupts the chain (1). There are many studies investigating the effect of fatigue on scapular kinematics in the literature (1,2). However, it was observed that the studies investigating the effect on swimmers were very limited. The aim of the study was to investigate the effect of scapular muscle fatigue on shoulder biomechanics and performance parameters for adolescent swimmers. It was hypothesized that the scapular muscle fatigue would effect 3-dimensional scapular kinematics during shoulder elevation and upper limb performance in adolescent swimmers.
METHODS: Twenty-seven asempthomatic adolescent athletes who were 12-17 ages with minimum of 3 years competitive attendance in swimming participated in the study. Fatigue protocol was created with 4 exercises chosen to create fatigue in scapular muscles. Before and after fatigue 3-dimensional scapular kinematics (scapular upward-downward rotation, internal-external rotation and anterior-posterior tilt) were analyzed during lifting and lowering of the 30, 60, 90 and 120 degrees humerothoracic elevation using an electromagnetic system. Before and after fatigue protocol functionality was assessed by modified push-up test, closed kinetic chain upper extremity stabilization test, and unilateral seated shot put test.
RESULTS: The results of this study showed that scapular muscle fatigue affects scapular kinematics and functionality in swimmers. The results of this study, in which the adaptation of the neuromuscular system and the changes in performance are examined in detail, show the basic biomechanical knowledge that will lead to development of rehabilitation and training programs, prevention of possible injuries and determination of injury risks in individuals who are interested in overhead sports such as swimming sports.
CONCLUSION: The results of this study showed that scapular muscle fatigue affects scapular kinematics and functionality in swimmers. The results of this study, in which the adaptation of the neuromuscular system and the changes in performance are examined in detail, show the basic biomechanical knowledge that will lead to development of rehabilitation and training programs, prevention of possible injuries and determination of injury risks in individuals who are interested in overhead sports such as swimming sports.

INTRA-CYCLE VELOCITY FLUCTUATION IN SWIMMING: A NEW APPROACH

GONJO, T., FERNANDES, R.J., VILAS-BOAS, J.P., SANDERS, R.

NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: In swimming, intra-cycle velocity fluctuation of the centre of mass (IVV-COM) has been investigated mainly using the coefficient of variation (CV) or detecting the difference between the maximum and minimum velocity during a stroke cycle (Vmax-min).

However, each method has its issues: (i) CV could provide overall information about IVV-COM, but it cannot show maximum or minimum amplitude values, and IVV-COM might be underestimated when the mean speed is high because CV is the standard deviation normalised by the mean value; (ii) Vmax-min shows the maximum amplitude but cannot present the overall IVV-COM during a stroke cycle. Fourier analysis would be useful to solve these constraints since it can produce detailed information on the amplitudes and patterns of waves contained in the original signal. Therefore, the purpose of the present study was to apply a Fourier analysis to investigating IVV-COM in swimming and suggest its advantages.
METHODS: Ten male elite swimmers performed four times 50 m front crawl trials in an indoor pool with a calibrated space at the centre of it. One stroke cycle of the swimmers at each trial was captured by six digital video cameras to obtain three-dimensional coordinates of pre-marked anatomical landmarks. COM location was determined by summing the moments of the segment COM mass about the X, Y, and Z reference axes, and the velocity of COM was obtained by differentiating the X displacement of COM over the whole stroke cycle by its duration. COM velocity curve over the analysed stroke cycle was decomposed into the frequencies that form the original signal. Frequencies that had a smaller amplitude than digitising error was excluded from the analysis. The power of primary frequencies detected by the Fourier analysis was compared using the Friedman test. The relationships between the amplitude of a dominant frequency and CV as well as Vmax-min were obtained using a Person's correlation coefficient to check if the Fourier analysis is applicable to obtain information provided by the available methods.
RESULTS: Fourier analysis showed that over 85% of IVV-COM components were harmonics with six peaks and less. Among the six harmonics, two peaks harmonic had the highest power ($p<0.05$). This result implies that the upper limbs motion is the primary source of IVV-COM in front crawl since it contains two propulsive actions in one cycle. There were strong correlations between the amplitude of a dominant frequency and both CV and Vmax-min ($r=0.87$ and 0.86, respectively; $p<0.001$), showing that Fourier analysis can also cover information obtainable by available methods (i.e., CV and Vmax-min).
CONCLUSION: Fourier analysis is a useful method to investigate IVV-COM in front crawl swimming. It gives us information on not only overall variability and the amplitude of COM speed, but also the indirect information of the source of the fluctuation by providing frequency components.

ANALYSIS OF MUSCLE COORDINATION DURING UNDERWATER DOLPHIN KICKING USING MUSCLE SYNERGY METHOD

YAMAKAWA, K., SHIMOJO, H., TAKAGI, H., SENGOKU, Y.
JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: In competitive swimming, underwater dolphin kick is utilized after dives and turns. While the several previous studies reported the muscle activity during dolphin kicking using surface electromyogram (EMG) (1) (2), the muscle coordination have not been discussed in terms of the muscle synergies. Therefore, the purpose of this study was to clarify the muscle coordination during underwater dolphin kicking using muscle synergy method. We hypothesized that two or three synergies are extracted in association with the kick phases which are divided by direction of the toe motion.
METHODS: Eight male collegiate swimmers performed the underwater dolphin kick swimming at their submaximal velocity (1.24—1.54 m/s) in a water flume. Three-dimensional motion analysis was conducted using a motion capture system, and the surface EMG was recorded from eight muscles. Muscle synergies were extracted using non-negative matrix factorization with the EMG data, and number of the synergies were determined according to criteria of the previous study (3). The contribution phase of each synergy was evaluated by the full width at the half maximum (FWHM). Durations of the FWHM were compared between the extracted synergies, and a relationship between the FWHM and the kick phases (downward kick, first upward kick and second upward kick) was analyzed.
RESULTS: Three synergies were identified in 7 of the 8 (87.5%) swimmers, and the percentage of the total variance accounted for with the three synergies were 94.7±1.9%. The synergy #1 mainly involved the frontal lower limb muscles (rectus femoris, vastus lateralis, adductor longus and tibialis anterior), the synergy #2 mainly involved the gluteal muscles (gluteus maximus and gluteus medius) and the synergy #3 mainly involved the dorsal lower limb muscles (biceps femoris and gastrocnemius). The order of the three synergies in contribution during the kick cycle was synergy #1, #2 and #3. There was no significant difference in the durations of FWHM between the extracted synergies. Furthermore, the duration of FWHM in the synergy #3 was significantly correlated with the one of the second upward kick phase ($r = 0.71$, $p < 0.05$). However, the durations of FWHM in the synergy #1 and #2 were not correlated with the ones of the downward and first upward kick phases.
CONCLUSION: Three muscle synergies were extracted from the EMG of the gluteal and lower limb muscles during underwater dolphin kicking in male collegiate swimmers. Furthermore, it was suggested that the co-activation of the dorsal lower limb muscles during the dolphin kicking was related to the second upward kick motion.

OP-MI07 Training and testing: Military / mixed

OCCUPATIONALLY SPECIFIC, OPERATIONALLY RELEVANT PHYSICAL FITNESS TESTS AND STANDARDS FOR US AIR FORCE EXPLOSIVE ORDNANCE DISPOSAL AIRMEN

BAUMGARTNER, N., WELCH, B., LATIMER, M., NEFF, J., FLERLAGE, E., RHODES, A., BECKER, J., MORALES, C., ALEMAN, H., HALE, K., BATTERTON, K.
US AIR FORCE EXERCISE SCIENCE UNIT

INTRODUCTION: The US Air Force employs a science-based physical fitness (PF) test with professionally recognized criterion health standards. Scores reflect degrees of health and general fitness, but do not necessarily reflect military task achievement. Physically demanding specialties, e.g., Explosive Ordnance Disposal (EOD), require occupationally-specific, operationally-relevant (OSOR) PF tests and standards based on physical duty requirements. Purpose: conduct a multi-step bona fide occupational requirements (BFOR) process to develop prototype EOD PF test and standards to meet OSOR requirements.
METHODS: A BFOR process was conducted for EOD. Performed physical demands analysis (PDA) that included focus groups, computer task assessment of EOD Airmen, observations of EOD operations, and interviews of senior EOD leaders. Per recent operational missions EOD Airmen scored each physical task for frequency, duration, intensity, and importance to mission success. PDA identified operationally-

required critical physical tasks (CPTs) which provided the basis for developing 8 physical task simulations (PTSs). Subjects (n = 92, 10 female, mean ± SD; age, 29.7 ± 5.8 yr, mass, 86.3 ± 13.0 kg, stature, 174.2 ± 7.7 cm) completed 8 PTSs and 31 PF tests to determine optimal PF test battery for predicting operational task success. Experienced EOD technicians reviewed PTS data to determine minimum effective times (MET) for task success. Successful performance equaled PTS completion above MET. Advanced statistical modeling was used to link PTSs and PF tests. Validation of final 9 PF tests was completed (n = 38, 8 female, mean ± SD; age, 27.8 ± 5.7 yr, mass, 83.3 ± 12.8 kg, stature, 173.6 ± 9.7 cm). Researchers implemented prototype PF test at 11 world-wide EOD units to determine feasibility.
RESULTS: Process narrowed 1107 occupational tasks to 113 preliminary tasks, then to 39 CPTs and identified six PF components and 14 physical movement patterns necessary to perform CPTs. Final 9 PF tests (row ergometer 1000 m, grip strength, medicine ball toss-back/side/log 9.1 kg, trap bar lift 5RM, pull-ups, farmer's carry 4 x 25 m, 2 x 22.7 kg sandbags, grip endurance beam 27.2 kg, simulated bomb suit shuttle run 13.6 kg vest, 22.7 kg sandbag, run 2414 m) selected per primary criteria: predictive validity of operational success, PF component and physical descriptor breadth, ease of administration, resource and subject skill requirements; secondary criteria: face validity, injury risk, subject matter expert input, literature, reliability, and field vs laboratory setting. Validation of prototype test components and standards elicited an 86.9% classification accuracy. Implementation at 87 units produced a 96.2% feasibility rate.
CONCLUSION: Study approach proved efficacious for developing a viable prototype PF test that addresses all operationally-required EOD critical physical tasks. Recommend official use at AF EOD units to ensure operational physical readiness.

SALIVA CORTISOL CONCENTRATIONS DURING MILITARY SURVIVAL TRAINING

OJANEN, T., HÄKKINEN, K., KYRÖLÄINEN, H.

FINNISH DEFENCE RESEARCH AGENCY

INTRODUCTION: Military survival training (SERE) exposes soldiers to both psychological and physical stress. These stressors have been shown to lead to changes in both hormonal profiles and physical performance (Morgan et al. 2000). The purpose of this study was to investigate changes in daily variation of saliva cortisol (SCOR) concentrations during SERE.
METHODS: A total of 26 (age 20±1yrs., height 180±7cm, body mass 76.1±10.4kg) male soldiers voluntary participated in the study. The SERE training consisted of garrison and field phases. The saliva samples were collected in Salivette tubes, two times per day (08:00 and 20:00±00:30) for ten days during the SERE training. In addition, body composition, shooting performance, and several physical performance tests (e.g. maximal isometric force, power, and endurance) were measured before (PRE) and after (POST) the field phase.
RESULTS: PRE training mean values in SCOR were in the morning 18.7±6.2 nmol/l and evening 4.6±3.0 nmol/l. During the SERE training the normal daily pattern in SCOR disappeared as the values were 27.9±12.3 nmol/l and 24.5±10.2 nmol/l at the end of SERE. Significant increases ($p<0.001$) were observed in SCOR throughout the SERE training compared to the PRE training values both in the morning (daily variation for mean changes was from 16.6% to 141%) and evening (from 17% to 663%) samples. Body weight (-4.5%) and fat mass (-29.2%) decreased significantly in the POST measurements, but no significant chance was observed in skeletal muscle mass. All physical performance variables decreased significantly by POST of SERE except for maximal isometric leg extension force. Shooting score also decreased (-10.6%) significantly in the prone position. Mean sleep time varied from 0.1 to 3.1 hours per night during SERE. The subjects were given only 500 kcal during the first phase and 1000 kcal during the second phase of SERE.
CONCLUSION: Liebermann et al. (2016) found that soldiers who were exposed to realistic and stressful situations had high SCOR concentrations during a military SERE training. The present study revealed that the cumulative effects of food restriction, sleep deprivation, and the highly stressful SERE training resulted in significant changes in SCOR concentrations, body composition and physical performance. In the present study we could see that the normal daily variation pattern of SCOR diminished during the present strenuous SERE training. In the future studies it would be interesting to follow the recovery of SCOR after SERE training.

VALID ASSESSMENT OF MILITARY FITNESS. AN APPLIED MOTOR TEST FOR COMPLEX TASK DEMANDS.

ROHDE, U.1, SIEVERT, A.1, RÜTHER, T.2, KELLER, E.3, HACKFORT, D.3, LEYK, D.1,2

(1) BUNDESWEHR INSTITUTE FOR PREVENTIVE MEDICINE; (2) GERMAN SPORT UNIVERSITY COLOGNE; (3) BUNDESWEHR UNIVERSITY MUNICH

INTRODUCTION: Specific physical fitness is frequently assessed with tests of basic or general motor skills or applied testing methods, because standard lab tests do not adequately reflect performance characteristics of complex task demands. This is especially true for military settings, where achieving and maintaining fitness levels predetermined by external factors is crucial. The Bundeswehr has defined fitness as a hierarchical, 3-level construct ranging from: (I) Fundamental/Baseline-Fitness, (II) Basic-Military-Fitness to (III) Task-Fitness and developed fitness tests to assess individual physical capacity accordingly. Fundamental/Baseline Fitness is monitored with the Basis Fitness Test (BFT)(1). To assess Level II of the construct, Basic Military Fitness, the Basic-Military-Fitness-Tool (BMFT) has been developed (2). It consists of four subtasks abstracted from physiological profiles of demand common for all soldiers: (A) Maneuver, (B) Dragging Loads, (C) Carrying Loads, and (D) Lifting Loads, incorporated into one single, timed sequence on a standardized course with standardized loads and distances. Unlike the BFT, BMFT testing is done in field uniform, boots, and protective gear (helmet/ballistic vest). This study has two aims : (1) validate the BMFT and its subtests against standard tests of basic motor skills and (2) determine the potential usefulness of the BMFT as diagnostic tool, e.g. for individualized training.
METHODS: 190 soldiers of different services and branches (170 male, age 29.4±7.3 yrs, 20 female, age 28.3±5.6 yrs) performed the BMFT. Results were validated against tests for endurance (1000m-run), speed (11x10 m shuttle-run), and strength (maximum voluntary isometric contraction: hand-grip, elbow flexors, knee extensors, and trunk flexors/extensors) using correlations and multiple linear regressions. In the military setting, all performance criteria must be met by all personnel, hence age and gender were not considered as factors.
RESULTS: : BMFT performance showed significant correlation with endurance (r=.53), speed (r=.42), and strength (r=[-.54, -.72]). The highest correlation was found with elbow flexors (r=-.72). 67% of the variance is explained by the combination of endurance, speed, and strength.
CONCLUSION: The capability characteristics of endurance, speed, and strength are strongly correlated with total BMFT and subtask A-D performance. Results indicate that the BMFT reproduces the demands of the tasks used for the definition of Basic-Military-Fitness. The BMFT is suitable to assess and monitor the required physical capabilities from basic- to pre-deployment training. Results from the anal-

yses can also serve to identify individual strengths and weaknesses overall, and in the subtasks A-D. Based on the analyses, results can also be used to design individualized physical training programs.

THE EFFECT OF MILITARY TRAINING ON BODY COMPOSITION AND BIOCHEMICAL MARKERS IN CZECH AIR FORCE PILOTS

GERYCH, D.1,2, VESELÁ, J.1, STRÍTECKÁ, H.2

1 CASRI - SPORTS RESEARCH INSTITUTE OF CZECH ARMED, 2 UNIVERSITY OF DEFENCE, FACULTY OF MILITARY HEALTH SCIENCES

INTRODUCTION: Czech Air Force pilots are highly trained and physically active individuals. Although there are no differences in basic military training among the pilots, there are significant differences between pilots concerning specific training based on the type of piloted aircraft. Compared to helicopter pilots, fighter pilots are regularly exposed to hypoxia, pressure and temperature changes, as well as, physical stress and strain due to gravitational forces induced by high accelerations. In order to integrate exercise and nutritional measures into an effective training program of military pilots, it is necessary to evaluate the effect of different aircraft piloting on body composition and biochemical markers in blood.
METHODS: 21 male fighter pilots (aged 37 ± 6 years) and 20 male helicopter pilots (aged 36 ± 7 years) were observed during the four-month period. Firstly, fat mass (FM) and fat-free mass (FFM) were measured using amplitude-mode ultrasound system (BodyMetrix™BX2000). Secondly, the basal metabolic rate (BMR) was assessed by the Katch & McArdle formula. Finally, the capillary blood was taken from all participants and immediately analyzed for biochemical markers related to metabolism of energy-yielding nutrients: cholesterol, high-density lipoproteins (HDL), low-density lipoproteins (LDL), triacylglycerols (TAG), urea, uric acid, and glucose. Biochemical analysis of blood samples was performed using a dry chemistry method. Unpaired two samples t-test was performed to compare fighter pilots (FP) with helicopter pilots (HP). The significance level was set 0.05.
RESULTS: The higher value of FM was found in helicopter pilots. Furthermore, a higher concentration of LDL and uric acid was found in helicopter pilots, whereas, a higher concentration of glucose was observed in fighter pilots. All measured parameters in both groups fall into the range for healthy individuals, although there was statistically significant differences between compared groups in FM (FP 12.0 ± 3.7 vs. HP 14.6 ± 4.2, $p<0.05$), the concentration of LDL (FP 2.19 ± 0.66 vs. HP 2.63 ± 0.71, $p<0.05$), uric acid (FP 314 ± 83 vs. HP 360 ± 58, $p<0.05$) and glucose (FP 4.95 ± 0.61 vs. HP 4.61 ± 0.42, $p<0.05$).
CONCLUSION: The results of this study indicate that helicopter pilots are prone to have a greater FM and higher blood cholesterol concentration in comparison with fighter pilots. Based on these results specific exercise and nutritional measures may be applied to improve health, fitness and the effectiveness of the specific military training program.

HIGH INTENSITY TREADMILL EXERCISE – REDUCING THE BREATH BY BREATH NOISE USING THE INDEPENDENT BREATH ALGORITHM

FRANCESCATO, M.P.1, KOSCHATE, J.2, CETTOLO, V.1, HOFFMAN, U.2

1. DEPARTMENT OF MEDICINE - UNIVERSITY OF UDINE; 2. INSTITUTE OF PHYSIOLOGY AND ANATOMY - GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: The "Independent breath" algorithm was recently proposed to calculate breath-by-breath gas exchange (Cettolo & Francescato, Eur J Appl Physiol, 2018, doi: 10.1007/s00421-018-3842-y). The algorithm was tested under moderate intensity cycle ergometer exercise, comparing its results with those yielded by other "classical" algorithms (i.e. the "Expiration-only" and the "Wessel" algorithms); an about 30% reduction of noise was found (Francescato & Cettolo, Eur J Appl Physiol, 2019, doi: 10.1007/s00421-018-4046-1). The performance of the "Independent breath" algorithm, however, has never been investigated under conditions where subjects might be submitted to different mechanical stresses potentially leading to a different noise.
Aim of the present work was to compare the breath-by-breath (BbB) oxygen uptakes during high running speed, as obtained with the "Independent breath" algorithm (V'O2IND) and with the corresponding values yielded by the "Expiration-only" (V'O2EXP) and the "Wessel" (V'O2WES) algorithm.
METHODS: Fourteen healthy subjects (6 F; 8 M; 33 ± 9 years old; 76 ±13 kg body mass) performed an incremental exercise to volitional fatigue on a treadmill (Pulsar, h/p/cosmos sports & medical GmbH, Germany); following at least 5 min running at 9.5 km/h, speed was set to 10 km/h and then increased each minute by 1.0 km/h. Respiratory flow, O2 and CO2 fractions were continuously recorded at the mouth (CPET Metalyzer 3B, Cortex, Germany), thus allowing the calculation of BbB oxygen uptakes with the investigated algorithms, implemented as computerised procedures. For each subject and each algorithm, a linear regression was calculated between the oxygen uptake values against time, including 5 min from the start of the incremental test; for each regression, the square root of the arithmetic mean of the squares of the residuals (RMS) was calculated. Standard statistical tests were used, including multivariate analysis of variance.
RESULTS: The slopes of the regression lines obtained for the V'O2 yielded by the three algorithms were not statistically different (Algorithm effect, p=NS), the grand average amounting to 0.165 ± 0.057 L/min2. The corresponding intercepts were significantly greater for V'O2EXP (2.76 ± 0.61 L/min) compared to those obtained for V'O2WES or V'O2IND (2.63 ± 0.57 L/min for both; Algorithm effect, $p<0.001$). The V'O2IND resulted in significantly lower RMS (0.204 ± 0.062 L/min vs. 0.237 ± 0.084 and 0.262 ± 0.104 L/min, for IND, WES and EXP, respectively; Algorithm effect, $p<0.005$). The slope of the regression line between the RMS of the V'O2IND with the corresponding values obtained for the V'O2WES or V'O2EXP algorithms was <0.66.
CONCLUSION: Results showed that, during an incremental test at high running speeds performed on a treadmill, the IND algorithm provided V'O2 data with a reduced overall noise (about 34%, expressed as RMS), while keeping constant the increase per minute (the slope) of the oxygen uptake.

EFFECTS OF 10 WEEKS FUNCTIONAL EXERCISE TRAINING ON FUNCTIONAL MOVEMENT SCREEN AND Y-BALANCE TEST IN YOUNG MALE

DAO, W.

SHANGHAI REAEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Functional motor ability is an important component of physical fitness, and can also reflect physical health and the quality of life. The purpose of this study is to investigate the effect of functional exercise training by the combination model of centralization training and individualized independent training in young male.
METHODS: A total of 30 male subjects (aged 20-40 years, average age 31 years) participated in the 10-week functional training intervention. According to the requirements of the training plan, 19 patients completed the intervention(IG1) and other 11 did not complete(IG2). During the intervention, subjects of lifestyle and physical exercise remained unchanged. FMS(Functional Movement Screen) and YBT(Y-Balance Test) of upper and lower limbs were measured one week before and after intervention. Functional training program based on the principle of combining centralized training with individualized independent training. Centralized training was the main method (once a week, 60-90 minutes each time), and individualized independent training was completed at other times (no less than 2 times a week, 30-60 minutes each time). The training involved 23 modules, such as breathing exercises, thoracic vertebral relaxation, hip flexion exercises, chop/lift exercises, arm flexion and extension exercises, and comprehensive movement patterns.
RESULTS: After 10 weeks functional training intervention, total FMS score and active straight Leg raise were significantly increased from baseline in IG1（P<0.05）, but were not observed in all single test and the total FMS score in IG2（P>0.05）. The results of Y-balance test in upper quarter were significantly improved in lateral reach and the composite score（P<0.05）, but were not observed in all three reach and the composite score in IG2（P>0.05）. The results of Y-balance test in low quarter was significantly improved in the composite score（P<0.05）, but were not observed in all three reach and the composite score in IG2（P>0.05）. The left-right difference of Y-balance test in upper quarter in superolateral reach and the composite score were significantly reduced in IG1（P<0.05）, but were not observed in all three reach and the composite score in IG2（P>0.05）. The left-right difference of Y-balance test in low quarter in the composite score was significantly reduced in IG1（P<0.05）, but were not observed in all results in IG2（P>0.05）.
CONCLUSION: On the whole, according to the changes of FMS and Y balance test results before and after intervention, we found that 10 weeks functional exercise training by the combination mode of centralization training and individualized independent training positively affected the functional motor ability in young male. In the future, we need to combine other functional motor ability indicators for further analysis.

OP-SH11 Psychology: Cognition

IMPROVING EXECUTIVE FUNCTIONING IN KINDERGARTEN CHILDREN – AN 8-WEEK INTERVENTION STUDY

BIRKLBAUER, J., PALK, A., MÜLLER, E.

UNIVERSITY OF SALZBURG

INTRODUCTION: Executive functioning (EF) critically relates to academic achievement throughout the school years (1) and predicts long-term success in life (2). At the same time, many children begin school lacking in EF skills (3). Besides direct training of EF and classroom educational programs, recent meta-analyses support the view that chronic physical activity with a higher cognitive engagement has beneficial effects on EF performance in school-aged children and adolescents (4). However, studies that investigate the long-term effect of EF-promoting classroom activities in combination with cognitively engaging physical activities on the improvement of EF in kindergarten children are still lacking.
METHODS: The efficacy of a group-based intervention focusing on basic components of EF was examined by a quasi-randomized control trial with 2 x 17 children 3-6 yrs old (53% female). The 8-wk intervention in a local kindergarten consisted of 2 x 45 min of versatile playful physical activities per week with moderate to vigorous intensities and cognitive demands on working memory, inhibitory control, and cognitive flexibility. Additionally, on each of the 42 kindergarten days, children were guided to play a (daily varying) classroom game (20-40 min) targeting at one EF component. Pre- and post-performance on EF subcomponents was assessed by an age-appropriate battery of five well-established tests.
RESULTS: MANOVA on main scores revealed a significant and large Time(2)xGroup(2) interaction effect ($p=.003$; $\eta^2=.489$) in favour of the intervention group (IG). Univariate analyses showed large training effects for inhibition skills ($p=.001$-$.042$; $\eta^2=.127$-$.410$) with the greatest improvements in behavioural inhibition (IG: +44.4%; CG: -3.7%). Medium to large effects were also found in short-term ($p=.062$; $\eta^2=.105$) and working ($p=.030$; $\eta^2=.139$) memory. In comparison to CG, cognitive flexibility improved by trend with a medium effect size ($p=.120$; $\eta^2=.073$). With the exception of behavioural inhibition, EF-improvement in IG correlated negatively with initial test performance ($p<.042$; $r>.498$).
CONCLUSION: In contrast to Diamond & Ling's (5) claim that EFs must be challenged throughout the entire school-day, our study results point out that a combination of physical and non-physical playful activities for only a limited period of time per day over several weeks in an ecological valid setting seems to be sufficient to improve EF substantially. Since our EF measures required activities different from anything the children practiced during the intervention program, we hypothesize that benefits may also generalize to real-world function. Results from correlation analyses affirmed the common observation that those with poorer EF tend to progress more from any EF intervention.

ACTIVE BREAK TO PROMOTE PHYSICAL ACTIVITY IN PRIMARY SCHOOL: EVALUATION OF PHYSICAL AND COGNITIVE FUNCTIONS AT BASELINE

MASINI, A.1, MARINI, S.2, NIGRO, F.2, TESSARI, A.3, LEONI, E.1, CECILIANI, A.2, DALLOLIO, L.1
UNIVERSITY OF BOLOGNA

INTRODUCTION: Classroom-based activity breaks (CBAB) are emerging as a promising way of increasing the frequency of total physical activity (PA) for students and positive learning outcomes. CBAB are characterised by short duration (10 minute per sessions) of PA led by the teacher inside the usual classroom. The literature states that this strategy can increase levels of physical activity during the weekend. Furthermore, CBAB can promote a reduction of adiposity in the long period.1 We are conducting a research to evaluate the feasibility and the efficacy of a CBAB intervention in terms of quality of life, cognitive functioning and level of physical activity. The study is currently on the phase of active break somministration to children. Here we present the results of the cross-sectional study at baseline and the analysis of correlations between the assessed variables.
METHODS: Study design: cross-sectional study in a primary school (children from 6 to 9 years) in Bologna (Italy). The assessed variables were: functional exercise capacity (6-MWT), coordination ability (standing long jump - SLJ), and dexterity (Harre test). In addition, working memory cognitive function (WMT) and physical activity level (Actigraph) were evaluated.
RESULTS: After defining a cut off for the WMT (≤3 or >3, as average value of results) we found that children with WMT>3 had a better result in both SLJ performance and functional status than children with WMT≤3. Using Mann-Whitney U Test, we found significant differences for: 6MWT (622 ±77 vs 698 ±82.4, p= 0.008), SLJ (103±25.9 vs 122.7±19.4, p=0.01), in the WMT≤3 compared to WMT>3 group, respectively. A trend also emerged in Harre test as the WMT>3 group performed better than the WMT≤3 one (21.7±4.7 vs 19.2±3.0, p=0.07). The Actigraph outcomes did not correlate with cognitive function or motor test.
CONCLUSION: There is a beneficial association between working memory cognitive function and physical activity performance. At baseline, results suggest an association between either cardiovascular fitness or performance test and childhood cognitive health. This suggests the importance of developing multiple aspects of PA for cognitive health already in early life. Our research hypothesis is that at the end of the intervention this association should be more relevant with an increase of the statistical significance of the results.

A 10WEEK EXERCISE PROGRAM IN PRIMARY SCHOOL CHILDREN MODERATES COGNITIVE PERFORMANCE VIA CHANGES IN TESTOSTERONE: A RANDOMIZED CONTROL TRIAL

AKKO, D.P., KOUTSANDRÉOU, F., WEGNER, M., BUDDE, H.
MEDICAL SCHOOL HAMBURG, LITHUANIAN SPORT UNIVERSITY, HUMBOLDT-UNIVERSITY OF BERLIN

Introduction
Being physically more active seems to enhance cognitive performance in children (Koutsandréou et al., 2016). The underlying neurobiological mechanisms in children need further investigations. Being more active influences the hypothalamic-pituitary-gonadal axis (HPG) with its hormone testosterone. The HPG is related to several neurobiological growth processes and therefore might offer an explanatory approach for enhanced cognitive processes. Testosterone changes through acute exercise bouts have shown to influence cognitive performance (Budde et al., 2010) and fine motor skills (Wegner et al., 2014).
Methods
66 children at the age of M = 9.4 years (SD = 0.6) were randomly assigned to an aerobic exercise group (AE), a coordinative exercise group (CE), and a control group (CON). During a 10-week intervention the AE and CE exercised three times a week for 45 minutes, while the CON participated in assisted homework sessions. The AE practiced at a mean intensity of 60-70% of HRmax. The CE completed a coordinative training with a lower intensity of 55-65% of HRmax. The letter-digit span task was performed to measure participants' working memory performance (WMP). Testosterone levels have been conducted as well before and after the intervention.
Results and discussion
A stepwise hierarchical regression analysis showed main effects for change in testosterone level and both exercise groups. An increase in testosterone was associated with improved WMP in all exercising children, B = .392, SE = .174, t = 2.26, p = .028. In addition, both participants in the AE, B = .729, SE = .207, t = 3.52, p = .001, as well as in the CE, B = .973, SE = .205, t = 4.74, p = .001, showed improvements in WMP. Only in the AE increases in WMP were moderated by testosterone changes over the period of intervention, B = .516, SE = .243, t = 2.13, p = .038. Therefore, children who experienced higher testosterone increase during the 10 weeks additional aerobic exercise benefited more in their cognitive performance.

EFFECT OF EXERCISE DURATION ON COGNITIVE FUNCTION IN ADOLESCENTS

COOPER, S.B., DRING, K.J., WILLIAMS, R.C., HATCH, L., MORRIS, J.G., SUNDERLAND, C., NEVILL, M.E.
NOTTINGHAM TRENT UNIVERSITY

INTRODUCTION: Cognitive function has important implications for adolescents in terms of learning at school and academic performance. Evidence has shown that an acute bout of exercise can have a beneficial effect on cognitive function in adolescents (Donnelly et al., 2016).

However, there are many factors that could mediate the exercise-cognition relationship, including the duration, intensity and modality of exercise. No previous studies have examined the effect of different exercise durations on cognitive function in adolescents.
METHODS: In a randomised, order-balanced, crossover design, 31 adolescents (13 boys, age: 12.2±0.4 y) completed three experimental trials (resting control, 30 min exercise and 60 min exercise). The exercise protocol consisted of a modified version of the Loughborough Intermittent Shuttle Test (LIST), completed for either 2 (30 min LIST) or 4 (60 min LIST) blocks. A battery of cognitive function tests (Stroop test, Sternberg paradigm and Flanker task) were completed 30 min pre-, immediately post- and 45 min post-exercise, assessing both response times and accuracy of responses. Data were analysed in R using mixed effect models, adopting a trial*time approach.
RESULTS: Response times on the simple level of the Stroop test were unaffected immediately post-exercise, but were enhanced 45 min post-exercise following 30 min LIST when compared to 60 min LIST (30 min: -31 ms, 60 min: +8 ms; p = 0.006). Response times on the number level of the Sternberg paradigm were enhanced 45 min post-exercise following both 30 min LIST (-62 ms; p = 0.002) and 60 min LIST (-38 ms; p = 0.018) when compared to the resting trial (-18 ms). Response times were also enhanced 45 min post-exercise on the three-item level following 30 min LIST (-57 ms) when compared to both 60 min LIST (-7 ms; p = 0.008) and resting (-12 ms; p = 0.004) trials. On the congruent stimuli of the Flanker test, response times were enhanced both immediately and 45 min following the 30 min LIST (imm: -38 ms, p = 0.007; 45 min: -47 ms, p = 0.004) and 60 min LIST (imm: -26 ms, p = 0.050; 45 min: -33 ms, p = 0.015) when compared to the resting trial (imm: +1 ms; 45 min: -6 ms). There was no change either immediately or 45 min post-exercise between any of the trials for any of the other cognitive outcomes (all p > 0.05).
CONCLUSION: Overall, these findings suggest that an acute bout of exercise enhances the speed of executive function (as assessed by the Stroop test and Flanker task) and working memory (as assessed by the Sternberg paradigm), when compared to rest. Furthermore, the study provides novel evidence that a 30 min bout of exercise may be more beneficial than a 60 min bout of exercise for some aspects of cognitive function in adolescents. This has important implications for schools and school policy makers who may use exercise to enhance cognitive function and academic achievement.

THE INFLUENCES OF CARDIORESPIRATORY FITNESS LEVELS ON VISUOSPATIAL WORKING MEMORY IN INDIVIDUALS WITH FAMILY HISTORY OF ALZHEIMER DISEASE

CHIU, Y.K., TSAI, C.L., PAN, C.Y., TSENG, Y.T., CHEN, F.C.
NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: A voluminous literature has documented the benefits of higher physical fitness on working memory [1,2]. However, thus far, no studies have yet been conducted that explore the potential correlation between physical fitness and neurocognitive performance in individuals with family history of Alzheimer disease (ADFH). Therefore, the present study aimed to investigate whether different levels of cardiorespiratory fitness produce divergent neuropsychological and neurophysiological effects on visuospatial working memory in the middle- and older-age adults with ADFH.
METHODS: Fifty participants were recruited and separated into two groups, high cardiorespiratory fitness (HCF) group (n=25, 53.08±7.53 yrs, estimated VO2 max=38.67±3.50 mL/kg/min) and low cardiorespiratory fitness (LCF) group (n=25, 58.2±7.97 yrs, estimated VO2 max=18.26±3.89 mL/kg/min), according to their levels of cardiorespiratory fitness assessed by the 1-mile walking test. The neuropsychological [e.g., reaction time (RT) and accuracy rate (AR)] and neurophysiological [e.g., electroencephalographic-derived event-related potential (ERP) P300 component] data were simultaneously collected when participants conducted the visuospatial working memory task. All independent variables were separately analyzed with a repeated-measures ANOVA.
RESULTS: Compared to LCF group, HCF group showed higher AR in the matching (p=.028) and non-matching (p=.002) probe stimuli when performing the visuospatial working memory task. However, LCF group showed comparable RTs in both stimuli as the HCF group. In terms of neurophysiological performance, although there were no significant differences in P300 amplitudes between groups (p=.157), the HCF group relative to the LCF group exhibited faster P300 latencies in the matching probe stimuli (p=.004).
CONCLUSION: The present findings indicated the facilitatory effects of cardiorespiratory fitness on the visuospatial working memory performance in individuals with ADFH. Accordingly, such a group should be encouraged to exercise regularly for enhancing the level of cardiorespiratory fitness in order to delay the degeneration of the cognitive functions.

PHYSICAL FITNESS AND COGNITIVE FUNCTION IN AN AGEING POPULATION: RESULTS FROM A CROSS-SECTIONAL AND RANDOMIZED CONTROLLED TRIAL

FAUDE, O.1, STREESE, L.1, DEISEROTH, A.1, SCHICKTANZ, N.2, HANSSEN, H.1
UNIVERSITY OF BASEL

INTRODUCTION: In a society characterized by demographic change, an increasing prevalence of cardiovascular (CV) disease and cognitive decline are evident and represent an enormous socio-economic burden. Both conditions are thought to be interrelated. The aim of the study was to analyze the role of physical fitness level and short-term high-intensity interval training (HIIT) on cognitive function in older active and sedentary adults with and without CV risk.
METHODS: Our study combined a cross-sectional and an interventional approach. Thirty-eight healthy active (HA; 17 women; age = 60 (SD 7) y; VO2peak = 42.5 (8.3) mL/min/kg), 36 healthy sedentary (HS; 26 women; age = 60 (SD 7) y; VO2peak = 29.9 (4.3) mL/min/kg) and 84 sedentary adults with increased CV risk (SR; 42 women; age = 59 (SD 6) y; VO2peak = 26.0 (4.3) mL/min/kg) were enrolled in the cross-sectional study part. All participants underwent a medical examination including a ramp test on a treadmill for determination of VO2peak and maximal heart rate. On a separate visit, participants conducted cognitive assessments. The Flanker task was used to measure inhibitory control of attention. The digit span task was applied as a measure of working memory. We further assessed verbal memory, the 5-point test for figural fluency function as well as the Mini-Mental State Examination (MMSE). The baseline test of the SR group served as pre-test for the following intervention. SR participants were randomized to take part in a 12-week HIIT (N = 40; 4x4 min Nordic Walking at 90-95% of maximal heart rate; 3 supervised sessions per week) or a control condition (CON; N = 34; general lifestyle recommendations). All baseline assessments were repeated after the intervention period.
RESULTS: None of the participants, showed signs of mild cognitive impairment or dementia at baseline as indicated by the MMSE score. In the cross-sectional analysis, we found a gradual decrease in cognitive performance for HS and SR relative to HA as the active and

healthy reference group. Interestingly, inhibitory control (-6% [90% confidence interval -11%,-1%]), figural fluency (-12% [-21%,-3%]) and verbal memory (-8% [-15%,-3%]) were reduced in SR compared to HA. During the 12-week intervention part, VO2peak increased in HIIT by 9%, whereas it decreased in CON by 4%. We found no notable between-group differences in the change scores of any cognitive performance indicator as a result of training.
CONCLUSION: Our results show that a high physical activity level is associated with improved cognitive performance. Clinically manifest cognitive impairments were not present at baseline, although cardiorespiratory fitness differed considerably between the active reference group and the sedentary healthy and diseased populations. Although differences in cognitive performance were apparent and likely result from long-term physical activity, 12 weeks of HIIT appeared to be too short to induce notable improvements in cognitive performance in older patients with CV risk.

Oral presentations

OP-SH10 Sport management

THE REFORM FOR RESTRUCTURING GERMAN COMPETITIVE SPORT AND THE PROMOTION OF TOP-LEVEL SPORT - GENESIS AND STATUS QUO

SCHULZE, E.1, WENDEBORN, T.2

1: LEIPZIG UNIVERSITY, 2: BUNDESWEHR UNIVERSITY MUNICH

INTRODUCTION: Comprehensive modernisation processes and reforms in competitive and top-level sport have been shaping the European sports landscape since the mid-2000s. Also, in Germany the concept for the restructuring of competitive sport and the promotion of top-level sport is intended to set a reform in motion and make German competitive sport "fit for the future" (DOSB, 2015, DOSB et al., 2016). The core element of the reform is the development, implementation and "establishment of a new potential-oriented funding structure" (DOSB et al., 2016, p. 4ff.). While the validity of influencing factors concerning top international sporting success has been analysed (De Bosscher et al., 2009), national reform measures have not been presented or evaluated in a public visible way. There is an increasing lack of knowledge about system-internal processes and procedures of the management of German competitive and top-level sport.
METHODS: This paper analyses the development process and the current status of the potential analysis system (PotAS) as a core element of the German reform (PotAS Kommission, 2018). The examination of structural and process knowledge within our field of investigation has been carried out by a qualitative content-analysis of existing documents (e.g. agendas, recommendations for resolutions, concept papers).
Results and discussion:
A total of three core characteristics can be identified in relation to the German reform and the linked potential-oriented funding system: (1) The objective is a prospective development, (2) The focus is on the framework conditions that determine successful competitive sports development, (3) The top-level professional associations are at the centre of the reform. The performance parameters of the top-level associations are being assessed using PotAS, "according to objective, transparent, sports-scientific and sports-related evaluation criteria that are relevant for a perspective performance" (PotAS Kommission, 2018, p. 1). It appears that although fundamental assumptions of the evaluation procedure are presented, there is no coherent picture of the genesis and the desired framework of effects. Therefore, it seems a necessary next step to interview persons and networks involved in the processes of problem definition and subsequent steps in the genesis process (expert interviews).

FROM TRACKSUIT TO TRENCH COAT: THE CHANGING POSITION OF THE SWEDISH MALE ELITE SOCCER COACH BETWEEN THE 1960S AND THE 2010S.

SVENSSON, R.

SCHOOL OF HEALTH SCIENCES

Introduction
The position of the coach in elite sports has changed radically over the last 50 years from being a somewhat peripheral figure limited to technique and fitness to a central position of managing players, training staff and representing the club for fans, the media and sponsors (Phillips 2000; Day & Carpenter 2016). Using the Swedish male elite soccer coach as an example, the aim of this thesis is to acquire a deeper understanding of this change. The purpose is to examine the changing position of the Swedish male elite soccer coach in relation to the changing conditions of elite soccer between the 1960s and the 2010s.
Theory and method
The history of the Swedish soccer coach is analysed through the lens of the Foucauldian perspective of governmentality (Foucault & Faubion 2002; Rose 1999; Walters 2012). Focusing on the constitution of subject positions, the thesis identifies the power/knowledge relationships formulated within the governmentalities of Swedish elite football clubs and the Swedish Football Association (SvFF). A text analysis of board minutes and annual reports from the Swedish elite soccer club IFK Norrköping, education material from coaching courses organised by SvFF and the transcripts of semi-structured qualitative interviews with former and still active Swedish elite soccer coaches has been conducted.
Result and discussion
The analysis shows that at the beginning of the 1960s the established power/knowledge relationship implied that, kitted out in a whole and clean tracksuit, the coach was expected to govern the players' techniques and fitness training twice a week. However, in order to be internationally competitive, in 1967 SvFF overturned the amateur regulations and instead allowed Swedish clubs to sign professional contracts with the players. From then on the coach was given more time to "conduct the conduct" of the players. In parallel, the clubs and

SvFF turned to scientific knowledge and expertise in the areas of physiology and tactics and later sport psychology, leadership and communication. As a consequence, new power/knowledge relationships were formulated which meant that the coach was not only expected to govern new and more dimensions of the players, but also a growing staff of assistant coaches. In addition, dressed in tailor-made trench coat, the coach became the club's outward face for attracting sponsors and communicating with the media and fans.

'ONE SIZE DOES NOT FIT ALL': COMMONWEALTH GAMES ASSOCIATIONS' GOLD COAST 2018 TEAM DEVELOPMENT FROM A STAKEHOLDER PERSPECTIVE

HOLLANDER, W.

UNIVERSITY OF JOHANNESBURG

The Commonwealth Games Federation (CGF) is an international sport federation that constitute 72 Commonwealth Games Associations (CGAs) that oversee amongst others the delivery of a quadrennial Commonwealth Games. As part of a philosophy of member development the CGF implemented The Gold Coast 2018 Development Grant Programme as funding strategy to facilitate the funding of CGAs towards the development of their teams (athletes and support structures) for the GC2018 Commonwealth Games. Where CGAs are dependent on stakeholders such as National Sport Federations, government, sponsors and others to deliver on Gold Coast 2018, the question arise to what extent the applications of CGAs for funding reflected the roles and responsibilities of stakeholders in the administration and preparation of athletes for Gold Coast 2018 teams.
Documents were analysed according to the criteria provided by the CGF for fund application, allocation and reporting while structured interviews and focus groups were analysed utilizing line-by-line open coding for theme generation and clustering according to axial coding. Trustworthiness of interviews and validity criteria for questions and emergent data was ensured through applying modalities of authenticity and member checking during interviews.
Sixty-nine out of 71 (97%) CGA applications for funding and 63 (89%) allocations and Mid-term reports were analysed. Twenty-seven (n=27) research participants from as many CGAs (38%) participated in interviews and 55 from 25 CGAs (34%) in focus groups. A total of 82 participants from 52 (73%) CGAs collectively participated in either interviews or focus groups.
Results indicated that the approach of CGAs to the application and use of GC2018 development funds relates directly to the capacity, level of professionalization and specialization of CGAs as well as number, level of professionalization and capacity of stakeholders such as NSFs/NSOs, government and sponsors.

SPORT FOR DEVELOPMENT OF SOCIETY: AN ANALYTICAL STUDY OF SOCIAL RESPONSIBILITY IN THE CONTEXT OF SPORT IN EGYPT

ABDELKHALEK, M.1, ABDELFATTAH, T.2, EL ADL, A.3, OKEDA, O.4

1 FACULTY OF PHYSICAL EDUCATION, MANSOURA UNIVERSITY, EGYPT. 2 BUSINESS SCHOOL, UNIVERSITY OF PORTSMOUTH, UK. 3 FACULTY OF ARTS, MANSOURA UNIVERSITY. 4 ALEXANDRIA UNIVERSITY, EGYPT

Sport for Development of Society: An Analytical Study of Social Responsibility in the Context of Sport in Egypt
INTRODUCTION: Sport is considered as a powerful tool for social and economic development around the world (Schulenkorf, 2017). Therefore, a wide range of organisations has become more aware of the value of social responsibility in the context of sport (SRS). While literature provides evidence of the role of sport in society development, most of the prior studies focused on the case of developed countries. The current study aims to investigate SRS in one of the developing countries in the MENA region, namely Egypt. It sheds light on SRS initiatives to determine the triangular relationship between sport, organisations and society and analyses the role of SRS in enhancing the philanthropic, social, environmental and economic development.
METHODS: The qualitative approach was utilised in two phases firstly; documentary analysis method was used to analyse the recent SRS initiatives (N=30). Consequently, semi-structured interviews were conducted with individuals who consist of social responsibility managers, academics and involved experts (N=27) (Smith and Sparkes, 2016). The interviews questions were about ideas that are exploring SRS and its implementation, motivations and returns.
RESULTS: The documentary analysis showed the applicability, feasibility and impact of SRS in sport organisations, non-sport organisations or NGOs. The main themes generated from the analyses were; (a) The scope and sitting of SRS implementation in organisations as mentioned before. (b) The motives of SRS implementation. (c) SRS's returns for organisations, society and individuals. (d) SRS's contemporary issues.
Discussion
The findings suggest that SRS has the power to appeal and communicate with people. Hence, all SRS initiatives are working on developing society. The scope of initiatives can be implemented individually or in a strategic partnership between sport organisations, non-sport organisations or NGOs sharing in the same goals. All organisations prefer to invest their abilities in SRS because sport is more attractive to people, especially youth. Besides, it has high popularity, globality and the mass media which can speech people through sport. Also, SRS has a positive effect on both society and individuals which often are in line with the Government development plans, so the government gives priority and support to SRS. The most critical SRS issues in Egypt are health, integration and refugees, family, women, peace, environment, youth empowerment, unemployment, counter-terrorism, and poverty.

A CRITICAL ANALYSIS OF TOO PROMINENT TO FAIL IN TIMES OF NEYMAR

SCHMIDT, D.

ISF AT FOM AND MASARYK UNIVERSITY

INTRODUCTION: Sales of the worlds most popular sport increased worldwide by nine percent from 2009-2013.In times of revenue growth, however, spending has increased disproportionately. Therefore, football companies go on average more often in bankruptcy than companies from other sectors. Nevertheless, they show a higher survival rate. Media, fans and even scientists are wondering how the future financial situation of football companies will look like at a time when a club like Paris Saint-German is paying over EUR 200 million for player Neymar.
METHODS: The aim of the article is to analyze, if football companies have a higher survival rate. This serves as a basis for discussing whether football companies are "too big to fail". It should be questioned whether the acceptance of the "too prominent to fail" would not be more appropriate. For this purpose, current article contributions and studies are analyzed with regard to the topic.
RESULTS: In order to prevent the cycle of indebtedness on the football market, more regulation is needed. After the financial crisis from 2007 onwards, the excesses of the financial industry could be contained through increased regulation. In the football sector, UEFA is attempting to impose stricter budget restrictions in the form of the "Financial Fair Plays". Some studies criticize that this regulation does not stem the problems of the football market. The transfer of Neymar in 2017 for more than EUR 200 million proves that the clubs can bypass the FFP. As in the financial industry and the "too big to fail" doctrine, this is still based on subjective assumptions of the supporting organizations. These can vary over time and be affected by global economic crises.
CONCLUSION: It can be assumed that the increasing transfer sums will increase the systematic risks in the future. In addition, it must be determined whether football companies will eventually be "too big to save". Because of the high capital requirements, the number of potential business people, investors, states or municipalities who have the financial means and legitimacy to support a football company is reduced. An improved approach to financial fair play could force football companies to balance their economies, leading to a lower rate of bankruptcy on the football market.

DELINEATING TALENT TRANSFER USING AN EVALUATION MANAGEMENT THEORY

CURY, R., SOTIRIADOU, P.

GRIFFITH UNIVERSITY & QUEENSLAND ACADEMY OF SPORT

INTRODUCTION: Talent transfer (TT) initiatives are implemented as an alternative strategy to identity and develop elite athletes. Studies on TT discussed its prospects as a high-performance talent identification and development process (Baker et al., 2018; Collins et al, 2014) and tried to identify the critical aspects of a successful TT program (MacNamara & Collins, 2014). Although insightful, these studies do not offer a global understanding of TT and how it is integrated into the sport development system (SDS). In order to address this gap, this study aimed to provide insights on two research questions: 1) How does the TT process take place? and 2) What are the critical aspects required to implement and manage a successful TT program?
METHODS: An exploratory case-study approach was conducted utilising an evaluation management theory; the theory of change (TOC). TOC helps design and evaluate social programs by understanding the phenomenon targeted (e.g., diabetes) and scrutinising its internal aspects (i.e., strategies/activities, direct outputs, expected outcomes and desired impact) (Patton, 2002). In this study, 10 in-depth semi-structured interviews were conducted with sports experts from an Australian-based TT program to understand TT and the nuances of the program implementation. The interviews were transcribed verbatim and analysed using content analysis. A comparative analysis across all interview data and cross-experts coding were used to validate the codes
RESULTS: The results help advance a preliminary description of TT as "an accelerated pathway in which sports organisations collaborate to offer (or receive) talented athletes who possess high-performance skills that enable them to rapidly transfer to a sport where they can achieve mastery in performance and obtain international sporting success within 3 to 5 years". Unlike the typical SDS where athletes evolve from grassroots sport to elite levels, the interviewees reported that TT athletes do not necessarily start from the foundational skill level and even when they do, their skill acquisition process is differentiated.
The findings also suggest that TT is a three-stage process including: I- Identification, II- Probation: initial sporting development and confirmation and III - Competitive development. A combination of sport science aspects and management arrangements emerged as essential for delivering TT programs successfully. Specifically, in order to identify and provide support to a TT athlete's accelerated development pathway, a team of sports experts from different fields is required. Also, the athlete motor and psychological skills and adaptive responses on those skills are used to determine their selection and progress throughout the TT stages.
CONCLUSION: The use of TOC helped uncover both sport science and management aspects related to TT. High performance managers, coaches and other sports experts can use those findings to gain deeper understanding of TT and rethink strategies when managing TT athletes or programs.

IS-SH03 Advances in understanding the role of fundamental movement skills on children's physical activity

OPTIMISING CHILDHOOD MOVEMENT IN IRELAND; THE FUNDAMENTAL 'BUILDING BLOCKS'

O BRIEN, W.

UNIVERSITY COLLEGE CORK

Motor competence is a critically important correlate of physical activity participation and health-related physical fitness. Fundamental movement skills (FMS) have received considerable empirical attention, and can be defined as the 'building blocks' of more advanced movements, required to participate in games, sports or other context specific physical activities. Yet, most recent research has shown that the majority of Irish children and youth are insufficiently active and fail to reach a level of proficiency across basic movement skills. The present study assessed the performance of seven FMS, as differentiated by gender, in a large sample of 5- to 16-year old Irish children.
Cross-sectional FMS data gathered between 2010, and 2018 were collected as part of longitudinal studies evaluating school-based physical activity interventions. Participants (N=1024; mean age: 12.43 ± 2.60 years) were conveniently sampled from 3 primary, and 8

post-primary schools, comprising of single gender, and mixed gender settings, across rural, and urban locations in Ireland. Objective measurements were assessed in conjunction with the behavioural components from the Test of Gross Motor Development-2 (TGMD-2) assessment protocol.
Overall, 21.8% of participants (n=223) were scored as either mastery, or near mastery (advanced skill proficiency) for all seven FMS. When broken down further, only 1.3% (n=13) of participants possessed complete mastery level across all 7 FMS. The highest skill performance was the run, with 83% achieving mastery; yet, the poorest skill performance was the horizontal jump, with 15% achieving mastery. There were significant differences in the mean composite FMS score (max value = 54), object control score (max value = 40), and locomotor score (max value = 14) between genders, with males scoring higher in all 3 domains ($p < 0.05$).
Considering the observed overall low levels of actual FMS proficiency, and the identified gender differences, further motor competence intervention work is needed in Irish children and youth. While positive steps are being taken to counteract these movement deficiencies amongst Irish children, trends in childhood FMS proficiency continue to remain low. Furthermore, it appears that females may need additional hours of instructional practice towards the acquisition of actual FMS proficiency.
Keywords: motor competence; fundamental movement skills; mastery; instructional practice;

UNDERSTANDING INTERACTIONS BETWEEN BIOLOGICAL AND BEHAVIOURS FACTORS AND MOTOR COMPETENCE IN PORTUGUESE PRE-SCHOOLERS.

VALE, S.
ESE-IPP

Motor competence is considered the degree of skilled performance in variety of motor tasks as well as the movement quality, coordination, and control underlying a particular motor outcome. The term motor competence also relates to a mastery of skills in different domains: motor, cognitive and social. The preschool years are particularly critical in terms of developing motor competence, which are fundamental to a physically active lifestyle in later life. Researchers recognize that the development of motor competence during early childhood is determined by the complex interaction between biological and behaviours factors, and the environmental conditions in which a child lives and grows. However, despite this recognition, there remains the degree to which motor competence, defined as gross motor skill competency, encompassing fundamental motor skills (FMS), motor coordination and motor fitness, impacts on physical activity and health during the preschool years. This lecture will explore and analyse the interactions between biological factors (e.g., age, sex and body composition), behaviours factors (daily physical activity and sedentary behaviour) and environmental conditions (school, PE classes and recess time) with motor competence during the preschool years. Providing an up to date overview of this topic is key for public health specialists, exercise scientists and physical educationalists to developing interventions designed to enhance PA and health during the preschool years.

EVALUATING INTERVENTIONS FOR CHILDREN'S PHYSICAL ACTIVITY, MOTOR COMPETENCE AND ACADEMIC PERFORMANCE

DUNCAN, M.
COVENTRY UNIVERSITY

Introduction
Development of motor competence is a key pillar of school Physical Education (PE) curricula worldwide, yet a leading antecedent of low motor proficiency is likely caused by early or single sport specialisation, where bias is directed towards sport-specific activity at the expense of more global fundamental movement skills (FMS) development. There is thus a need to examine the efficacy of movement interventions aimed at enhancing FMS in children. The aim of this work is to present results from two recent interventions that have used innovative approaches to create positive trajectories of children's FMS and academic performance.
Methods
Both studies were conducted following institutional ethics approval, parental informed consent and child assent. In study 1, 74 preschoolers (39 boys, aged 3-4 years) from 3 preschools were randomly allocated to one of: a combined movement and storytelling intervention; a movement only intervention or; a storytelling only intervention. Pre, post, and 8 weeks post intervention FMS was assessed using Test of Gross Motor Development-2 (TGMD-2) and language ability was assessed using the naming vocabulary subscale of the British Ability Scales for preschoolers. In study 2, 79 children (42 boys, aged 6-7 years) were randomly allocated to either a 6 weekly movement intervention with cognitive challenge (n =48) or a control group (n = 31) who undertook statutory PE. Pre and post FMS was assessed using the TGMD-2 and inhibitory control and attentional focusing were assessed using the Head, Toes, Knees, Shoulders Task (HTKS, Pontiz et al., 2008).
Results
Results from study 1 indicated significantly greater improvement in both FMS ($P = .0001$) and language ability ($P = .0001$). Pre to post intervention for the combined movement and story-telling group compared to the movement only or story-telling only groups. However, for the period post intervention to eight weeks post intervention FMS and language ability significantly increased of a similar magnitude for all groups ($P<0.01$). Results from study 2 indicated that FMS significantly increased pre to post intervention ($P =.009$) for the movement intervention with cognitive challenge group but not the control group. Likewise scores for the HTKS task significantly increased ($P = .0001$) for the intervention group but not the control group.
Discussion
Results from study 1 suggest that combining movement and storytelling is superior to movement only or storytelling interventions in enhancing both FMS and language ability in preschoolers. Results from study 2 suggest that combining cognitive demand with movement training, over a 6 week period, enhances inhibitory control and attentional focusing as well as FMS, thereby augmenting physical and cognitive development in children in a manner that is superior to changes expected from normal development in 3-4 year olds.

IS-PM03 The skin circulation as a target for lifestyle intervention and innovation in measurement

THE CUTANEOUS CIRCULATION IN AGEING AND DISEASE

ALEXANDER, L.

PENNSYLVANIA STATE UNIVERSITY

The cutaneous microcirculation is often regarded as an ideal model to interrogate the workings of the vascular system since it provides an early signal of dysfunction caused by disease and ageing. This presentation will use in vivo and in vitro models to examine the deleterious effect of ageing and disease (hypercholesterolemia and hypertension) on skin blood flow and also highlight how the skin could potentially be targeted in treatment of these diseases. The impact of pharmacological and lifestyle interventions (including nutrition and exercise) in augmenting skin blood flow in these population will also be presented.

EXERCISE TRAINING AND MICROVASCULAR FUNCTION IN FEMALES

JONES, H.

LIVERPOOL JOHN MOORES UNIVERSITY

Reproductive hormones have an influential role on the cutaneous microcirculation including thermoregulatory control and cardiovascular disease risk. This presentation will examine the impact of reproductive hormones on the control of skin blood flow at various stages of adult female life. Specifically, the changes in circulating reproductive hormones on the control of cutaneous blood flow will be examined across the menstrual cycle, with menstrual dysfunction and with hormone suppression. This presentation will highlight how the microvessels can be affected by elevated testosterone, osetrogen suppression and how skin blood flow can contribute to menopausal symptoms. Finally, the presentation will examine how interventions such as exercise can enhance the function of the cutaneous microvessels.

NEW INSIGHTS INTO STRUCTURAL AND FUNCTIONAL ADAPTATION OF SKIN MICROVESSELS IN HUMANS

GREEN, D.

THE UNIVERSITY OF WESTERN AUSTRALIA

Skin microvessels are important physiologically because they play a key role in thermoregulation and, consequently, integrative physiological responses to exercise and body heating. Skin microvessels are important clinically because abnormalities contribute to microvascular disease manifestations, such as diabetic ulceration. It is conceivable, given that microvascular disease precedes macrovascular disease, that repeated assessment of microvascular dysfunction may present an opportunity for early cardiovascular disease detection and treat-to-target vascular prevention. A major limitations to the study of microvascular function in the human skin has been the widespread and relatively uncritical adoption and utilisation of laser Doppler flowmetry. Principal among the many limitations of this approach is the lack of capacity to visualise microvessels and assess changes that occur within individual vessels, including the possibility of structural and morphological changes in the density and/or size of microvessels. In this presentation we present a promising new imaging modality for non-invasive in vivo assessment of microvascular structure and function in humans, including the measurement of blood flow and velocity through individual vessels with diameters as small at 10 microns. Examples will be given of the utility of this approach, including responsiveness to local heating protocols, changes with reactive hyperemia and a recent revisiting of a 500 year old experiment in which we proved Harveys proof.

IS-EX01 ECSS-ACSM Exchange symposium: Sport eligibility and classification in the paralympic games

ECSS-ACSM EXCHANGE LECTURE: WHO IS ELIGIBLE FOR THE PARALYMPIC GAMES AND WHY ARE THERE SO MANY CLASSES?

THOMPSON, W.

GEORGIA STATE UNIVERSITY

Challenging the interests of para-sport is the threat of one-sided and predictable competition, in which the athlete with minimal impairment always wins. To prevent this, para-athletes are placed in categories for competition based on the impact of impairment on performance; these are called sport classes. The International Paralympic Committee (IPC) Classification Code encourages para-sport governing bodies to develop evidence-based classification systems, determining which athletes are eligible to compete in a sport and how athletes are grouped together for competition. In this symposium two world experts will present the recent state of the art on this topic. Prof Walter Thompson will represent ACSM and will give an overview on "Who is eligible for the Paralympic Games and why are there so many classes?". Prof Yves Vanlandewijck represents ECSS and will talk about "The IPC Classification Code and Position Stand on the Scientific Principles of Athlete Classification".

OP-PM22 Respiration / Pulmonary

SYSTEMIC BUT NOT LOCAL REHYDRATION RESTORES DEHYDRATION-INDUCED ALTERATIONS IN LUNG FUNCTION IN HEALTHY ADULTS

MARSHALL, H., GIBSON, O.R., ROMER, L.M., HULL, J.H., KIPPELEN, P.

BRUNEL UNIVERSITY LONDON

INTRODUCTION: Water transport and airway hydration are vital for the normal physiological functioning of the lungs. Water supply to the airways stems primarily from the bronchial circulation which, in turn, arises from the systemic circulation. Information on the effects of systemic water loss on lung function is limited and contradictory(1,2,3). Thus, our primary aim was to clarify the impact of systemic dehydration on lung function in healthy adults. To gain mechanistic insight, we compared two modes of dehydration (fluid restriction vs exercise) and two modes of rehydration (systemic vs local).
METHODS: Ten participants (2 females; age 29 ± 8 y; mass 62.8 ± 8.5 kg; height 173 ± 10 cm) with normal baseline lung function performed four experimental visits in a randomised order. Two visits involved 28 h of fluid restriction (FR) and two visits required participants to exercise for 2 h in the heat (EX). Lung function was assessed using spirometry and body plethysmography in a euhydrated (EUHY), dehydrated (DEHY), and rehydrated (REHY) state. Rehydration occurred over 1 h, either as oral fluid (systemic) or as nebulised isotonic saline inhalation (local). Hydration status was quantified via changes in body mass and plasma osmolality (Posm). Differences were assessed using repeated-measures ANOVA. Values are means ± SD.
RESULTS: Both FR and EX induced a similar state of mild dehydration, with a reduction in body mass (2.5 ± 0.4% and 2.6 ± 0.7%, respectively; both $p<0.001$) and an increase in Posm (292 ± 5 to 300 ± 4 mOsm·kg-1 and 293 ± 6 to 300 ± 4 mOsm·kg-1, respectively; both $p<0.001$). Following FR and EX, lung function was impaired with no differences between dehydration methods. After DEHY, forced vital capacity (FVC) decreased by 153 ± 126 ml, residual volume (RV) increased by 208 ± 173 ml and functional residual capacity (FRC) increased by 119 ± 191 ml (all $p<0.01$ vs EUHY). Total lung capacity and forced expiratory volume in 1 s did not change ($p>0.05$ vs EUHY). Systemic rehydration fully restored body mass, Posm and FRC, and partially restored FVC and RV to EUHY values (29 ± 190 ml and -45 ± 137 ml vs EUHY, respectively). Local rehydration did not restore hydration status or lung function.
CONCLUSION: Mild systemic dehydration, induced by exercise or fluid restriction, resulted in impaired small airway function in healthy adults. In this state, systemic rehydration restored lung function; however, local rehydration had no effect, thus suggesting that an increase in plasma osmolality may contribute to small airways dysfunction.

EFFECT OF EXPIRATORY LOADED BREATHING DURING MODERATE EXERCISE ON INTERCOSTAL MUSCLE OXYGENATION

BRETONNEAU, Q., PICHON, A., DE BISSCHOP, C.

UNIVERSITÉ DE POITIERS

INTRODUCTION: During exercise, the work of breathing is higher in patients with airway obstruction than in healthy subjects, due to expiratory resistances and pulmonary hyperinflation. In this context, we hypothesized that the strength developed by intercostal muscles and their stretch may compress capillaries, impairing blood supply and thus tissue oxygenation.
METHODS: Twelve healthy participants (24 ± 2 years) performed two sessions of moderate exercise (18 min) by breathing freely with and without a 20-cmH2O expiratory threshold load (ETL, Threshold PEP, Respironics, USA). Tissue saturation index (TSI) and concentration changes from rest (Δ) in oxygenated, deoxygenated and total haemoglobin ([O2Hb], [HHb] and [tHb]) were measured in the 7th intercostal space using near-infrared spectroscopy (Oxymon Mk III, Artinis, The Netherlands). Dyspnea (Borg scale), inspiratory capacity (IC) and ventilatory variables were likewise measured (Metalyzer 3B, Cortex, Germany). Two-way repeated measures ANOVA was conducted to test the interaction effect between ETL and exercise duration, followed by a Tukey post-hoc analysis when necessary.
RESULTS: Dyspnea, total respiratory cycle duration and inspiratory duty cycle were higher by breathing with ETL. TSI was lower in ETL condition than in Ctrl all along exercise (51% vs 58%; $p < 0.01$) while Δ [O2Hb] and Δ [tHb] became lower during exercise. In ETL condition, IC decreased from rest to exercise (-0.4 L; $p < 0.05$). Furthermore, changes in [O2Hb] and in dyspnea were correlated with those in expiratory flow rate ($r = -0.66$; $p = 0.02$).
CONCLUSION: During exercise with ETL, pulmonary hyperinflation occurred and intercostal muscle oxygenation was impaired. Altered muscle oxygenation and exacerbated dyspnea were not correlated with the degree of pulmonary hyperinflation, but with the increase in expiratory flow rate. Impaired muscle oxygenation could be due to a limited increase in blood volume resulting from a strong muscle contraction, as suggested by the high increase in expiratory flow in some subjects with ETL.

BREATHING RESISTANCE IN AUTOMATED METABOLIC SYSTEMS AND EFFECTS ON OXYGEN UPTAKE AND PULMONARY VENTILATION IN ELITE ATHLETES

ROSDAHL, H., JENSEN, K., AINEGREN, M.

**THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES, **THE UNIVERSITY OF SOUTHERN DENMARK, ODENSE, ***MID SWEDEN UNIVERSITY, ÖSTERSUND*

INTRODUCTION: Automated metabolic systems are commonly used to measure VO2 with related variables in the normal population and elite athletes. However, there is a lack of information both about the resistance to breathing (RES) of these systems and the effects of RES on measurements of VO2 with related variables. On this background we performed a first study to scrutinize RES with three automated metabolic systems and a custom-built Douglas Bag system and a second study to examine the effects of RES on pulmonary ventilation (VE) and VO2 in athletes with high VO2max and VE.
METHODS: In the first study (1) a metabolic simulator (Vacumed 17056, Ventura, USA) was used to create ventilation at 45, 90, 135, 180 and 225 L/min using the standard hardware of three stationary metabolic systems and a custom-built Douglas Bag system. To investigate RES (Pa/L/s), pressure differences were measured between ambient conditions and the inside of the hardware through an adapter between the mouthpiece and breathing valve. In the second study VO2 and VE were measured twice with the Douglas Bag Method (DBM) at submaximal and maximal exercise with four elite rowers and three elite XC-skiers (whole group average VO2 max and VE was 6.2 and 190 L/min). One measurement was with a standard DBM hardware setup (low RES) and one with extra valves added to the inspiratory and expiratory sides of the breathing valve to achieve a RES comparable to levels found with stationary automated metabolic systems in study one (high RES).
RESULTS: Significant differences were found in RES between all four metabolic systems at all levels of VE (both insp. and exp.). RES for the automated systems ranged between 38 and 169 Pa/L/s at the different levels of VE while DBM showed lowest RES and about half of total RES as compared to the other systems. During submaximal and maximal exercise with elite athletes was no difference found in VO2 between the low RES (range 40-71 Pa/L/s) and high RES (range 152 -168 Pa/L/s) conditions whereas VE and FEO2 were significantly lower and FECO2 significantly higher at all workloads with high RES ($P < 0.05$).
CONCLUSION: Common automated metabolic systems show a higher RES than previous recommendations (59 Pa/L/s, ref 2). A major source of RES are the breathing valves and a minor part are the hoses. Elite athlete's breathing pattern and expired FEO2 and FECO2 are effected by a high RES similar to levels of common metabolic systems while VO2 at both submaximal and maximal levels are unaffected.

RESPIRATORY MUSCLE ENDURANCE IN ADULTS WITH CYSTIC FIBROSIS MEASURED BY INSPIRATORY RESISTIVE AND ISOCAPNIC HYPERPNEA TESTS

GRUET, M., LARRIBAUT, J., VALLIER, J.M., CAMARA, B., MELY, L., QUETANT, S., WUYAM, B., BAILLIEUL, S., GORIOT-RAYNAUD, N., VERGES, S.

UNIVERSITÉ DE TOULON, LAMHESS. GRENOBLE ALPES UNIVERSITY, HP2, INSERM, FRANCE.

INTRODUCTION: Peripheral muscle dysfunction (e.g. lower-limb weakness) is common in cystic fibrosis (CF) and associated with exercise intolerance (Gruet et al. 2017). On the other side, despite the lung disease history of CF, respiratory muscle strength seems preserved in these patients (Heinzmann-Filho et al. 2012). Much less is known about respiratory muscle endurance (RME) for which no standard evaluation exists. This bicentric study aims to determine whether RME is reduced in adults with CF.
METHODS: Thirty-two adults with CF (FEV1 = 57±22% pred) and 20 age-matched healthy controls performed respiratory function assessments including spirometry (e.g. maximal voluntary ventilation, MVV), maximal inspiratory and expiratory pressures (MIP, MEP) and two different RME tests: an inspiratory resistive breathing endurance test (IRB) and an isocapnic hyperpnea endurance test (IHE) conducted until exhaustion. IRB consisted in intermittent 3-s inspirations/5-s forced expirations manoeuvers, starting at 30% of baseline MIP, with 10% MIP increment every 20 respiratory manoeuvers. IHE consisted in isocapnic hyperpnea at increasing levels of minute ventilation, starting at 30%MVV, with 10%MVV increment (i.e. obtained by increasing breathing frequency) every 3 minutes (Vincent et al. 2016). Main outcomes of IRB were MIP at exhaustion in absolute values and expressed as % of baseline MIP. Main outcomes of IHE were peak minute ventilation in absolute values and expressed as %MVV.
RESULTS: T tests for independent samples or Mann-Whitney U tests revealed no significant differences between CF and controls for MIP (120±26 vs. 118±32 cmH2O; $p=0.54$) and MEP (164±51 vs. 155±46 cmH2O; $p=0.23$). Peak minute ventilation during IHE was lower in CF in absolute values ($p < 0.01$) but not when expressed as %MVV (55±13 vs. 57±12 %; $p=0.40$). MIP at exhaustion during IRB was decreased in CF when compared to controls in absolute values (57±22 vs 85±18 cmH2O; $p<0.01$) and when expressed as % of baseline MIP (58±12 vs. 67±12 %; $p=0.01$).
CONCLUSION: This is the first study reporting comprehensive assessments of respiratory muscle endurance in CF using two standardized tests involving different breathing patterns. The present findings indicate that, although respiratory muscle strength is not altered in adults with CF, small differences may exist for respiratory muscle endurance. The manner of measuring endurance is probably crucial to detect potential dysfunction in CF respiratory muscles. The clinical significance (e.g. exercise intolerance, altered quality of life) of such abnormalities remains to be elucidated.

MODELLING THE SLOW COMPONENT: THE EFFECT OF STARTING VALUES ON THE RESULTING PARAMETER ESTIMATES

DRAPER, S.

HARTPURY UNIVERSITY

INTRODUCTION: Breath-by-breath oxygen uptake data are a composite of the underlying response and the breath-to-breath fluctuations that constitute 'noise' on this signal. Despite the majority of studies investigating exercise intensities above the gas exchange threshold (where the slow component is present), the bi-exponential model used has not been examined to ensure it is sensitive enough to adequately estimate parameters. Such an analysis has only occurred in moderate (1, 2) and severe intensity exercise (3), where a single exponential function was used. All iterative models require starting (estimate) values to be entered, and it is possible these affect the derived parameter estimates. Until this possible effect is understood it is impossible to the properly evaluate the quality of the model being used. Therefore the purpose of the present study was to investigate the effect of altering these starting values on the derived parameter estimates.
METHODS: Six male participants each completed six transitions (8 minutes) at 25% of the difference between gas exchange threshold and maximal oxygen uptake. Data were interpolated, and modelled for each person and the average for each parameter was used as the underlying response to test the bi-exponential model. Studies typically use two transitions to model slow component data (4) and so the typical SD of residuals from two transitions was superimposed onto the underlying response to perform a Monte-Carlo analysis. Starting values were manipulated ranging from -50% to +50% of the actual underlying curves. Ninety five percent confidence limits were calculated as the 1.96 x SD of residuals. All data were analysed using SPSS (IBM, Portsmouth) (nonlinear regression) and were unconstrained.
RESULTS: Results demonstrated that both the returned parameter estimates and the variability of these values (95% confidence limits) were affected by starting values. The mean values from each simulation showed that starting values would need to be within 10% of the actual value to return values with 5% of the actual for all parameter estimates. The 95% confidence limits were wide for the key slow component parameter estimates (amplitude and time constant) even when starting values were at or close to the actual values.
CONCLUSION: These results show that that bi-exponential modelling of oxygen uptake kinetics is heavily influenced by the starting values used in the iterative methods for model fitting. Authors in this area should make more explicit how data were modelled and report all parameter estimates. Furthermore these results suggest that the confidence intervals for slow component parameters are wide and we should be cautious how these are interpreted.

PHYSIOLOGICAL ASSESSMENT OF DIFFERENT SAILING TECHNIQUES IN YOUNG ELITE WINDSURFERS

ROBERTO, S., MILIA, R., GHIANI, M.G., DONEDDU, A., MELIS, A., CRISAFULLI, A.

UNIVERSITY OF CAGLIARI

INTRODUCTION: Starting from 1993, Olympic boardsailing has been considered a high intensity physical activity since a new sail technique, called "pumping" (P), was allowed. Pumping is a maneuver during which athletes pull the sail rhythmically so that it acts as a wing. As compared to the old technique without pumping (WP), where only the upper body musculature was involved, P requires the recruitment of both the upper and the lower body musculature. This allows to obtain more efficient board propulsion with light and moderate wind conditions. The aim of present investigation was to compare oxygen uptake (VO2) during the two different technique: P and WP sailing.
METHODS: Five elite windsurfers (4 males, 1 females, 13.8±1.78 yrs) agreed to participate in the present investigation. They underwent a preliminary cardiopulmonary exercise test on cycloergometer up to exhaustion in the laboratory to assess their maximum VO2, maximum heart rate (HR), and anaerobic threshold. After the preliminary test, they underwent a simulation of sailing competition in the sea during upwind sail with P and WP manoeuvres. Throughout the simualtion, cardiopulmonary variables were measured with a portable gas analyser (VO2000, MedGraphics).
RESULTS: Analysis revealed a significant higher value of VO2 and HR during P as compared to WP (p= 0.0208 and p= 0.0178 respectively). Furthermore, average level of VO2 and HR during sailing were lower than the level achieved at maximum workload in the preliminary laboratory test and close to level reached at anaerobic threshold.
CONCLUSION: Our data are in good agreement with previously research showing that Olympic class windurfing can be considered a high-intensity activity and that P adds a significant metabolic requirement in comparison to WP. The new technique of P increases the aerobic demand in comparison with the old technique WP. Results also suggest to use of specific aerobic training programs in order to develop the specific adaptations required by the elevate aerobic demand.

THE EFFECTS OF SEX DIFFERENCES ON THERMOREGULATORY RESPONCES TO ICE SLURRY INGESTION

IWATA, R.1, HAMADA, Y.1,2, LEE, J.K.W.3, TAKAHASHI, M.4, SUZUKI, K.1, MIYASHITA, M.1

1: WASEDA UNIVERSITY , 2: JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE , 3: NATIONAL UNIVERSITY OF SINGAPORE , 4: WASEDA BIOSCIENCE RESEARCH INSTITUTE IN SINGAPORE

INTRODUCTION: It has been known that men and women respond differently to thermal stress. Ice slurry ingestion is widely used for endogenous pre-cooling in sports (1). The magnitude of reduction in deep body temperature at the onset of exercise is important for

maintaining or improving exercise performance in the heat (2). However, the volume of ice slurry used in most of the previous studies was 500 g or more (2). Such volume may not be appropriate for women to consume at once. The aims of the present study were to examine 1) sex differences in resting thermoregulatory responses after repeated ingestion of ice slurry and 2) the different volumes of repeated ice slurry ingestion on resting thermoregulatory responses.
METHODS: Twelve men (mean ± S.D. age 23 ± 2 years, % body fat 19 ± 6 %) and twelve women (mean ± S.D. age 21 ± 2 years, % body fat 27 ± 5 %) completed three, 100-min laboratory-based trials in a random order: 1) 8g/kg ice slurry (IC8), 2) 4g/kg ice slurry (IC4) and 3) 8g/kg control water (CON) (20°C). During the trial, the participants ingested each drink at 10, 20, 30 and 40 min after 10 min rest. Then, the participants remained at rest for 60 min in a thermo-neural environment room (i.e., room temperature, 25 ± 2°C and relative humidity, 39 ± 7%). Rectal temperature (Tre), skin temperature (Tsk), rating of thermal sensation (RTS) and rating of thermal comfort (RTC) were measured during the entire experimental trials.
RESULTS: There was no sex difference in Tre, Tsk, RTS and RTC among trials ($p>0.05$). The combined analysis of all individuals data showed that the time-averaged changes in Tre over 60 min (i.e., from the end of each drink ingestion) was greater in the IC8 trial (-0.49 ± 0.36°C) compared with the IC4 (-0.32 ±0.03°C) and CON (-0.25 ± 0.32°C) trials (main effect of trial, $p<0.05$). There was little difference between the IC4 and CON trials. The time-averaged changes in Tsk over 60 min was greater in the IC8 trial (-0.22 ± 0.91°C) compared with the CON (0.37 ± 0.13°C) trials (main effect of trial, $p<0.05$). There was no difference between the IC8 and IC4 trials, and the IC4 and CON trials.
CONCLUSION: There was no sex difference in the pre-cooling effect of IC8 and IC4. IC8 induced greater Tre reduction compared with IC4 and CON. These findings may indicate that the efficacy of reducing deep body temperature in hope to enhance or maintain endurance performance in the heat needs to be of sufficient ingestion volume, regardless of sex.

LOW FERRITIN STATUS AND HEPCIDIN RESPONSE TO EXERCISE IN FEMALE ATHLETES

ALFARO-MAGALLANES, V.M., BARBA-MORENO, L., BENITO, P.J., CUPEIRO, R., ROMERO-PARRA, N., RAEL, B., BENÍTEZ, J.A., PEINADO, A.B.

FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCE . UNIVERSIDAD POLITÉCNICA DE MADRID.

INTRODUCTION: Oestrogen and progesterone have been postulated to influence hepcidin levels in vitro, animals, and humans.1 Regarding female athletes, the different hormonal states throughout a menstrual cycle could influence the well-known hepcidin up-regulation mediated by interleukin-6 (IL-6) increments produced after exercise.2 Moreover, ferritin status is a key regulator of hepcidin response after exercise, since post-exercise hepcidin levels have been reported to be lower when pre-exercise ferritin levels are compromised.2 The purpose of this study was to clarify which stimulus is overriding the others by comparing the hepcidin response to exercise in different hormonal states with low ferritin reserves throughout the menstrual cycle in female athletes.
METHODS: Fifteen eumenorrheic endurance-trained females (35.6±4.2 yrs; 58.1±5.2 kg; 163.9±5.9 cm; VO2max: 50.3±3.6 ml·kg-1·min-1) performed three continuous running sessions of 40 min at 75% of the VO2max velocity throughout different phases of the menstrual cycle (EFP=early follicular phase, MFP=mid-follicular phase, LP=luteal phase). Blood samples were taken pre-exercise, 0h and 3h after exercise. For statistical analysis, baseline and the mean between 0h and 3h samples (post-exercise) were considered for hepcidin and IL-6. Ferritin levels and sex hormones were measured pre-exercise.
RESULTS: Mix linear model showed no differences between menstrual phases for ferritin (EFP=25.4±5.7; MFP=28.3±5.7; LP=29.2±5.7 ng/ml; $p=0.641$). Furthermore, hepcidin levels were higher post-exercise (73.9±6.3 ng/ml) compared with pre-exercise (69.7±6.3 ng/ml; $p=0.023$) but no differences were observed between menstrual cycle phases ($p=0.971$) or menstrual cycle and time interaction ($p=0.799$). IL-6 showed differences for phase, time and phase-time interaction ($p=0.036$; $p<0.001$; $p=0.027$; respectively). IL-6 were higher post-exercise (4.5±0.7 pg/ml) in comparison with pre-exercise (2.5±0.7 pg/ml; $p<0.001$). Finally, the most relevant result was that post-exercise IL-6 was higher during the LP (6.4±0.9 pg/ml) than in the EFP (3.7±0.9 pg/ml; $p=0.017$) and MFP (3.5±0.9 pg/ml; $p=0.003$).
CONCLUSION: Baseline ferritin and post-exercise hepcidin response did not fluctuate during the menstrual cycle, suggesting that female sexual hormone fluctuations are not powerful enough to override the ferritin status as regulator of hepcidin response to IL-6.2 In addition, IL-6 seems to be higher post-exercise during the luteal phase, but this does not seem to produce a higher increment in hepcidin levels. This suggests that ferritin is mitigating a possible higher response of hepcidin to IL-6 increments in this menstrual phase.2 Hence, ferritin seems to be the main marker to consider when predicting the response of hepcidin after training.

SEX DIFFERENCES IN MUSCLE FUNCTION AND MYOCELLULAR RESPONSE TO A STRENUOUS MILITARY FIELD EXERCISE

LANDER, E.1, VIKMOEN, O.2, TEIEN, H.2, HELKALA, K.3, RAASTAD, T.1

1: NORWEGIAN SCHOOL OF SPORT SCIENCES, DEPARTMENT OF PHYSICAL PERFORMANCE 2: NORWEGIAN DEFENCE RESEARCH ESTABLISHMENT, COMPREHENSIVE DEFENCE DIVISION 3: THE NORWEGIAN DEFENSE UNIVERSITY COLLEGE, NORW

INTRODUCTION: Exposure of extreme stress during military operations can affect the soldiers' operability for several weeks (1). However, there is limited information on the myocellular response to arduous military operations and the molecular regulation in the recovery phase. Furthermore, it is not known whether there are sex differences to such extreme stress. Therefore, the objective of this study was to investigate the impact of a strenuous military field exercise on muscle function and regulators of autophagy, protein synthesis and energy production, and to identify possible sex differences in the acute response and in the recovery phase.
METHODS: Soldiers (F=8, M=10) from the Norwegian Defence Cyber Academy conducted a 10 days long strenuous military field exercise. Maximal leg extension force was tested before (Pre), after (Post0), one week after (Post1) and two weeks after (Post2) the exercise. Skeletal muscle biopsies were obtained from m. vastus lateralis at Pre, Post 0 and Post 1. Biopsies were analyzed for the following proteins by western blots: 4E-BP1, S6Kp70, AMPK, Ulk1, COX-IV, HADH, Citrat Synthase, Na+K+, SERCA1, SERCA2 and αB-Crystallin. Data was analyzed by a two-way ANOVA for sex differences and one-way ANOVA for time differences.

RESULTS: Maximal force was reduced for the whole group by 9±11% at Post 0($p<0.05$) and was still 8±12% lower than Pre at Post 2 ($p<0.05$), with no sex differences. The ratio pAMPK/totAMPK increased 39±40% at Post 0 ($p<0.05$) and 48±46% at Post 1 ($p<0.001$). Na+K+ decreased at the same time points with 7±12% ($p<0.05$) and 12±13% ($p<0.05$) respectively. Other significant changes from Pre to Post 1 were a 14±32% increase in 4E-BP1 ($p<0.01$), a 17±29% reduction in COX-IV ($p<0.05$) and a 18±21% reduction in citrate synthase ($p<0.05$). The only significant difference between sexes was found for Ulk1 at Post 0 ($p<0.05$), where women decreased 22±15% and men increased 16±17%. There was a tendency for differences between sexes in Na+K+ at Post 0 ($p=0.065$) where women at the same time point had a 14±9% reduction in Na+K+ ($p<0.05$). There were no significant changes in S6Kp70, αB-Crystallin, SERCA1, SERCA2 or HADH.
CONCLUSION: These results indicate that a strenuous military field exercise leads to similar reductions in maximal force for men and women together with increased catabolism and/or inhibited anabolism, which last for at least one week. There was a sex difference in the change in protein levels of Ulk1, but this was not related to any difference in reduction of maximal force. The results indicate that there may be sex differences in the myocellular response to a military field exercise, but further investigations are needed.

DO ADOLESCENTS PERCEIVED PARENTAL SUPPORT ARE DIFFERENT BY GENDER TO PARTICIPATE IN REGULAR SPORT?

LAGOA, M.J.1, AIRES, L.2, SÁ, C.1, VIANA, J.L.1, SILVA, G.1

1 RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT CIDESD, UNIVERSITY INSTITUTE OF MAIA, ISMAI PORTUGAL; 2 CIAFEL, UNIVERSITY OF PORTO, PORTUGAL

INTRODUCTION: Few adolescents in Portugal attain health recommendations for Physical activity (PA) intensities. Additionally girls still have demonstrating less PA index than boys and less sport participation. Parents are those responsible for the introduction of their children to a physical or sporting activity and are guarantors of transport, access, and emotional and economic support. Thus, parental involvement has been associated with sport participation, but there is controversy in the results found regarding gender. Therefore, the aim of this study was to evaluate gender differences in relation to perceived parental support between sport participation (SPG) and not sport participation (NSPG) adolescents.
METHODS: Portuguese adolescents (n=862, mean age 12.7±1.6 years; SPG n=518 in the same group girls n=224) took part in a school-based program, named Family in Move. This program aims to identify barriers, motivations and family perceptions, related to healthy lifestyles. The adolescents' PA was assessed by questionnaire (Ledent, Cloes, & Piéron, 1997) good reliability and strong intraclass correlation coefficients for Portuguese population (Mota et al., 2002); PA index was obtained according to the total sum of points with the highest score possible of 22. The family's demographic information and adolescents' perceived parental support were assessed by questionnaire (Ommundsen, Page, Ku, & Cooper, 2008). Data was analysed by independent sample t-tests. To analyse the effect of perceived parental support and gender on adolescents' participate sport, univariate analysis of variance, with Bonferroni adjustments was performed.
RESULTS: Results showed that girls had significantly less PA índex than boys in both groups (SPG 14.1±0.2 vs. 15.4±0.2, $p<0.001$; NSPG 9.7±0.2 vs. 11.3±0.3, $p<0.001$). Adolescents perceived more parental support in SPG than NSPG (3.0±0.1 vs. 2.4±0.1, $p<0.001$) and girls perceived less parental support than boys (2.7±0.9 vs. 2.9±0.9, $p<0.009$). Furthermore, interaction between sport participation groups and gender was significant for perceived parental support ($F = 4.29$, $p<0.039$, $\eta 2= 0.05$).
CONCLUSION: Our results showed that girls had less PA index and perceived less parental support than boys. And girls' participation in sport can depend on perceived parental support. Therefore, adolescents' perceived parental support specifically on girls may be an important element to consider and improve in interventions for girls' sport participation promotion.

OP-BN11 Biomechanics: Running

THE EFFECT OF STRENGTH TRAINING ON DISTANCE RUNNING MECHANICS

TROWELL, D.

DEAKIN UNIVERSITY/AUSTRALIAN INSTITUTE OF SPORT

INTRODUCTION: Concurrent strength and endurance training improves running performance more than running training alone;(Alcaraz-Ibañez, 2018) however, the mechanisms underpinning these changes are unclear. Biomechanical and neuromuscular mediators have been hypothesised to explain these improvements but this has yet to be corroborated by assessment of these mediators during over-ground running.(Paavolainen, 1999) The aim of this study was to determine whether changes in performance following concurrent strength and endurance training are associated with changes in stride characteristics and lower-limb joint kinetics.
METHODS: Twenty-seven (17 male, 10 female) distance runners, without previous strength training experience, were randomly allocated to either an experimental group or control group. In addition to their normal running training, the experimental group undertook supervised strength training two days per week for 10 weeks at the Australian Institute of Sport gymnasium. Strength training exercises included ankle bouncing, the barbell back squat, hurdle jumps, forearm plank, A-skip drill, single-leg deadlift, split scissor jump, side-stepping with a Thera-band, countermovement jumps and the glute-bridge. Total training time was matched for both groups. Running performance and biomechanics were measured before and after the intervention period. Running performance was assessed using a 2 km time trial on a 400 m athletics track. Biomechanical data were collected using a VICON motion analysis system (Oxford Metrics Ltd, Oxford, UK) and eight in-ground Kistler force plates (Kistler Group, Winterthur, Switzerland) during overground running at 3.89 m/s and maximal sprinting on a 110 m indoor synthetic running track. A number of discrete stride parameters and kinematic and kinetic variables

were exported for analysis. An ANCOVA was performed (SPSS v19; IBM, Armonk, NY) on each dependent variable using baseline scores as the covariate.
RESULTS: Concurrent strength and endurance training significantly improved 2 km running performance ($F(1,24)=8.93$, $p < .05$) more than endurance training alone. After 10 weeks of strength training, there were no significant changes in stride parameters, or peak hip flexion or extension torque and power during swing, peak knee flexion torque during swing or peak plantarflexion torque or power during stance.
CONCLUSION: The results of this study show that concurrent strength and endurance training does not appear to change peak hip, knee and ankle torques or power generation/absorption during running. Improvements in performance may be related to other factors not examined in this study. Further research is needed to determine how concurrent strength training improves distance running performance. Improved understanding of these mechanisms may have important implications for the design of efficient athlete training programs.

EFFECT OF RUNNING-INDUCED FATIGUE ON LOWER LIMB KINEMATICS AND KINETICS DURING A SIDE CUTTING MANOEUVRE IN MALES AND FEMALES

OXENDALE, C.L., SMITH, G.

UNIVERSITY OF CHESTER

INTRODUCTION: Inconsistencies in fatigue-induced modifications in side cutting mechanics likely reflect the non-uniformity of fatigue protocols (1) and analysis procedures utilised (2), and therefore warrant further investigation. Thus, the purpose of the study was to assess the effect of running-induced fatigue on side cutting mechanics in males and females.
METHODS: Eight males (stature: 175.5 ± 8.0 cm, mass: 74.6 ± 8.5 kg, age: 21.6 ± 2.2 y) and eight females (stature: 165.8 ± 8.5, mass: 63.1 ± 13.5 kg, age: 21.3 ± 3.2 y) took part in the study. Participants completed a multi-directional running fatigue protocol consisting of 12 bouts of intermittent running with numerous directional changes (~230). 20 m sprint time and three dimensional kinematic and kinetic data during five successful trials of a 45° cutting manoeuvre on the dominant side, were collected pre- and post- fatigue. Knee angles, vertical (v) and anterior-posterior (y) ground reaction force (GRF) were determined at 40 ms post initial contact and peak knee joint moments were assessed. Effect of fatigue was assessed using magnitude-based inferences and effect sizes. Coefficient of variation (CV) was used to assess within-subject GRF variability.
RESULTS: There was a very likely increase in 20 m sprint time for women (ES; ±90% CI: 1.2; ±0.5) and men (0.7; ±0.3). After fatigue, both women (23.7 ± 8.6° cf. 21.2 ± 7.8°; 0.3; ±0.2) and men (25.3 ± 5.2 ° cf. 23.9 ± 4.4°; 0.2 ±0.3) showed a possible decrease in knee flexion angle. Knee extension moment likely decreased post fatigue in males (3.6 ± 0.4 cf. 3.4 ± 0.2 Nm.kg-1; -0.5; ±0.5) but not in females. The variability of yGRF possibly decreased in females (CV: 13.6 ± 10.3 cf. 10.2 ± 5.7 %; -0.3; ±0.4). No changes in knee abduction angle, moment, vGRF and yGRF were observed.
CONCLUSION: Fatigue caused similar kinematic but not kinetic sagittal plane alterations in men and women, however such alterations are unlikely to increase ACL injury risk (3). The reduction in yGRF variability indicates a possible decline in force producing capacity in women following fatigue.

IMPACT ACCELERATIONS IN RECREATIONAL RUNNERS WITH AND WITHOUT A HISTORY OF INJURY.

BURKE, A.1,2, CONNOR, S.2, DILLON, S.1,2, WHYTE, E.2, GORE, S.1,2, MORAN, K.1,2

DUBLIN CITY UNIVERSITY, IRELAND.

INTRODUCTION: Recreational running is extremely prevalent, with running related injuries (RRIs) being a persistent burden (1). While it has been hypothesized that impact loading is a contributing factor, there has been mixed evidence to support this, particularly with regard to the use of ground reaction force. Recently, impact accelerations have been advocated because of their advantages over force plates (e.g. segment specific loading, low cost, portable). Few studies have compared runners who have never been injured (INJ0) with runners who have a retrospective RRI history (INJR) (1). We conducted a novel study to explore the differences in peak impact accelerations (Peakaccel) and rate of acceleration (Rateaccel) between INJ0 and INJR males and females.
METHODS: Accelerometers (Shimmer, Ireland) were used to compare Peakaccel and Rateaccel of the tibia in 50 INJ0 and INJR male and female runners during a 15 minute running trial. INJR runners were matched with controls (INJ0) by gender, running experience and cumulative training mileage within the previous three months (INJ0: n = 25; 44.7 ± 8.5yrs; 297.5 ± 210.2km) and (INJR: n = 25; 42.2 ± 6.2yrs; 299.1 ± 205.2km). A two-way between-groups analysis of variance explored the effect of injury status and gender on tibial accelerations. Significance at $P \leq 0.05$.
RESULTS: There was statistically significant interaction effects with a medium effect size for both Peakaccel ($F=4.64$, $p=0.04$, $\eta 2=0.09$) and Rateaccel ($F = 6.30$, $p = 0.02$, $\eta 2 = 0.12$) between gender and injury status. INJR females demonstrated significantly greater Peakaccel (7.5 ± 3.1g vs 5.3 ± 1.5g) and Rateaccel (652.7 ± 447.4 g/s vs 284.9 ± 120.5 g/s) than INJ0 females. No difference was evident between INJR males and INJ0 males for either Peakaccel or Rateaccel (5.3 ± 1.2g vs 5.4 ± 1.1g; 314.4 ± 150.57g/s vs 327.6 ± 172.5g/s) and no difference was evident between male and female runners who had never been injured.
CONCLUSION: It has been suggested that elevated levels of loading through high impact accelerations may increase the risk of RRI potential. The present study found this to be true for females, similar to Davies et al., (2015), but not for males. This also is the case for Rateaccel. While it is unclear whether this reflects an altered movement pattern due to injury, or is related to the cause of injury, it may be important for females with high Peakaccel and Rateaccel to alter their running technique to reduce these impact loads. This highlights the value of biofeedback and gait re-education, which has been demonstrated to be an effective method of impact acceleration reduction in runners (2).

EFFECTS OF SHORT AND LONG COMPRESSION STOCKINGS ON IMPACT ACCELERATIONS DURING AN INTENSE RUN ON TREADMILL.

GIL-CALVO, M.1, SANCHIS-SANCHIS, R.1, APARICIO, I.1,2, JIMENEZ-PEREZ, I.1,3, GISBERT, M.J.2, ENCARNACIÓN-MARTÍNEZ, A.1, PÉREZ-SORIANO, P.1

1. RESEARCH GROUP IN SPORTS BIOMECHANICS . UNIVERSITY OF VALENCIA. 2. AITEX . 3. RESEARCH GROUP IN MEDICAL PHYSICS . UNIVERSITY OF VALENCIA.

INTRODUCTION: Prolonged exposure to shock waves produced during running is associated with an increase on injury risk. The use of long compression stockings has shown higher attenuation and lower impact forces (1,2). However, there is not information about the effects of short compressive socks on impact transmission during running. Thus, the aim of the study was to compare the effects of short and long compression stockings on tibial and head accelerations during running on treadmill.
METHODS: 16 healthy runners (age: 31(9) years; weight: 70.3(9.4) kg; height: 1.77(0.04) m) performed two tests on different days. Each test consisted in 5 minutes of warm up, increasing speed progressively until 12 km/h, and 30 minutes of run at 12 km/h on treadmill. Participants wore two different compression garment conditions, previously randomized: 1) long compression stockings (ultra, Lurbel®)(LS); 2) short compression stockings (sock gravity, Lurbel®) (SS). Before each test, participants run for a week with the compression garment assigned as adaptation period. Acceleration parameters (head and tibial peak acceleration, magnitude and shock attenuation) were measured each 5 minutes during the running test, using two tri-axial accelerometers (BlauTic®, Spain, sampling frequency: 415 Hz) placed in the dominant tibia and in the forehead. Data were filtered and analysed using Matlab (The Math Works Inc., USA).
RESULTS: No significant differences were found between short and long compression stockings in tibial peak acceleration and tibial magnitude ($p>0.05$). Nevertheless, in head peak acceleration, no significant differences ($p>0.05$) were found between both conditions until minute 30, when a greater peak acceleration was found with short garments [LS vs SS: 2.57(0.2) G vs 2.62(0.25) G; $p=0.035$]. Moreover, short stockings produced greater head magnitude accelerations than long ones in: min 5 [LS vs SS: 2.32(0.26) G vs 2.48(0.28) G; $p=0.01$], min 10 [LS vs SS: 2.32(0.28) G vs 2.49(0.30) G; $p=0.02$], min 15 [LS vs SS: 2.29(0.28) G vs 2.48(0.32) G; $p=0.03$], min 20 [LS vs SS: 2.55(0.18) G vs 2.67(0.19); $p=0.04$], min 25 [LS vs SS: 2.53(0.18) vs 2.67(0.17); $p=0.02$] and min 30 [LS vs SS: 2.57(0.20) vs 2.62(0.25); $p=0.01$]. Finally, no differences between short and long compression garments were found in shock attenuation ($p>0.05$).
CONCLUSION: Short compression stockings seem to produce similar behaviour in tibial impact transmission than long compression stockings. On the other hand, in head accelerations, the use of long stockings showed better results than the use of short ones. Nevertheless, shock attenuation was similar with the two conditions studied.

MUSCLE MORPHOLOGY AND STRENGTH DETERMINANTS OF ELITE SPRINT RUNNING PERFORMANCE

MILLER, R.1,5, BALSHAW, T.G.1, MASSEY, G.2, MAEO, S.3, JOHNSTON, M.4,5, ALLEN, S.J.1, FOLLAND, J.P.1

(1) LOUGHBOROUGH UNIVERSITY, UK; (2) EXETER UNIVERSITY, UK; (3) RITSUMIEKAN UNIVERSITY, JAPAN; (4) SWANSEA UNIVERSITY, UK; (5) BRITISH ATHLETICS, LOUGHBOROUGH, UK

INTRODUCTION: Whilst some preliminary research has related muscle morphology with sprint running performance (1, 2), these studies have examined only a limited number of lower body muscles, relatively small groups (<20), and not included elite level sprinters (e.g. 100m <10.40 s). Additionally, no research study to date has measured both size and strength characteristics. This study aimed to compare muscle morphology, and strength characteristics, of elite vs sub-elite sprinters vs untrained controls; and assess the relationship of these measures with seasons best 100m sprint performance (SB100).
METHODS: Eight elite sprinters (E; Age 25±5 yr, body mass 83.5±6.9 kg, height 1.82±0.07 m, SB100 10.19±0.15 s, including four athletes with sub-10s personal best), 24 sub-elite sprinters (SE; 22±2 yr, 74.9±7.5 kg, 1.77±0.08 m, 10.86±0.26 s) and 11 control participants (C; 26±3 yr, 75.2±5.6 kg, 1.80±0.08 m) completed a 3T magnetic resonance imaging scan (Discovery MR750w, GE Healthcare, Chicago, IL, USA) to determine the volume of 6 muscle groups (hip, knee and ankle flexors and extensors) and 19 individual muscles and isometric strength assessment of five muscle groups (hip and knee extensors and flexors, plantarflexors). One-way ANOVA and post-hoc Bonferroni adjustments were used to compare absolute and relative (to body mass) muscle volume and strength between the groups, and Pearson's correlation was used to assess relationships between these measures and SB100.
RESULTS: Absolute volume of the hip flexors and extensors, knee flexors and 9 individual muscles were larger in E vs SE ($p<0.05$). Relative to body mass, E and SE had greater volume of 4 muscle groups than C (hip and knee flexor and extensors; $p<0.05$). Only one muscle group (hip extensors; $p=0.003$) and one individual muscle (gluteus maximus, $p=0.001$) had greater relative volume in E vs SE. E and SE had similar absolute and relative torque for all muscle groups. Absolute volumes of five muscle groups ($r=-0.495$ to -0.689, $p<0.05$) and 16 individual muscles ($r=-0.409$ to -0.662, $p<0.05$) were negatively correlated to SB100 (i.e. greater volume, faster time). SB100 was also negatively associated with relative volume of two muscle groups (hip extensors, $r=-0.560$, $p=0.001$; knee flexors, $r=-0.481$, $p=0.006$), and four individual muscles (gluteus maximus, $r=-0.580$; sartorius, $r=-0.485$; gracilis, $r=-0.377$; tensor fasciae latae, $r=-0.454$; All $p\leq0.037$). Whilst absolute hip flexor ($r=-0.391$, $p=0.036$) and knee flexor torque ($r=-0.432$, $p=0.017$) were negatively correlated with SB100 relative knee extensor torque was positively associated with SB100 ($r=0.414$, $p=0.026$; i.e. more torque, slower time).
CONCLUSION: Greater lower-body muscularity, principally of the hip extensors and knee flexors, and the gluteus maximus in particular, were strongly associated with faster sprinting performance.

DIFFERENCES IN HORIZONTAL AND VERTICAL FORCE-VELOCITY-POWER PROFILE BETWEEN FEMALES OF 100-M SPRINTERS AND 100-M HURDLES.

PARADISIS, G., STAVRIDIS, I., POLITI, K., FRAGOULIS, E.

NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: The women's 100-m sprint running event consists of reaching athletes' maximal running velocity and covering this distance in the shortest time. On the other side, the athletes of the 100-m hurdles event generate as much speed as possible over the distance while clearing the barriers. In both events, during the entire acceleration phase, athletes' try to generate high levels of horizontal force and apply it with effectiveness onto the ground, despite increasing velocity (1). This study aimed to compare the horizontal and vertical force-velocity-power (F-V-P) profile between female sprinters and hurdles.
METHODS: 10 high-level athletes, 5 sprinters (Mean ± SD: age 24 ± 3.1 years; height 1.71 ± 0.06 m; weight 60.3 ± 2.1 kg; 100-m personal best 11.79 ± 0.2) and 5 hurdles (age 18.8 ± 1.6 years; height 1.69 ± 0.05 m; weight 58.6 ± 4.8 kg; 100-m hurdles personal best 14.3 ± 0.3) performed 2 maximal 40-m sprints (F-V horizontal profile) and maximal Squat Jumps with additional loads from 0 to 100% of body mass (F-V vertical profile). For the sprint-acceleration performance, velocity-time data was recorded by a high-speed camera (300 fps, Casio Exilim EX-F1) and obtained from the video analysis by Kinovea (0.8.15) to calculate the variables of F-V horizontal profile (2). The variables of the F-V vertical profile were obtained by using a contact mat system (Chronojump, Boscosystem) that was used to calculate the jumps heights (3). The horizontal F-V-P profile (theoretical maximal values of force (HZT-Fo), velocity (HZT-Vo) and power (HZT-Pmax), the proportion of the theoretical maximal effectiveness of force application in the anterior-posterior direction (RFmax%)) and the vertical F-V-P profile (theoretical maximal values of force (VTC-Fo), velocity, (VTC-Vo) and power (VTC-Pmax)) were examined.
RESULTS: The 100-m female sprinters showed higher statistical differences for HZT-Pmax (2.18 ± 0.78, d = 1.7, $p<0.05$) and RFmax% (2.7% ± 1.1%, d = 0.17, $p<0.05$) than 100-m female hurdles. No statistical differences were observed between athletes for HZT-Fo (0.8 ± 0.4, d = 1.15, $p>0.05$), HZT-Vo (0.2 ± 0.1, d = 1.35, $p>0.05$), VTC-Fo (0.1 ± 4.0, d = 0.015, $p>0.05$), VTC-Vo (0.4 ± 0.3, d = 0.72, $p>0.05$) and VTC-Pmax (3.4 ± 2.6, d = 0.82, $p>0.05$).
CONCLUSION: The higher horizontal Pmax and RFmax values displayed by 100-m sprinters are likely to be related to differences in the acceleration phase between the two events, as in the 100-m hurdles event the athletes achieve early rising of the torso, compared to those of the sprint running events, and thus greater force output in the vertical direction upon contact with the ground.

OP-BN12 Neuromuscular fatigue I

INDIVIDUAL ANALYSIS OF CENTRAL AND PERIPHERAL FATIGUE INTERACTIONS ACROSS DIFFERENT MUSCLE GROUPS

CHARTOGNE, M., RAHMANI, A., NICOLON, L., MOREL, B.

LE MANS UNIVERSITY

INTRODUCTION: Most studies focusing on neuromuscular fatigue distinguish central fatigue, a decrease in neural activation of the muscles due to numerous spinal and supraspinal factors, from peripheral fatigue, an attenuated contractile response to neural input induced by biochemical changes at the myocyte level. However, fatigue origins and amplitudes are not only task-dependant but vary also among individuals. Therefore, the aims of this study were to identify whether there is large differences between individuals and if they are consistent among different muscle groups.
METHODS: Thirty-four physically active volunteers (18 females: 21.6 ± 2.1 years; 56.3 ± 5.8 kg; 1.66 ± 0.07 m and 16 males: 25.6 ± 6.4 years; 74.0 ± 8.4 kg; 1.79 ± 0.06 m; mean ± SD) completed two randomized fatiguing tests of the ankle plantar flexor and the finger flexor muscles. The tests consisted of 60 4-s maximal isometric voluntary contractions interspersed by 1-s of rest. Non-linear regression techniques were used to fit the force-time curve with a mono-exponential function. The asymptote (i.e., critical force) was expressed in percentage of the pre-fatigue maximal force and considered for further analysis. Neuromuscular function was assessed before, during (every six contractions), and at the end of the fatiguing tests using the twitch interpolated technique. The relative pre-post differences of voluntary activation and evoked force were considered.
RESULTS: For both muscle groups, large individual differences [mean ± SD (maximum/minimum) for ankle plantar and finger flexors, respectively] were observed for the critical force [43.1 ± 13.5% (73.1/16.9%) and 43.2 ± 10.5% (68.9/22.9%)], the voluntary activation decrease [14.3 ± 10.8% (31.6/-8.1%) and 14.0 ± 9.2% (35.9/0.0%)] and the evoked force decrease [32.5 ± 18.5% (68.8/-3.6%) and 52.0 ± 20.0% (87.2-3.5%)]. Strong positive correlation ($r = 0.65$) was found between the critical force of the plantar and the finger flexors. Negatives correlations were found between the relative pre-post voluntary activation and evoked force for both plantar ($r = -0.82$) and finger ($r = -0.57$) flexors. Positive correlations were found between plantar and finger flexors for both relative pre-post differences of voluntary activation ($r = 0.50$) and evoked force($r = 0.63$). All correlations presented above were statistically significant ($p < 0.05$).
CONCLUSION: Amplitude and etiology of neuromuscular fatigue were i) similar between different muscles ii) highly variable among individuals despite a homogeneous population. As the evoked force decrease was negatively correlated to the voluntary activation decrease, we can assume that the peripheral perturbations are centrally regulated. Thus, to individually identify the etiology of neuromuscular fatigue would be particularly relevant for training optimization in sport or physical activity-based care in clinical population.

CRITICAL PERIPHERAL FATIGUE THRESHOLDS AMONG DIFFERENT FORCE-VELOCITY CONDITIONS: AN INDIVIDUAL-BASED APPROACH TO BETTER UNDERSTAND THE FATIGUE ETIOLOGY

MOREL, B., LAPOLE, T., HAUTIER, C.

LE MANS UNIVERSITÉ

INTRODUCTION: During high intensity exercise, metabosensitive muscle afferents are thought to inhibit the motor drive command to restrict the level of peripheral fatigue to an individual's critical threshold (1). However, no evidence exists of an individual relationship between peripheral fatigue and the decrease in voluntary activation reached after prolonged all-out exercise. Moreover, there is no explanation for the previously reported large decrease in voluntary activation despite low metabolic stress during high force contractions (2).

METHODS: Thirteen active men randomly completed two maximal intensity isokinetic knee extension tests (160 contractions) under conditions of low force - high velocity (30°.s-1) and high force – low velocity (90°.s-1). The range of motion was adapted to each contraction velocity to standardize the contraction time (1 s, passive flexion 2 s) and provide a similar 'central point' of 120° (180° is full extension) for the resting length of the quadriceps muscle (i.e. 30°.s-1: 105°-135°; 90°.s-1: 75°-165°). Neuromuscular testing including maximal torque, evoked torque and voluntary activation, was done every 20 contractions. The exponential modeling of these variables over time allowed us to predict the stable state (asymptote) and the rate of decrease (curvature constant).

RESULTS: For both high and low force contractions the evoked torque and voluntary activation asymptotes were negatively correlated (r^2=0.50). The evoked torque asymptotes of the high and low force conditions were positively correlated (r^2=0.49). The evoked torque and voluntary activation curvature constant were negatively correlated for the high force contractions (r^2=0.64) but positively correlated for the low force condition (r^2 = 0.29).

CONCLUSION: The individual thresholds for the decreases in voluntary activation and evoked torque modeled in each condition are negatively correlated which support the idea that metabo-activation of group III/IV muscle afferents are keeping "peripheral fatigue" under this critical threshold by restraining central motor drive. Furthermore, although the average thresholds for "peripheral fatigue" differed between low versus high force contractions, the present results show that an individual would show similar sensitivity to intramuscular metabolic perturbations regardless of the force generated. Finally, the negative correlation between the rate of the decrease in voluntary activation and evoked torque during the high force contractions suggests that, in this condition, central inhibition was not triggered by peripheral perturbations at the very beginning of the exercise.

CHANGES IN MUSCLE MEMBRANE EXCITABILITY DURING FATIGUING CONTRACTIONS: GROWING EVIDENCE OF THE NEED OF A SEPARATE ANALYSIS OF THE FIRST AND SECOND M-WAVE PHASES

RODRIGUEZ-FALCES, J., PLACE, N.

PUBLIC UNIVERSITY OF NAVARRA

INTRODUCTION: There is growing evidence, gained from various exercise protocols and muscles groups, that the first and second phases of the muscle compound action potential (M wave) changed in a completely different manner during and after prolonged intense exercise. The present study aims at summarizing these findings by examining the changes in muscle membrane excitability during and after intermittent and sustained maximal voluntary contractions (MVCs), by assessing separately the changes in the first and second M-wave phases

METHODS: M waves were evoked by supramaximal single electrical stimulation to the femoral nerve delivered (1) between 48 successive MVCs of 3s (intermittent protocol); (2) superimposed at 10-s intervals on an ongoing MVC sustained for 3 min (sustained protocol); (3) at various time points (1s, 5s, 10s, 15s, 30s, 1 min, 2 min, 5 min, 10 min, and 30 min) after a sustained 3-min MVC (after-a-contraction protocol). The amplitude, duration, and area of the M-wave first and second phases were measured separately, together with muscle conduction velocity, force, and temperature. M waves were recorded from the quadriceps and biceps brachii

RESULTS: During the intermittent MVCs, the amplitude of the first phase increased uninterruptedly for the first three minutes (12-16%, $P<0.05$) and stabilized at a plateau for the last minute. Conversely, the second phase initially increased for 55-75s (11-22%, $P<0.05$), but then decreased for the rest of the protocol. The enlargement of the first phase occurred in parallel with a decline in conduction velocity, and an increase in M-wave duration

During the sustained 3-min MVC, the amplitude of the first phase increased progressively for the first minute (+33-43%, $P<0.05$) and then it remained stable for the rest of the contraction, whereas the second phase initially increased for 25-35s, when it reached a peak (+30-50%, $P<0.05$), after which it decreased for the subsequent minute, before stabilizing.

The amplitude of the first phase was increased immediately after (1s) the sustained 3-min MVC and this enlargement remained for 2 min in the recovery (+8-12%, $P<0.05$), whereas the second phase was increased 1s after exercise (+13-18%, $P<0.05$), but decreased rapidly afterwards, returning to control levels within 30s. After the 30-min recovery time, both parameters were significantly lower than control values ($P<0.05$)

CONCLUSION: It is concluded that the enlargement of the first phase is the electrical manifestation of impaired muscle membrane excitability, possibly due to the increase in extracellular K+ concentration. The results confirm that only the amplitude of the first phase, but not that of the second phase or the peak-to-peak amplitude, can be used reliably to detect changes in membrane excitability, as the second phase might be critically affected by changes in muscle architecture

EFFECT OF MUSCLE-TENDON UNIT LENGTH ON DIFFERENCE IN NEUROMUSCULAR FATIGUE BETWEEN BOYS AND MEN

PIPONNIER, E., RATEL, S., CHALCHAT, E., BONTEMPS, B., JULIAN, V., BOCOCK, O., DUCLOS, M., MARTIN, V.

UNIVERSITY OF CLERMONT-AUVERGNE

INTRODUCTION: The torque level has been proposed as a potential contributor to the difference of fatigability between children and adults. The aim of the present study was to compare the development and etiology of neuromuscular fatigue between muscle-tendon unit (MTU) lengths among two muscles [i.e. knee extensor (KE) and plantar flexor (PF) muscles] in order to vary difference in torque level between boys and men. We hypothesized that (i) when difference in torque level is reduced, i.e. at short MTU length (S), boys and men could display a similar development and etiology of neuromuscular fatigue and (ii) in contrast when difference in torque level is greater,

i.e. at optimal MTU length (O), boys would display a greater fatigue resistance than men owing to a lower peripheral fatigue and greater central fatigue.
METHODS: Twenty-two children (9-11 years) and 23 adults (18-30 years) were involved in this study. They performed a fatigue protocol with the KE and the PF at different MTU lengths (S and O), consisting in repeating voluntary maximal contractions until reaching 60% of the initial torque. Magnetic nerve stimulations were delivered to quantify the maximal voluntary activation (VA) with the twitch interpolation technique. Potentiated twitch amplitude (twpot) was used as a general indicator of peripheral fatigue.
RESULTS: The difference in torque level between boys and men was twice lower at S (KE: 123 N.m and PF: 54 N.m) than O MTU length (KE: 223 N.m and PF: 112 N.m).
With the KE muscles, boys and men performed the same number of repetitions at S MTU length (33.7±15.4 vs. 40.9±14.2 repetitions, respectively), while boys performed more contractions than men at O MTU length (39.7±18.4 vs. 14.8±3.2 repetitions, P<0.001, respectively). Twpot decreased to a greater extent in men than in boys at both MTU lengths (S: -9.3±15.4% vs. -3.0±18.4%; O: -50.7±14.6% vs. -15.9±18.7%, respectively). However, in both groups, twpot decreased less at S than O MTU length (P<0.001). Boys and men displayed the same VA decrement at S MTU length (-17.4±11.4% vs. -14.7±10.9%, respectively), while boys showed a higher decrement than men at O MTU length (-36.4±20.3% vs. -5.9±6.1%, P<0.001, respectively).
In contrast, with the PF muscles, no age group x MTU length effect was found on total number of repetitions, twpot and VA. Boys and men performed the same number of repetitions, whatever the MTU length (14.5±5.2 vs. 15.4±5.0 repetitions, respectively). At all MTU lengths, boys displayed a lower twpot decrement than men (-9.9±16.4% vs. -20.0±18.8%, P<0.05, respectively) and greater VA decrease (-24.6±16.6% vs. -13.9±11.6%, P<0.001, respectively).
CONCLUSION: KE MTU length has an effect on difference in the development and etiology of the neuromuscular fatigue between boys but this effect is not observed in the PF muscles. Therefore, the torque level does not seem to be the main contributor to neuromuscular fatigue difference between children and adults.

THE NEUROMUSCULAR FATIGUE INDUCED BY A SIMULATED MIXED MARTIAL ART FIGHT

GIBOIN, L.S., GRUBER, M.
UNIVERSITÄT KONSTANZ

INTRODUCTION: Mixed martial art (MMA) is a recent fight sport with a fast growing popularity and professionalism. However, the physiological demands of this hybrid sport remain largely unknown. This lack of knowledge can act as a brake in regard to the professionalization of the sport and the development of elite performance. Here, we attempted to quantify the neuromuscular fatigue induced by MMA fight simulation.
METHODS: We measured maximal isometric voluntary force (MVF), potentiated twitches at rest (Ptw) and voluntary activation (VA) with the interpolated twitch method in the knee extensor muscles of MMA competitors (n=9) before, during (in between rounds) and up to 15 min after a fight simulation.
RESULTS: Linear mixed models indicated a significant reduction of MVF, Ptw and VA (all < 0.001). An effect of VA (p = 0.004), but not of Ptw (p = 0.56) was found on MVF, even though the largest reduction across time of VA (90 ± 7 % of baseline, 5 min after the end of the simulation) was smaller than the largest reduction of Ptw (69 ± 26 % of baseline, at the end of the simulation).
CONCLUSION: The fight simulation induced neuromuscular fatigue in knee extensor muscles. Despite the fact that the peripheral component of muscle fatigue was larger than the central one, MVF was more sensitive to central than peripheral fatigue. We speculate that central components of physiological and psychological origin compensate for the peripheral fatigue and regulate performance during and after the fight simulation.

Oral presentations

IS-SP01 From ankle sprain to chronic ankle instability ...And how to avoid it - Sponsored by Adidas [Clinical track]

A "FATAL CAREER": DEVELOPMENT OF CHRONIC ANKLE INSTABILITY IN SPORTS – THE BIOMECHANICAL PERSPECTIVE

GEHRING, D.
UNIVERSITY OF FREIBURG

After a lateral ankle sprain it is very likely that chronic ankle instability (CAI) can develop. It is thought that CAI comprise both, an impaired structural protection that is often referred to as mechanical ankle instability, as well as an impaired function of the neuromuscular system to control the ankle during daily and sportive activities. With regard to the complexity of this phenomenon a set of criteria has to be defined in order to specify the definition of CAI.
After presenting the epidemiological relevance of the problem and the framework definitions, this talk will give an overview about the current state of research with regard to biomechanical and functional changes that are associated with CAI. Ankle and whole body mechanics as well as neuromuscular and functional impairments will be reviewed. Results from meta-analysis will be presented indicating that systematic impairments in CAI-patients could only be uncovered for some dimensions like for instance postural control. While those results give us sound information for therapy, there still seems to exist a gap in evidence-based knowledge why people with CAI have a disability in stabilizing their ankle joint during highly dynamic, injury-related movement. Consequently, new ways in trying to elucidate the phenomenon of CAI are needed and will be discussed at the end of the talk.

PREVENTION OF PRIMARY AND SECONDARY ANKLE SPRAINS – THE PHYSIOTHERAPEUTIC PERSPECTIVE

DELAHUNT, E.
UNIVERSITY COLLEGE DUBLIN

Lateral ankle sprains are the most frequently incurred lower limb musculoskeletal injury incurred by individuals who participate in sports and recreational physical activities. Following lateral ankle sprain injury there is a high propensity for the development of recurrent ankle injuries. Hence, the prevention of index (first-time) and recurrent lateral ankle sprain injuries is of primary concern to sports medicine clinicians. This presentation will detail the most up-to-date evidence on the efficacy and effectiveness of lateral ankle sprain prevention

protocols. The presentation will focus specifically on the primary prevention of lateral ankle sprain, as well as the prevention of recurrent ankle sprains following index lateral ankle sprain. The strength of the available peer-reviewed literature on these topics will be evaluated, presented and discussed. The presenter will provide attendees with a clinically applicable, evidence-informed and theoretically underpinned overview of contemporaneous strategies for the prevention of index and recurrent lateral ankle sprains.

CLINICAL ASPECTS OF ACUTE AND RECURRENT ANKLE SPRAINS – THE ORTHOPAEDIC PERSPECTIVE

LOHRER, H.

EUROPEAN SPORTSCARE NETWORK, WIESBADEN-NORDENSTADT, GERMANY

Keywords: Ankle, Instability, Sprain, Chronic ankle instability

Lateral ankle ligament injuries are very frequent in all kinds of sports. Initial lateral ankle ligament injuries result from forced inversion and, if not adequately treated, bear a substantial risk of remaining sequelae. This entity is called chronic ankle instability. Mechanic instability, functional or perceived instability, and recurrent sprain are thought to be constitutional components for chronic ankle instability.
Under clinical aspects, it is very important to differentiate mechanically stable from unstable ankles. Manual stress testing, radiographic stress testing and ankle arthrometry can measure mechanical instability while the functional component can be evaluated by different questionnaires. There is a complex interaction between mechanic and functional components in chronic ankle instability.
Analogue to the treatment of initial ankle ligament lesions, conservative therapy is also initially indicated for chronic ankle instability. Passive (external orthotic ankle devices) and active (sensorimotor training) is the initial treatment of choice. If symptoms persist, operative treatment to stabilize the lateral ankle is recommended for cases with a proven mechanical instability. Comparison of the different operative techniques demonstrated clear advantages of the anatomic reconstruction procedures.
An algorithm for allocation acute and chronic ankle injuries to a specific treatment is necessary to avoid chronic ankle instability.

OP-BN13 Sport technology I

HEAD IMPACT TELEMETRY IN NON-HELMETED COLLISION SPORTS: TOWARDS SETTING MINIMUM REPORTING STANDARDS

WILLIAMS, E.M.P., GREYBE, D., JONES, C.M., BROWN, M.R.

SWANSEA UNIVERSITY

INTRODUCTION: The issue of neurocognitive deterioration following repetitive head impacts in contact and collision sports has been widely addressed in scientific literature. Many studies have been dedicated to deriving appropriate methods and metrics to quantify and characterize head impact exposure in collision sports. The majority of these are focused on helmeted sports, using helmet-mounted or externally-worn head impact sensors which do not comply with World Rugby clothing regulations. Additionally, externally-worn sensors which are not rigidly coupled to the skull have also been reported to give a significant overestimation of recorded impact acceleration values.
METHODS: There is no accepted means to reliably monitor head impact exposure in rugby union or alert medical staff in real-time to potentially noteworthy collisions which may be unobservable visually. To address this challenge, a novel, real-time head impact telemetry system has been developed with the objectives of reliably measuring head impact exposure in rugby union. This World Rugby-approved system is in the form of a bespoke, instrumented mouthguard measuring linear and rotational acceleration of the head. The system wirelessly transmits this data in real-time to a pitch-side tablet where medical staff have the new opportunity to utilize this information to inform and immediately adapt wellbeing strategies. System validation trials of the system were performed using a crash test dummy (CTD), where linear and rotational acceleration values were found to be within the calibration limits of the CTD. 3D human motion capture systems and field-testing with video were also performed over a 24-month period. Training (12 months) and competition (4 months) head impact data were then collected from professional rugby union players. Recorded head impact magnitude values were compared to previous rugby head impact studies
RESULTS: Video-verified impacts were included in this analysis. The peak linear acceleration (PLA) value recorded in professional rugby union competition over eight recorded matches was 44g and the corresponding peak rotational acceleration (PRA) recorded was 8800 rad/s/s from a player making a tackle. These values for professional rugby union were orders of magnitude lower than those reported in previous studies for junior under 11 rugby league (PLA: 123g, PRA: 22,928 rads/s/s), sub-elite Australian Rules football (PLA: 153g, PRA: 21,890 rads/s/s) and women's rugby league (PLA: 91g, PRA: 13,646 rads/s/s . These previous studies were all conducted using head-mounted sensors.
CONCLUSION: Without secure sensor-skull coupling, head impact telemetry systems record unrealistically high impact values. Publication of such studies can have significant implications for the sport, including insurers opting not to cover any neurological injury. It is proposed that a sport-agnostic and sensor-agnostic international scientific advisory group is set up with the objective of setting minimum recording and reporting standards.

IMPROVED NONLINEAR SPORTS PERFORMANCE DUE TO ALTERNATIVE SHOE CLOSURE BASED ON ADJUSTABLE TENSION LACING

PRYHODA, M., WATHEN, R., SHELBURNE, K., DAVIDSON, B.

UNIVERSITY OF DENVER

INTRODUCTION: The neuromuscular interaction paradigm of shoe design considers the shoe—both the upper and lower—as a key mechanism to augment the environment in which a foot operates (1), and consequentially, whole-body athletic performance. The objective of this study was to investigate how three alternative shoe closures affected biomechanical performance compared to standard lacing in high-level athletes during high-speed direction changes in vertical and lateral movements.
METHODS: Ten male athletes performed two repetitions of six countermovement jump repeats (CMJ) and six lateral skater jump repeats (LSJ) while wearing an Adidas adizero ubersonic 3.0 shoe with standard lace closure (S) and three adjustable tension closures from Boa

Technology: medial shoe closure (M), lateral shoe closure (L), and a tri-strap shoe closure (T). Full-body segment motions and ground reaction forces were collected during the CMJ and LSJ. CMJs were performed at a maximum jump height with ground reaction force (GRF) recorded from each foot during the landings. LSJs were performed at a width equal to shoulder height, and GRF recorded from the dominant foot landings. Biomechanical performance measures included ground contact time, eccentric rate of force development (RFD), peak GRF, peak propulsive mass power, eccentric work, and propulsive work. The effect of M, L, and T closures relative to S within each athlete was evaluated using a cumulative ordinal scoring from -12 to 12 based on comparison of the mean and 95% confidence intervals (CIs) within each of the six biomechanical performance measures. A score of 0 was when the mean of the closure was within the CI of the S closure, a score of +1 or -1 when the mean of the closure was above or below the CI of S, and a score of +2 or -2 when the CI of the closure did not overlap with the CI of S. Percentage of athletes (SD) that improved (Score>0) per closure and median [IQ range] score for each performance variable were calculated.
RESULTS: All adjustable tension closures demonstrated improvements over standard closure S. Closure L increased performance in 80(13)% and 70(14)% of athletes during CMJ and LSJ, respectively. Closure T improved performance in 60(15)% of athletes for both CMJ and LSJ. Closure M improved performance in 60(15)% and 50(16)% of athletes in CMJ and LSJ, respectively. For closure L, performance variables with the greatest changes were ground contact time (1 [0 2] for CMJ and 1.5 [-0.25 2] for LSJ), eccentric work (1.5 [0.25 2] for CMJ and 2 [0 2] for LSJ), and propulsive work (1 [0 2] for LSJ).
CONCLUSION: The performance improvements demonstrated by each adjustable tension closure across both movements lend support for the neuromuscular interaction paradigm of shoe design. The lateral closure provided performance benefits in more athletes compared to the other closures, and affected performance variables that spanned across power transfer, agility, and endurance.

PACING RELIABILITY AND ACCURACY USING PACING AIDS COMPARED TO SELF-PACED SWIMMING

MCGIBBON, K.E., PYNE, D.B., SHEPHARD, M.E., OSBORNE, M.A., THOMPSON, K.G.
UNIVERSITY OF CANBERRA

INTRODUCTION: Pacing is considered crucial to success in swimming, however little is known about the methods and tools utilised by coaches to entrain pacing strategies. With recent technology advancements in swimming there are a wide a range of new training tools and devices available to coaches, including various pacing aids. The primary aim of this study was to evaluate the reliability and accuracy of pacing with two pacing aids: Tempo Trainer ProTM, a device placed underneath a swimming cap which transmits audible beeps, and LumaLanesTM LED swim training system, a strip of underwater lights on the bottom of the pool, compared to self-paced swimming.
METHODS: Highly trained national level swimmers (n=16, 7 males, 9 females, 17 ± 3 y) completed two swimming testing sessions separated by 24-48 h. In the first session, swimmers completed 18 x 200-m freestyle efforts alternating randomly between two sub-maximal paces relative to each swimmers' 200-m freestyle personal best (PB) time (PB+20 s, PB+30 s). The second session included 6 x 100-m efforts at 200-m race pace plus 3 s in each swimmer's main stroke. To assess reliability swimmers completed two (race pace) or three (sub-maximal) trials in each experimental condition: underwater lights (UL), tempo trainer (TT) and self-paced (SP). Swimmers were instructed to evenly pace each effort and both pacing aids were programmed for even 50-m splits.
RESULTS: Reliability was high across all conditions and sub-maximal paces for 50-m splits and overall 200-m times (intraclass correlation (ICC) >0.8, coefficient of variation (CV) ≤2.2%, typical error (TE) ≤2.2 s). ICC's were highest with UL (range 0.91-0.99) and TT at PB+30 s (0.92-0.99), and lowest with SP at PB+30 s (0.81-0.89). In race pace trials reliability was high across all conditions (ICC ≥0.99, CV ≤1.4%, TE ≤0.6 s). Participants swam faster than target 200-m time in SP trials at PB+30 s (-2.9 s, -2.1 to -3.7 s; mean, 90% confidence interval, p=0.00), and too slow in TT trials at PB+20 s (1.0 s, 0.3 to 1.5 s, p=0.01). In race pace trials participants swam slower than 100-m target time in TT trials (0.4 s, 0.1 to 0.7 s p=0.02). Across all trials pacing was closest to even with UL, however with TT and SP swimmers typically swam too fast in the first lap and too slow in the second and third laps.
CONCLUSION: The LumaLanesTM swim training system and Tempo Trainer ProTM are reliable pacing aids. During slower sub-maximal swimming these pacing aids may be more reliable than self-paced swimming, however the Tempo Trainer has limitations at higher speeds. Although pacing accuracy relative to overall target times was high in some Tempo Trainer and self-paced trials, each lap was not evenly paced. The continuous visual feedback provided by underwater lights aided even pacing. Pacing aids need to be reliable, robust and easy to use, for routine use in swimming programs.

ESTIMATION OF GROUND REACTION FORCE UTILIZING AN IMU PLACED ON DIFFERENT LOCATIONS OF THE BODY DURING VERTICAL JUMPING

MCBRIDE, J.M., PEREZ, P.S., GURCHIEK, R.D.
APPALACHIAN STATE UNIVERSITY

INTRODUCTION: Athletes need to accelerate in activities such as jumping or running to optimize performance which is the result of ground reaction force (GRF). Measurement of GRF from a force plate has obvious limitations for use during actual playing conditions. Single inertial measurement units (IMU) are currently being utilized to estimate GRF in human movement tasks in a variety of settings. However, limited data is available concerning the effect of IMU location on estimation of GRF during vertical jumping.
METHODS: Eight male subjects stood on a force plate (FP) while performing a series of 10 countermovement jumps. An IMU was placed on the sacrum, back and chest of each subject as well. Custom scripts written in MATLAB (MathWorks, Natick, MA) were used to perform data analysis. IMU data was time-synchronized via cross-correlation with FP data and low-pass filtered at 15 Hz to remove any bias. A combined sensor approach using a two-segment model was also analyzed using the average of the back and chest acceleration modeled the upper body acceleration and the sacral sensor modeled the lower body. Statistical significance for all statistical tests was set a priori at a level of ≤ 0.05.
RESULTS: The range of the peak GRF from each sensor was between 1,792 ± 278 N to 2,054 ± 346 N, and was compared to the FP measurement of 1,727 ± 291 N. The range of the bias between the sensors and FP was 57 N and 162 N and the relative error was the lowest for the sacrum location (3.9%) and highest for the chest location (15.9%). All IMU estimates of peak force from the sacrum, upper back, chest, and combined showed significant relationships (p ≤ 0.003, r = 0.89 to 0.99). The RMSE for peak force was between 88 N and 360 N, which indicates that the sacrum achieved the smallest differences for GRF estimates, while the chest IMU was the least accurate in estimating GRF. Bland-Altman analysis showed where all measurement differences were normally distributed and showed no linear trend with the measurement means. IMU estimates of average force ranged from 1,015 ± 158 N to 1,057 ± 165 N and relative error ranged from 1.2% (sacrum) to 5.8% (chest). The RMSE for average force was the highest in the chest IMU (67 N) and the lowest in the

sacrum IMU (14 N). Each IMU location as well as the combined IMUs demonstrated significant relationships ($p \leq 0.001$, $r = 0.93$ to 1.00). The bias in the IMU estimate of average force was between 8 N and 30 N.
CONCLUSION: Locations currently used for IMUs appear to be effective for estimating GRF during vertical jumping. The sacrum location or a combined sensor approach utilizing the chest, upper back and sacrum appear to be the most valid. Future research might aim to examine other locations such as the abdominal area as well. GRF estimates from IMUs during vertical jumping could potential aid professionals in athletics who seek to optimize performance.

DOES ACCELEROMETER MEASURE MUSCLE VIBRATIONS?

TRAMA, R., HAUTIER, C., FOURÉ, A., BLACHE, Y.

UNIVERSITÉ CLAUDE BERNARD LYON 1

INTRODUCTION: Soft tissue vibrations (i.e. accelerations) have been widely studied in order to understand the underlying mechanisms of muscular adaptations to vibrations, namely, the muscle tuning paradigm (1). However, quantification of such vibrations are made with accelerometers stuck on the skin. One may wonder whether such measurements truly reflect the behaviour of the muscle because of potential artefacts coming from the skin and subcutaneous fat (2).
Consequently, the purpose of this study was to assess to what extend skin accelerometers reflect real muscle vibrations measured through ultrafast echography.
METHODS: Muscle vibrations were quantified for 15 participants, after an induced shock on a relaxed and contracted (40% MVC) vastus lateralis muscle. Muscle vibrations were quantified with a bi-axial accelerometer (1000 Hz) stuck on the skin of the muscle belly and with ultrafast echography (1000 Hz), considered as the "silver standard reference". BRISKF algorithm was used to track the features in the echography video, and acceleration signals were analysed in the time-frequency domain with a wavelet transform (3). Linear mixed models were used to assess the effect of the method and the level of muscle activation on vibrations. Linear regressions were used to assess the relationship between the subcutaneous fat thickness and the differences between the two methods.
RESULTS: For the antero-posterior axis, accelerometer overestimated the acceleration overall energy by 300%, but was reliable to estimate median frequency and damping properties. By contrast, for the medio-lateral axis, accelerometer was reliable to quantify the overall energy, but underestimated the vibration median frequency up to 10 Hz (25%) and the damping properties up to 12/s (30%). Muscular activation led to increase the overall vibration energy and median frequency for both axes and both methods of measurement. Similarly, muscle activation increased damping properties for the lateral axis for both methods of measurement. However, damping properties in the antero-posterior axis increased only when measured with the echography (15%). Finally, correlation between the differences of median frequency between the methods and subcutaneous fat depth was found for the antero-posterior axis ($p<0.001$ and $r^2=0.63$, and $p<0.01$ and $r^2= 0.45$, respectively for the relaxed and contracted conditions), leading to a decrease of 2.5% per centimetre of fat.
CONCLUSION: Some of muscle vibration parameters were not accurately estimated by the accelerometer, and subcutaneous fat thickness impaired the measure of the median frequency depending on the axis studied. Future works could focus on developing correction model to better estimate the muscle vibration, and functional movement vibration analysis could be a future step to better understand muscle vibration when running.

THE EFFECT OF TWO DIFFERENT FREQUENCIES AND TYPES OF CONCURRENT STRENGTH AND AEROBIC TRAINING PROGRAMS ON PHYSICAL PERFORMANCE IN OLDER ADULTS

ORESKÁ, L.1, VAJDA, M.1, BUZGÓ, G.1, CVECKA, J.1., TIRPÁKOVÁ, V.1, SLOBODOVÁ, L.2, UKROPEC, J.2, UKROPCOVÁ, B.1,2, SEDLIAK, M.1

1: FACULTY OF PHYSICAL EDUCATION AND SPORTS, COMENIUS UNIVERSITY; BRATISLAVA, SLOVAKIA 2: INSTITUTE OF EXPERIMENTAL ENDOCRINOLOGY, BMC, SAS, SLOVAKIA

INTRODUCTION: Higher physical inactivity is closely associated with advanced age and worse physical performance due to gradual muscle loss and strength that lead to declining of musculoskeletal system function, physical ability and general health (1). These changes negatively affect the quality of life in older adults (2). However, concurrent strength and aerobic training may positively influence physical performance thus indirectly improve general health (3). The aim of the study is to determine and compare the effect of two different frequencies and types of concurrent strength and aerobic training on physical performance in older adults.
METHODS: A total of 60 healthy and active older adults (14M/46F), who participated in the quasi-experimental study, were selected into the first concurrent strength and aerobic training group (1.TG: n=30, 7M/23F, 66.1±4.7 yrs, 80.4±17.8kg), who trained with frequency two training sessions per week (one strength training session; one aerobic-coordination training session) and second training group (2. TG: n=30, 6M/24F, 66.2±5.6 yrs, 76.7±18kg) who trained with frequency three training sessions per week (two combined strength-aerobic training sessions; one aerobic-coordination training session). Pre and post measurements of 10 meters maximal walking speed, chair stand test and maximal voluntary strength in an isometric extension of knee joint were performed.
RESULTS: Both programmes significantly decreased time (s) of maximal walking speed (n=59, pre: 4.9±0.7s, post: 4.7±0.8s, main effect: p=0.023), time (s) of chair stand test (n=59, pre: 9.9±1.7s, post: 8.9±2.0s, main effect: p<0.001) and increased maximal voluntary strength in isometric extension (n=55, pre: 234.0±65.0 N/m, post: 260.4±2.2 N/m, main effect: p<0.001). Both training groups significantly improved in isometric extension (1TG: n=30, pre: 253.6±71.4 N/m, post: 283.8±84 N/m, p=0.009; 2.TG: n=26, pre: 212.1±49.6 N/m, post: 235.2±45.5 N/m, p<0.001). Only 2.TG decreased their time in maximal walking speed (n=29, pre: 5.1±0.7s, post: 4.7±0.7s, p=0.008) and chair rise test (n=30, pre: 9.9±1.4 s, post: 8.8±1.3s, p=0.002).

CONCLUSION: Both types of concurrent strength and aerobic training improved strength ability of older adults. However, only concurrent strength and aerobic training, with frequency three times per week, was also able to improve functional mobility in older adults.
The study was funded by APPV-15-0086 (J.U., B.U.) and by grant of Comenius University.

THE ACUTE EFFECTS OF DIFFERENT MODES OF SPRINT INTERVAL TRAINING IN OLDER ADULTS

YASAR, Z., DEWHURST, S., HAYES, L.

UNIVERSTY OF CUMBRIA

INTRODUCTION: Currently, ageing is associated with a loss in physical function. Previous exercise research has targeted this, with the aim to reverse, decelerate, or, ameliorate this age associated physiological decline. Presently, there is limited research on the effects of sprint interval training (SIT) in older adults. The aim of this study was to compare the acute physiological and psychological responses to SIT.
METHODS: Eleven participants (8 males, 3 females; age 68 Â± 6 years; height 172 Â± 9; weight 70 Â± 14; body mass index 24 Â± 4; with a current physical activity of 350 Â± 141 minutes each week equal to or above a moderate intensity) completed the study. Following familirisation, participants were required to perform three SIT sessions (3 x 20 s all-out sprints, interspersed by 3-minutes self-paced recovery) with different modes of exercise (cycling, static sprinting, and stepping) in a crossover counterbalanced research design. Physiological (peak oxygen uptake, peak heart rate, peak blood lactate) and psychological (enjoyment, peak perceived exertion) measures were conducted to assess the acute effects of differential modes of SIT.
RESULTS: No significant differences were observed between exercise modes for peak oxygen uptake (VO2peak) (P=0.193, Î·p2=0.031). No significant differences were observed between exercise modes for peak heart rate (HRpeak) (P=0.698, Î·p2=0.077). Significant differences were observed between exercise modes for peak blood lactate (BLapeak) (P=<0.001, Î·p2=0.827). BLapeak was higher in cycling vs static sprinting (P=0.03), and cycling vs stepping (P=<0.001). Moreover, BLapeak was higher for static sprinting vs stepping (P=0.009). Significant differences were observed between exercise modes for peak perceived exertion (RPEpeak) (P=0.005, Î·p2=0.695). No differences were observed between cycling and static sprinting for RPEpeak (P=1.000). However, RPEpeak was higher in cycling vs stepping (P=0.043), and higher in static sprinting vs stepping (P=0.005). No significant differences were observed between exercise modes for enjoyment (P=0.214, Î·p2=0.029).
CONCLUSION: In summary, all three exercise modes were similar for physiological intensity, excluding the difference in BLapeak between all modes, indicating a difference in metabolic stress. Perceived exertion was higher for cycling and static sprinting than it was for stepping. All exercise modes were equally enjoyable, which suggests that differnces in perceieved exertion did not interfere with the enjoyment between cycling and static sprinting vs stepping.

INFLUENCE OF INERTIAL RESISTANCE LOW ROW EXERCISE ON PHYSICAL ABILITIES AMONG OLDER ADULT WOMEN

SPUDIC, D., CVITKOVIC, R., SAŠEK, M., VODICAR, J., PORI, P.

UNIVERSITY OF LJUBLJANA

INTRODUCTION: It has been shown that older adults are able to successfully gain muscle mass, maximum strength and power which also reflects on their physical abilities. Inertial devices, of which vital concept represents eccentric overload, give more robust results on muscle functions and could present an effective way of resistance exercise among older adults. On a personally constructed and validated inertial low row device we previously discovered linear relationship between the progressive load and angular momentum. Moreover, the eccentric overload has also been shown in submaximal type of repetition executions. While we have already explored the effects of the inertial resistance exercise effects on lower extremities among older adults, the purpose of the present study was to examine effects on strength variables and consequently physical abilities of upper extremities among older adult women.
METHODS: In the study, in which 60 healthy older adult women (years 66,1±5,0, BMI 27,6±5,6) voluntarely participated, we compared the effects of two progressive 8-week programmes of different types of resistance exercise on two groups of older adult women - one taking part in the traditional exercising using seated low row pulley device, and the other working with the self-constructed inertial low row device. Exercise intensity in the inertial group was relatively adjusted according to the initial self-developed measurements of the peak angular momentum and equalized time under tension while executing exercises. The strength variables were gathered first by using the self-developed inertial software, then one repetition maximum tests and finally some other field tests adjusted for older adults. We used a two-way ANOVA for repeated measures to assess exercise-related differences in results based on the tests performed by the groups.
RESULTS: There were no differences in the body composition, grip strength and shoulder mobility variables, while the other test results significantly improved over an 8-week resistance exercise protocol. There was a significant main effect of time (initial vs. final) found across variables angular frequency, concentric peak force, eccentric peak force, concentric peak power and eccentric peak power, biceps curl 1RM, pulley low row 1RM, plate tapping time, Sørensen test time and overhead sitting ball throw length. However, there was neither significant treatment group (inertia vs. pulley) main effect nor interaction of time and treatment group conditions found in the abovementioned variables.
CONCLUSION: In comparison to other studies the add-value of self-constructed device used in this research is the possibility of progressively adjusting the intensity of the exercise to an individual. Both exercise programs possitively effect task specific and also reflects on non-task-specific variables, such as throwing power and lower back extensors endurance. One could argue that the reasons for the above mentioned implications were the participants gender, sample bias, limited time of exercise intervention, explicit type of contractions and resistance exercise protocol used. The progressive resistance exercise using the self-constructed low row inertial device has resulted to be a useful and economical alternative to the traditional resistance exercise among older adults.

EFFECTS OF SEATED ISOKINETIC ECCENTRIC TRAINING AND DETRAINING ON MOBILITY, BALANCE, STRENGTH, MUSCLE SIZE AND ARCHITECTURE IN OLDER ADULTS

KAY, A.D.1, ASHMORE, L.1, HILL, M.W.2, MINA, M.3, BLAZEVICH, A.J.4

1: UON , 2: CU , 3: UOD 4: ECU

INTRODUCTION: Substantial increases in lower-limb strength, muscle mass and mobility occur in older adults following eccentric resistance training, however the impact on static balance (postural sway) is unknown with limited data describing detraining effects follow-

ing the cessation of training. As static balance may be influenced more by ankle than hip and knee musculature, the present study examined the impact of a 6-week isokinetic eccentric training programme targeting the hip, knee, and ankle extensor musculature and 8 weeks of detraining on neuromusculoskeletal characteristics in older adults.
METHODS: Maximal eccentric lower-limb force, vastus lateralis (VL) thickness, pennation angle and fascicle length, static balance (postural sway), and mobility (Timed-Up-and-Go [TUG]) were measured in 15 participants (age = 69.5 ± 5.9 y, mass = 75.5 ± 15.3 kg, height = 1.6 ± 0.1 m) before and after the 6-week training programme using dynamometry, sonography, and force platform analyses. All measures were then re-examined 8 weeks later to quantify detraining effects. Training was performed twice-weekly on a recumbent stepper (BTE Eccentron) using an alternating unilateral isokinetic eccentric leg press motion for 5 min (week 1) or 10 min (weeks 2-6) at 50% MVC and 40 contractions per minute. An additional 5 min of straight-legged unilateral eccentric dorsiflexions were performed on each limb to target the ankle plantarflexors. Strength was reassessed every 2 weeks to ensure subjects' training intensities remained at 50% MVC, with rate of perceived exertion (RPE) recorded after each training session.
RESULTS: Significant ($P < 0.05$) increases in lower-limb eccentric strength (39.4 ± 25.0%), VL muscle thickness (9.9 ± 6.8%), pennation angle (5.0 ± 5.0%), fascicle length (4.8 ± 4.4%), and decrease in TUG time (7.7 ± 6.4%) were detected immediately after the 6-week training programme; no change in any postural sway metric occurred. RPE remained low-to-moderate throughout the programme (3.6 – 4.5 out of 10). Eight weeks later, strength (30.5 ± 28.7%), muscle thickness (7.1 ± 6.5%), pennation angle (4.9 ± 6.8%), and mobility (8.2 ± 6.1%) remained significantly greater than pre-training levels.
CONCLUSION: Substantial improvements in strength, muscle size and mobility were achieved whilst training with low RPE, however no improvement in static balance occurred. Nonetheless, limited regression eight weeks after the completion of the training programme is indicative of a prolonged functional benefit. As older adults are more prone to periods of inactivity, these findings have important practical implications for exercise prescription where clinicians aim to develop and preserve functional performance.

EFFECT OF A 12-WEEK MICT, HIIT OR HIIT + RT PROGRAM ON BODY COMPOSITION IN POSTMENOPAUSAL OVERWEIGHT/OBESE WOMEN AND IMPLICATIONS FOR FAT OXIDATION RATE DURING MODERATE-INTENSITY EXERCISE

DUPUIT, M.
LABORATOIRE AME2P

INTRODUCTION: Estrogen deficiency after menopause promotes upper body obesity, including visceral fat mass (FM), which exposes post-menopausal women to a higher risk of cardiovascular disease (CVD). The aim of this study was to compare body composition changes induced by MICT, HIIT or HIIT + RT programs in postmenopausal overweight/obese women after a 12-week cycling program (3 days/w) and to determine if these modifications are related to a greater fat oxidation rate (FOR) during moderate-intensity exercise.
METHODS: Twenty seven participants were randomized to three groups as follows: MICT [40-min at 55-60% of HRmax], HIIT [60 x 8s at 75-85% of HRmax, 12s active recovery] and HIIT + RT (HIIT + 8 whole-body exercises for 1 set of 8-12 repetition maximum). Dual-energy x-ray absorptiometry (DXA) was used to measure whole-body and abdominal/visceral FM and fat-free mass (FFM). Nutritional intake and physical activity levels were recorded in 7-day self-reports. FOR was determined in fasting conditions before and after the training period at rest, during a moderate intensity exercise (40 min at 50% VO2max) and for 20 min of the recovery period.
RESULTS: Energy intakes and physical activity levels did not vary in any of the three groups during the protocol. Overall, body weight and total fat mass (FM) decreased over time. However, significant abdominal and visceral FM losses were only observed in the HIIT and HIIT + RT groups. When comparing changes induced by HIIT and HIIT + RT expressed in percentage, HIIT + RT was more effective in altering total FM, total FFM and muscle mass. Whatever the training modality, FOR did not change at rest but increased to the same extent in the three groups during the moderate-intensity exercise and the recovery period.
CONCLUSION: The different training modalities were beneficial in improving body composition in postmenopausal overweight/obese women but HIIT and HIIT + RT were more effective than MICT in decreasing abdominal and visceral fat mass. HIIT-induced greater fat mass losses were not related to higher FOR during or after submaximal exercise. Only HIIT + RT improved FFM, including muscle mass.
These results show that HIIT or HIIT + RT can be proposed as alternative training programs to protect against central obesity and could be used to counteract CVD risks in postmenopausal women.

THE EFFECT OF VITAMIN D SUPPLEMENTATION AND NORDIC WALKING TRAINING ON MUSCLE STRENGTH AND POSTURAL CONTROL IN ELDERLY POPULATION

MIESZKOWSKI, J., NIESPODZINSKI, B., KOCHANOWICZ, A., KORTAS, J., ZIEMANN, E., ANTOSIEWICZ, J.
GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT, GDANSK

INTRODUCTION: Nordic Walking (NW) and vitamin D concentration (Vit D) alone have been shown to contribute to the health and performance of elderly people. However, the interaction between these two factors has yet to be explored. The aim of this study was to evaluate the impact of the dose of vitamin D3 supplementation and a 12-week programme of Nordic Walking training on the muscle strength and postural control in elderly people, considering also the relation between the impact of the vitamin D3 dose and the type of training applied
METHODS: 42 women over 60 years of age (69.02 ± 5.56 years) were recruited and divided in two NW groups: a high-intensity interval training group (HI-NW) and a moderate-intensity continuous training group (MI-NW). Individuals from each group completed a 12-week NW training program (3 times a week/2 hours) combined with randomized vitamin D supplementation (HD=high dose: 4000 IU/day or LD=low dose: 800 IU/day). Body composition, postural control, muscle strength and vitamin D serum concentration were measured twice; before and after the intervention. To investigate the interaction between supplementation and training a mixed-design analysis of variance (ANOVA) was performed.
RESULTS: The HI-NW group, regardless of supplementation dose, increased their Vit D and elbow torque performance. On the other hand, in the MI-NW group the same Vit D outcome was seen only with HD supplementation and was also associated with increased leg muscle mass.
CONCLUSION: The impact of the dose supplementation on Vit D and body composition was related to the type of NW training.

NEURAL PROCESSES DETERMINING THE VISUOMOTOR REACTION SPEED OF ELITE YOUTH TABLE TENNIS ATHLETES

HÜLSDÜNKER, T., MIERAU, A.

LUNEX INTERNATIONAL UNIVERSITY OF HEALTH, EXERCISE AND SPORTS

INTRODUCTION: The visuomotor reaction time represents a crucial performance determinant in many ball and team sports requiring fast visuomotor reactions. Previous studies have shown the visuomotor reaction performance is strongly affected by the speed of neurophysiological and especially visual processes. However, while research in this field is currently limited to adult badminton athletes, this study aimed to validate previous findings in a group of highly trained youth table tennis players. The results will shed light on the generalizability of neural performance determinants for different disciplines and provide valuable information for visuomotor diagnostics and training in elite sports.
METHODS: 37 highly trained international youth table tennis players (mean age: 14 years) from 23 nations participated in this study. All players were nominated by the International Table Tennis Federation (ITTF) or the European Table Tennis Union (ETTU). On the behavioral level we measured the athletes' EMG onset and visuomotor reaction time (VMRT) in response to visual motion stimuli presented on a computer screen at two different motion velocities. In addition, a 64-channel EEG system was used to investigate the stimulus and response-locked event-related potentials (ERPs) in the brain's visual motion sensitive area MT as well as the pre- and supplementary motor cortex (BA6) reflecting the speed of neural visual and motor information processing, respectively.
RESULTS: The VMRT (232 vs. 258 ms, P<0.001) and EMG onset (181 vs. 206 ms, P<0.001) were significantly accelerated in the fast motion velocity condition which was accompanied by an earlier stimulus-locked N2 (187 vs. 193 ms, P<0.001) and later response-locked N2-r (17 vs. -0.1 ms, P<0.001) peak activation of area MT. Further, the N2 and N2-r ERPs in area MT were strongly correlated to EMG onset and VMRT in both velocity conditions and explained between 80-90% of the variance in visuomotor reaction speed using multiple regression analyses. In contrast, neural processes in BA6 did not differ between stimulus velocity conditions and did not contribute to the regression model.
CONCLUSION: The results indicate faster visuomotor reactions to be associated with a higher speed of visual motion perception and processing in the motion sensitive area MT while motor processes seemed to play, if at all, a minor role. These findings support our previous studies in badminton players and emphasize the performance-determining role of visual processes across different visuomotor demanding disciplines and age groups. In light of this generalizability, explicit visual training paradigms specifically addressing the brain's visual system may be promising to facilitate the visuomotor reaction speed in elite athletes from different sports.

INVESTIGATING THE ALTERED RESTING-STATE FUNCTIONAL CONNECTIVITY IN BASEBALL PLAYERS WITH DIFFERENT SKILL LEVELS

CHANG, C.Y.1,2, HUNG, T.M.1, YEN, N.S.2,3

1 NATIONAL TAIWAN NORMAL UNIVERSITY;2 NATIONAL CHENGCHI UNIVERSITY;3 NATIONAL CHENGCHI UNIVERSITY

Introduction
Long-term motor skill training has been reported to induce neuroplasticity both in brain structure and function. The majority of neuroimaging studies suggested that the primary resting-state networks, which were executive functions with motor control, including default mode network (DMN) and sensory motor network (SMN), altered with the different training experience. However, findings were not consistent, such that gymnasts, endurance runner, and badminton players showed different training alternation in resting-state functional connectivity (rsFC). Hence, the aim of this study was to investigate the effects of baseball training experience on DMN and SMN in the resting-state.
Methods
Twelve skilled baseball batters, fifteen intermediate baseball batters, and fifteen healthy adults without any baseball training experience participated in this study. The functional connectivity of brain regions with DMN and SMN in three separate groups was examined using one-sample t-test compared with zero. Furthermore, the correlations of each seed from three groups were compared by a one-way ANOVA. Additionally, we also performed the correlation analysis between rsFC and total training hours as well as training intensity. All brain images were acquired on a 3T MRI scanner and analyzed statistically with DPABI software running under MATLAB R2016b.
Results
The rsFC across three groups in SMN including the bilateral postcentral gyrus and supplementary motor area (SMA) revealed increasing activation as a function of baseball skill level. Skilled baseball batters were found to have stronger coupling between the bilateral postcentral gyrus, as well as the right postcentral gyrus and SMA. The coupling between the left postcentral gyrus and SMA demonstrated a greater connective strength in baseball batter groups than that of the control. Moreover, both total training hours and training intensity were found in positive relationship with functional connectivity between the right postcentral gyrus and SMA. On the other hand, we did not find any significant rsFC changes in DMN.
Conclusion
We provided evidences to support an association between baseball skill levels and functional connectivity of SMN. Moreover, the baseball training experience including total training hours and training intensity were positively related to rsFC changes in sensory motor network. These results are in opposite to that of gymnasts' study which found that training hours were negative correlated to the connective intensity of SMN (Wang et al., 2016). It is possible that different motor skill experience may contribute to neuroplasticity in functional connectivity in different ways.

SEEKING THE OPTIMAL TRAINING LOAD IN VARIABILITY FOR LEARNING A BALANCE TASK. A RANDOMIZED CONTROLLED TRIAL

BARBADO, D., CABALLERO, C., COVES, A., HERNANDEZ-DAVÓ, J.L., URBAN, T., ROLDAN, A., REINA, R., SABIDO, R., MORENO, F.J.

MIGUEL HERNÁNDEZ UNIVERSITY OF ELCHE

INTRODUCTION: Several researches manipulated training inducing motor variability (i.e. variable practice) to enhance motor exploration and consequently, foster learning. However, variable practice has not always delivered as positive results as it could be expected. This controversy could be due to the lack of adjusting the load of induced variability to individual features. We evaluated the effects of four practice conditions, inducing different magnitudes of motor variability, on the learning of a balance task in individuals classified according to their initial performance and their intrinsic variability.
METHODS: A total of 160 young individuals were distributed in four practice group: (CP: constant practice; LV: low induced-variability; MV: moderate induced-variability: HV: high induced-variability) for learning a balance tracking task on an unstable seat over a force platform. In the pretest, posttest and retest sessions (72 h) participants performed three 60 s trials of the task, adjusting their centre of pressure (COP) to a sinusoidal moving target (2º of the center of mass inclination amplitude; 0.05 Hz) displayed on a screen. Participants completed 3 training sessions one day apart consisted on six 60 s trials. CP group practiced the task unaltered. For LV, MV and HV groups, a white-based noise of 1º, 2º and 3º amplitude was respectively added to the target trajectory, increasing its displacement variability. Mean radial error (MRE) of COP was used to quantify balance performance. The structure of the intrinsic motor variability, was assessed using the scaling index α of the Detrended Fluctuation Analysis. Participants were sub-grouped according to their initial performance (good: low MRE; poor: high MRE) and intrinsic variability (high: low α; low: high α). Mixed ANOVAs were carried out to assess learning and differences according to sub-classifications.
RESULTS: Good performance participants from HV group showed higher learning rate than their counterpart from CP group. No between-group differences were observed in poor performance participants. Participants with low α scores belonging to CP group displayed higher learning rate than HV group ($p<0.05$). High α scores participants showed higher learning rate ($p<0.05$) when they practiced under high variability conditions (i.e. HV and MV groups).
CONCLUSION: Good performance individuals as well as those displaying a low motor exploration (i.e. low intrinsic variability), seem to take advantage of practicing under high variability conditions. Conversely, variable practice could hinder motor learning in those participants who display high intrinsic motor variability. Thus, constant practice seems to facilitate adaptive processes in those participants who are already exploring different motor configurations to accomplish a given task.

CHANGES IN MOTOR SYNERGIES DURING LEARNING A DISCRETE TASK

CABALLERO, C., BARBADO, D., COVES, A., HERNÁNDEZ-DAVÓ, J.L., MORENO, F.J.

MIGUEL HERNANDEZ UNIVERSITY

INTRODUCTION: Motor variability plays a functional role in human adaptive behaviors (Barbado, et al., 2017). For instance, intrinsic motor variability has been related to facilitation of motor learning (Wu et al., 2014). Yet, this relationship between motor variability and the ability to adapt is less clear in tasks in which a decrease of variability is an index of better performance (Terrien et al., 2016). When multiple configurations of the system are suitable for achieving the task goal, the role of variability could be related to the exploration of the motor synergies (Latash, 2008) and the exploitation of synergic configurations. The aim of this study was to assess motor synergies variability and their relationship with the learning of a discrete motor task.
METHODS: Thirty-five participants performed a pretest, a training period, two posttest (1' and 10' apart respectively) and two retests (24 h and 1 week apart), of 100 trials each, of computer simulation task of a ball throw using a joystick. The participants had to push the joystick to release a ball from the bottom of the screen to a target located at the upper-left corner. The training period consisted in 6 series of 100 trials each. In this task participants did not see the ball trajectory, but feedback about the success was given. The ball trajectory was computed through a dynamometer (FSSB R3) connected to the joystick, which measured anterior-posterior and medial lateral forces. Performance was measured by the hit ratio (HR), also the absolute error (AEx) was measured. The forces configurations variability that allowed to hit the target (GOODV) and the orthogonal variability of that synergies (BADV) (Latash, 2008) were calculated. Participants were classified as low variability group (LVG) and high variability group (LVG) according to their initial GOODV. A mixed ANOVA was used to test the training effect and the differences between groups.
RESULTS: LVG showed a significant improvement in HR in posttests and retests compared to the pretest. HVG showed no differences in HR. HVG reduced AEx from the pretest to the second posttest ($p = .017$) and first retest ($p = .032$), as well as its GOODV and BADV from the pretest to the rest of evaluations. LVG showed no differences in those variables.
CONCLUSION: A reduction of variability showed by HVG can be related to early stages of learning, in which learners reduce movement fluctuations to search the best configurations to accomplish the task. In later stages of learning, learners show lower variability around synergies (LVG), exploiting the solutions found to improve performance. Advanced stages of learning in which learners increase GOODV reducing BADV has not been found.

NOVEL TOOLS FOR THE RAPID ONLINE DATA ACQUISITION OF TMS CORTICOSPINAL EXCITABILITY

GREY, M.J., VAN DE RUIT, M.

UNIVERSITY OF EAST ANGLIA

INTRODUCTION: Neuroplasticity is believed to be critical for motor learning and neurorehabilitation. One way to assess neuroplasticity is to use transcranial magnetic stimulation (TMS) to measure corticospinal excitability. Whereas both stimulus response (SR) curves and corticospinal excitability maps provide more information than does a single set of MEPs at fixed intensity, their use is restricted by the time

it takes to acquire the data (typically 15+ min). This time is longer than a participant's ability to maintain attention and it is too time consuming for use in clinical and sport settings. As a result, these techniques have been restricted to the laboratory environment.
METHODS: We have developed MATLAB graphical user interfaces and CED Signal 7.0 scripts to implement the rapid acquisition of TMS stimulus response curves and maps. We have reduced the interstimulus interval (ISI) and provided visual feedback to optimise stimulation delivery.
RESULTS: Reliable data may be acquired with an ISI of 1.5-2 s and 80 stimuli. We have demonstrated that reducing the ISI does not cause any accumulating effects on CSE with such a limited number of stimuli. We have demonstrated that SR curve and map data may be acquired in less than two minutes with the Magstim Rapid stimulator (biphasic pulses) and less than 4 minutes with the Magstim 200 stimulator (monophasic pulses).
CONCLUSION: Importantly, the rapid acquisition of curve and map data allow the resulting curve/map to be visualised whilst the participant is in the room rather than off-line, thus ensuring data quality. These results demonstrate rapid acquisition of TMS measures is possible in the laboratory, but perhaps more importantly, provides a method for to evaluate neuroplasticity in the clinical and sport environments.

BRAIN REGIONS RELATED TO ANTICIPATION SKILL FOR FEINT MOVEMENT IN SPORTS SETTING: AN FMRI STUDY

KAWATA, Y.1,2, SHOJI, T.3, EIJI, K.4

1 JUNTENDO UNIVERSITY, 2 GRADUATE SCHOOL OF JUNTENDO UNIVERSITY, 3 SOPHIA UNIVERSITY, 4 JUNTENDO SHIZUOKA HOSPITAL

INTRODUCTION: Expert players can predict opponents' movement with deceptive actions. In fMRI studies, some cortical areas related to anticipation skill has been reported (Bishop et al., 2013; Wright et al., 2013). However, the neural mechanisms underlying anticipation skill in sports setting are still unclear. Thus, this study aimed to clarify neural mechanisms underlying anticipation skills in feint movement in sports setting.
METHODS: Participants were 10 high-skilled players (Mage = 21.2, SD = 0.58) and 10 low-skilled players (Mage = 21.0, SD = 0.70). We used functional magnetic resonance imaging scanner to measure blood flow while presenting task and control video clip. We used ABA block design and referred the video-based task (Bishop et al., 2013). In task, participants predicted an oncoming opponents' movement, while in control, they predicted the direction of a walking man. Response time and accuracy were recorded. Preprocessing and analysis of image data were performed using the Statistical parametric mapping.
RESULTS: In behavioral results, the high-skilled players showed significantly more rapid and accurate judging of the opponent action compared with low-skilled male players (ps < .001). Imaging results showed that soccer players recruited and left middle frontal gyrus and left occipital pole when anticipated situation (ps < .001).
CONCLUSION: Left middle frontal gyrus is related to judgement and left occipital pole is associated with visual perception These functions may contribute for great anticipation skill to feint movement. Prefrontal cortex and occipital cortex were associated anticipation skills in sports setting.

OP-SH12 Psychology: Motivation

THE TEMPORAL ORDERING OF MOTIVATION AND SELF-CONTROL: CROSS-LAGGED EFFECTS MODELS

JORDALEN, G., LEMYRE, P.N., DURAND-BUSH, N., IVARSSON, A.

NORWEGIAN SCHOOL OF SPORT SCIENCES; NORWEGIAN SCHOOL OF SPORT SCIENCES; UNIVERSITY OF OTTAWA; HALMSTAD UNIVERSITY

Introduction
Mechanisms leading to energy depletion and exhaustion in performance settings, such as high-level sports, highlight how individuals' self-control capacity may influence their motivation (Englert, 2017), ranging from intrinsic and autonomous to extrinsic and more controlled forms (Ryan & Deci, 2017). Investigating the temporal ordering of these concepts combining a self-determination theory framework (Ryan & Deci, 2017) and psychosocial theories of self-control (Friese, Loschelder, Gieseler, Frankenbach, & Inzlicht, 2018), the current study questioned the motivational processes associated with self-control depletion.
Methods
Young high-level winter sport athletes from Norwegian elite sport colleges (N = 321; female n = 98, male n = 173, and n = 50 did not report gender; 16–20 years) were recruited and consented to participate. Autoregressive and cross-lagged effects between six types of motivation regulations and self-control competencies were investigated in two- and three-wave analyses (5 and 10 week time-lag, respectively). We hypothesized that self-control capacity would be more influenced by athletes' motivation than vice versa, and that autonomous types of motivation would predict self-control capacity positively while controlled types of motivation would offer a negative prediction.
Results and Discussion
Using Bayesian structural equation modeling (Muthén & Asparouhov, 2012), analyses revealed credible self-control → motivation → self-control cross-lagged effects in the three-wave analyses, and motivation → self-control credible effects in the two-wave analyses. The hypothesized ordering between variables was partly confirmed, as findings were dependent on the time-lag between measurement time points. Thus, interaction effects between psychological constructs evolved in different patterns over time (Gelman, 2015), and athletes motivation might be driven by powerful volitional competencies rather than simple desires, needs, or drives. Further, the predicted motivation and self-control associations were confirmed, emphasizing that athletes self-control capacity benefits from autonomous types of motivation.

THE PHYS-CAN STUDY "FINDING MY OWN MOTIVATION" - A MIXED METHODS STUDY OF EXERCISE AND BEHAVIOUR CHANGE SUPPORT DURING ONCOLOGICAL TREATMENT.

MAZZONI, A.S.1, CARLSSON, M.1, BERNTSEN, S.1,2, NORDIN, K.1,2, DEMMELMAIER, I.1

UPPSALA UNIVERSITY

1: Uppsala University, 2: University of Agder

Background
Physical exercise has been reported safe and beneficial during oncological treatment (1). However, exercising during such treatment may be challenging and requires strategies to increase exercise motivation. Behaviour change support, including specific behaviour change techniques (BCTs), may be used to facilitate exercise in persons undergoing oncological treatment (2), but more detailed knowledge is needed to inform health care and improve clinical practice. The aims of this study were therefore to explore the motivational experiences of exercise combined with behaviour change support, and to describe how specific BCTs were valued among persons exercising during oncological treatment.
Methods
A mixed methods design was used. A study-specific questionnaire was answered by 229 participants with breast, colorectal or prostate cancer who completed or dropped out from a six-month exercise program during oncological treatment. Among these participants, 18 were selected, based on a maximum variation sampling strategy, and interviewed. The interviews were analysed with thematic analysis as described by Braun and Clarke (3) and the responses from the questionnaire with descriptive statistics.
Results
An overarching theme 'Finding my own motivation' with five themes 'Health gains and mastery', 'Learning', 'Affinity', 'Commitment' and 'Managing challenges' were identified from the interviews. The overarching theme can be understood as the result of an individual motivational process experienced through the exercise program. The themes can be seen as incentives involved in this process fostering autonomy, competence and relatedness. The questionnaire demonstrated that the most valued specific BCTs were social support from coaches, structuring the physical environment with scheduled training sessions, self-monitoring with resistance training log, and feedback based on heart rate monitor and fitness tests.
Conclusion
The results reflect the importance of finding incentives and creating an environment that fosters feelings of autonomy, competence and relatedness to facilitate and motivate persons to exercise during oncological treatment. Some specific BCTs appear to be particularly valuable and may be implemented and used by health professionals to increase patients' motivation to exercise during oncological treatment. Further research is needed to evaluate the effect of behaviour change support on exercise adherence during oncological treatment and how to individualize exercise in patients with low motivation and limited experience of exercise.

UNDERSTANDING SPORT COMMITMENT AMONG ADOLESCENT ATHLETES: THE ROLE OF A SELF-DETERMINATION PERSPECTIVE

BERKI, T., PIKÓ, B.

UNIVERSITY OF SZEGED

Introduction
Both Self-Determination theory and Sport Commitment model describe background of motivation. However, the link between the two constructs is not well established yet. Therefore, the goal of this study was to identify the associations between sport commitment and self-determination.
Method
Participants were 214 adolescent athletes (M=16.84 years; SD=1.38). The Sport Commitment Questionnaire-2 was used to measure sport commitment types and sources of commitment. It contains 48 items which could be answered by a five-point Likert-type scale. Sport motivation was measured with the revised Sport Motivation Scale (SMS). The questionnaire contains 19 items and 7 subscales. The answers varied on a seven-point Likert-type scale.
Results
Using stepwise regression Enthusiastic Commitment (R2=.62) was significantly predicted by Cognitive Intrinsic (beta=.20), Integrated Regulation (beta=.33), Amotivation (beta=-.19), Introjected Regulation (beta=.18) and Effective Intrinsic (beta=.14). Constrained Commitment (R2=.30) was determined by Amotivation (beta=.26), External Regulation (beta=.36) and Cognitive Intrinsic (beta=-.18). Sources of commitment predicted SMS as the following: Amotivation (R2=.32) was predicted by Sport Enjoyment (beta=-.44), Personal Investment-Loss (beta=.30), and Other Priorities (beta=.27). External Regulation (R2=.31) were predicted by Social Constrained (beta=.43), Sport Enjoyment (beta=-.23), Social Support-Informal (beta=.20). Desire to Excel-Mastery (beta=.40) and Personal Investment-Loss (beta=.26) determined Introjected Regulation (R2=.32). Identified Regulation (R2=.43) was explained by Desire to Excel-Mastery (beta=.42), Valuable Opportunities (beta=.19) and Personal Investment-Loss (beta=.14). Integrated Regulation (R2=.47) was explained by Desire to Excel-Mastery (beta=.39) and Valuable Opportunities (beta=.36). Cognitive Intrinsic (R2=.55) was significantly predicted by Desire to Excel-Mastery (be-

ta=.43), Personal Investment-Loss (beta=.18), Social Support-Informal (beta=.13), Other Priorities (beta=-.10) and Sport Enjoyment (beta=.10). Effective Intrinsic (R2=.41) was determined by Desire to Excel-Mastery (beta=.38) and Valuable Opportunities (beta=.32).
Discussion
Constraint Commitment is at one end of the self-determination continuum with Amotivation and External Regulation and Enthusiastic Commitment at the other end with intrinsic motivation, although this construct showed relations with external values as well. While obligatory reasons for commitment were linked to amotivation and extrinsic motivation, enjoyment and opportunities were associated with Intrinsic Motivation. Furthermore, there are sources in complex relationships with self-determination, e.g., Personal Investment-loss appeared in Amotivation, extrinsic and intrinsic motivations as well. Thus we believe that due to these complex associations of Sport Commitment it is hard to separate them on the Self-determination continuum.

DEFINING THE MOTIVATIONAL STRUCTURE OF HUNGARIAN MALE AND FEMALE ATHLETES IN TEAM SPORTS WITH THE NEW H-SMS QUESTIONNAIRE

PAIC, R., KAJOS, A., MESZLER, B., BENKE, S., PRISZTÓKA, G.Y.
UNIVERSITY OF PÉCS

INTRODUCTION: Motivation is essential element of learning and individual development, and also responsible for eliciting different behaviours, defining and maintaining their direction until achieving one's aim (Tóth, 2015). Sport motivation is the combination of personality and social factors, and cognitive processes, which become dominant when a person takes part in physical exercise, starts competing with others or aims for perfection (Roberts, 1992). Self-determination theory (SDT) represents a theoretical framework that can be applied to human sport motivation and places the individual's autonomy, competence and relatedness into the center of personal tenacity, creativity and improved efficacy (Deci & Ryan, 2000). For this reason, sport motivation is an essential component of one's sport performance. Revealing the athlete's motivational structure can give the coaches important information regarding the motives of their athletes.
METHODS: We used the validated Hungarian Sport Motivation Survey (H-SMS) (Paic et al, 2017) to collect data from athletes competing in the first divisions of the Hungarian National League in basketball and handball. A total of n=162 athlete filled the survey from which n=78 were male (handball) and n=84 female (basketball) players. We used independent sample t-test and correlation analysis to compare the motivational structure of the sample and to reveal the correlations of the factors.
RESULTS: Means of the sample for each factor were the following: Intrinsic regulation (INTRI) 5.01, SD=1.07 (Cognitive 5.32, SD=1.05, Effective 4.69, SD=1.23), Integrated regulation (INTEG) 4.81, SD=1.44, Identified regulation (IDEN) 4.96, SD=1.24, Introjected regulation (INTRO) 5.28, SD=1.32, External regulation (EXTE) 2.97, SD=1.33 and Amotivation (AMOT) 2.23, SD=1.36. We identified significant differences between women basketball and men handball players in the factors of Amotivation (p=.00), External regulation (p=.046,), and Identified regulation (p=.009). Results also show significant correlations between Intrinsic motivation with all factors except Amotivation and External regulation. Furthermore, significant correlation can be determined between Amotivation and External regulation.
CONCLUSION: We can notice the high value of the Introjected regulation factor which is consistent with the results of our previous studies (Paic et al, 2018), and also with other researches (Doganis, 2000; Nuñez et al, 2006; Bara et al, 2011; Burtscher et al, 2011) findings. High Introjected regulation means that the individual carries out sporting activities because of pride, self-esteem or to avoid anxiety and other negative feelings. The high Introjected regulation is typical for Hungarian athletes in general. In our case, the direct reason is no longer present, but this negative context is already integrated into the personality. It's important for a coach to try to change the athletes perception in order to affect their motivational structure.

EXPERIENCING REDUCED PERFORMANCE DUE TO INJURY AND THE IMPLICATIONS FOR BASIC PSYCHOLOGICAL NEED SATISFACTION FOR YOUTH ELITE NORWEGIAN HANDBALL PLAYERS

GJESDAL, S., BJØRNDAL, C.T., LUTEBERGET, L.S.
NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction
According to Self-determination theory (Deci & Ryan, 2000), all humans have three innate basic psychological needs, namely the need for autonomy, competence and relatedness. The satisfaction of the three has been associated with positive outcomes in sport (Adie, Duda, & Ntoumanis, 2012). However, most studies investigating basic psychological needs focus on the influence of the psychosocial environment. Thus, what remains to understand is how other aspects pertaining to the sport participation may influence need satisfaction. One such aspect is being injured, which has been shown to be a pressing concern for development and performance in youth and senior handball (Bjørndal, Andersen, & Ronglan, 2017).
Methods
This study examines the relationship between the degree to which injury hindered performance, and basic psychological need satisfaction in youth elite handball players from five different sport schools (N = 188). Injuries were reported using the OSTRC-Q (Clarsen, Rønsen, Myklebust, Flørenes, & Bahr, 2014). It is a quantitative study, with two time points (one week apart) resulting in a crossed-lagged structural equation model.
Results
Competence and relatedness were found invariant across the two time points, autonomy was not. The structural model showed good fit ($S\text{-}B\ \chi^2$) = [df = 124, N= 187] = 174.283, p< .0020; CFI = .96; RMSEA = .05 [.03-.06], and SRMR = .08). Competence (β= .56, 95% CIBC: .33, .79), relatedness (β= .78, 95% CIBC: .67, .90) and reduced performance (β= .56, 95% CIBC: .53, .83) showed moderate temporal stability. When accounting for previous levels, reduced performance due to injury negatively predicted competence (β= .56, 95% CIBC: .53, .83) and relatedness (β= -.16, 95% CIBC: .67, .90).
Discussion
Taken together, these findings suggest that experiencing reduced performance due to injury can have implications of the basic psychological need satisfaction in young handball players, showing that other factors than psychosocial ones may play a role therein.

HARMONIOUS PASSION AND SELF-ORIENTED PERFECTIONISM ARE RELATED TO WELL-BEING IN ELITE TRAMPOLINISTS

SCHIPHOF-GODART, L., KORTE, I.M., HASE, A., KRIJGER-HOMBERGEN, M.

THE HAGUE UNIVERSITY THE NETHERLANDS

Elite trampoline athletes invest considerable time and effort aiming for a flawless performance. While harmonious passion (HP) [1] and self-oriented perfectionism (SOP) [2] may be helpful in order to attain high performance levels, obsessive passion (OP) and socially prescribed perfectionism (SPP) reflect a strong internal pressure to practice and perform and thus may lead to decreased well-being, notably in the case of failure during competition [3,4]. The aim of this study was to assess whether differences in athletes' type of passion (HP and OP) and perfectionism (SOP and SPP) were related to their well-being and intention to quit (ITQ) after successful or unsuccessful performances.
Competitive performance in 51 male and female Dutch elite trampolinists (age 15,8 +/- 4,0) was assessed by calculating their performance consistency over four qualification competitions in six consecutive weeks (execution scores of qualification routines within 1 standard deviation of the individual's mean execution score). All athletes also completed Dutch translations of the Multidimensional Perfectionism Scale, Passion Scale, and the Life Satisfaction Scale [5] and athletes' ITQ was assessed. Partial correlations for HP and OP and SOP and SPP respectively were realized in order to correct for the strong correlations between both types of passion and perfectionism.
HP and SOP were correlated with LF when corrected (partial correlation) for OP and SPP (0,41 $p < 0,05$; 0,35; $p < 0,05$), but OP and SPP were not. OP was negatively correlated with ITQ ($r = - 0,46$; $p < 0,05$), but HP was not. No significant differences were found for successful versus unsuccessful athletes.
These results demonstrate that maladaptive forms of passion and perfectionism in elite athletes are related to decreased well-being, but also to athletes' intention to persist in their sport. Although no relationship between athletes' passion or perfectionism and performance was found, previous studies have shown a negative effect on coping with competitive stress and anxiety due to these maladaptive traits [1,4]. Athletes thus might benefit from concentrating on the positive forms of passion and perfectionism.

MATCH-FIXING AS THREAT TO SPORT

MRAVEC, L.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY

The basic characteristics of sport is the improbability and uncertainty of the result. That is the first and upmost characteristics, what attracts spectators by not knowing, who is going to win. There is a direct relation, where match-fixing influences sport as such. Match-fixing was here long time ago, but with modern technologies of betting industry, also loosing a game became a win from financial point of view and therefore match-fixing is a number one threat for modern sport. There are areas of sport that are more vulnerable to match-fixing, mostly those, on which you can bet offline or online, but no one is safe. There are statements by match-fixers, that organized crime switched from drug trafficking to match-fixing, because the risk of being prosecuted is very low due to lack of evidence and/or legal loopholes. The most vulnerable persons in match-fixing are mainly players and referees. It is obvious, that these participants are the most approached targets, because they have a direct influence on the outcome of a game/match. Some of main motivations to do so are financial gain, advantage for a team or money laundering. This paper will also discuss available legal tools in the fight against match-fixing. The methodological approach adopted in this paper is a brief examination of the use of the term match-fixing and reputable investigative reporters, who are following themes focusing mainly on this selected negative aspect that pose a threat to the essence sport. It is a better understanding, what is match-fixing, how it works and how come can be a threat to sport. Other methodological approach for investigating the research problem will be based on the study of literature, mainly legal acts/ conventions and professional texts. This paper will consist of clear and convincing interpretation and discussion of this negative aspect in sport and its proposed adjustment and regulation through legislation and presentation of examples of good practice in different sport areas. The basic motif in researching this threat to sport is to understand the extent to which sport enjoys such a large degree of autonomy, and now often creates space to circumvent the rules of society. Not only does it have its own relative autonomy, it is also regulated differently in each country, even within EU Member States. Match-fixing is a real threat to sport as we know, because it strikes at the essence and basic characteristics of sport. If no steps are taken to minimize it, it will be the beginning of the end of modern sport with its essential aspect – the uncertainty of outcome. Sport industry is raising volume of money and it is a trigger, which attracts organized crime. It is not the fault of sport that organized crime has chosen sport as a new and better way of investment, but is the responsibility of the sports stakeholders to stick with rules and preserve the essence of sport.

CHANGES IN PERFORMANCE RESULTS OF RUSSIAN FEMALE MIDDLE- AND LONG-DISTANCE RUNNERS BEFORE AND AFTER AN IMPLEMENTATION OF ATHLETE BIOLOGICAL PASSPORT.

ILJUKOV, S.

SPORTS MEDICINE

INTRODUCTION: Both the prevalence of doping in athletic populations and the efficiency of programs to combat the illicit use of performance enhancing substances and/or methods is unknown. The purpose of pur research is therefore to evaluate the performances of female middle- and long-distance runners before and after an implementation of a new anti-doping strategy (the Athlete Biological Passport, ABP) in a country accused of systematic doping.
METHODS: A retrospective analysis of the results of Russian national championships from 2008 to 2017 was performed. The eight best female performances for 800 m, 1500 m, 3000 m steeplechase, 5000 m and 10000 m from the semifinals and finals were analyzed. Also, the yearly number of athletes fulfilling standard qualifying criteria for international competitions was evaluated.
RESULTS: Four events (800 m, 1500 m, 5000 m (all $p < 0.001$), and 10000 m ($p < 0.05$)) out of five showed statistically significant deterioration in the performances when comparing results before and after the introduction of the athlete biological passport. 3000 m steeplechase was the only event that did not show statistically significant change in performance. The highest relative decrease in the number of runners who meet highest standard qualification for international competition was observed for 5000m event (46.2 %), followed by 1500m (42.1 %), 800m (38.1 %), 10000m (16.7 %), and 3000 m steeplechase (0.0 %) events.
CONCLUSION: The implementation of the athlete biological passport was followed by a significant reduction on the performance of female middle- and long-distance runners in a country accused of systematic doping. Thus, it can be speculated that the more stringent anti-doping testing, more specifically the introduction of the "Athlete Biological Passport" is a key reason for this reduction in performance.

IS ANTI-DOPING A FAILURE? THE CASE OF PROFESSIONAL CYCLING

FABIEN, O., FINCOEUR, B.

UNIVERSITY OF LAUSANNE

Introduction
Anti-doping seems to face a major crisis (Dimeo & Møller, 2018). Its health and ethical grounds, often presented by sports organizations and governments as uncontroversial, have been questioned (e.g., Mazanov, Huybers, & Barkoukis, 2018). Anti-doping is criticized for being inefficient and, to some extent, unfair (Kayser & Smith, 2008). As a result, several researchers have suggested to implement a harm reduction approach (e.g., Kayser, 2018; Waddington & Smith, 2009) or even to legalize doping (Savulescu, 2015). However, it seems that there is often a lack of empirical observations of sporting culture to support either current policies or alternative avenues. Elite cycling, that is one the sports mostly associated with doping scandals and tarnished reputation (López, 2015), then offers a relevant case study to consider several possible effects of anti-doping policies.
Methods
This presentation will rely on results from various research projects within professional cycling:
- a seminal WADA-funded study (2006-2009) based on 70 qualitative interviews among youth riders and staff;
- a second UCI- funded project (2011-2017) based on up to 100 interviews among ten WorldTour teams, and analysis of UCI quantitative databases;
- finally, an ongoing research project funded by the Swiss National Science Foundation, based on a new set of 80 interviews, and observations within professional teams.
Results and discussion
There is a large array of reasons and situations that can explain doping use (Fincoeur, Cunningham, & Ohl, 2018). In particular, cultural aspects have been highlighted in the academic literature. Yet, there is evidence that doping in cycling is no longer a team-organized practice (Fincoeur, Gleaves, & Ohl, 2019), and attitudes and discourses of elite cycling actors towards doping have far changed over the last two decades (decreased acceptance). Although behavioral changes remain difficult to assess, several other major changes occur in the way elite teams organize riders' training and support: increasing use of scientific tools, clearer division of work within the teams, new role of physicians, etc. Thus, it is questionable to conclude that anti-doping has been a complete failure while considering the numerous changes concerning doping patterns and attitudes. Doping use today seems to increasingly rely on individuals, being then partly a result of a lack of supervision, and social and economic precariousness (Aubel & Ohl, 2014, 2015). Policies may have also had unexpected consequences on work conditions. We then observed decreased autonomy among riders, and weakened social links due to the increased division of work and scientification. In particular, use of alcohol and legal drugs such as antidepressants have been reported.

USE OF ILLICIT DRUGS BY YOUTH ATHLETES

OLIVEIRA, A., ALMEIDA, F.R.

STATE UNIVERSITY OF LONDRINA

Introduction
The abuse of illicit drugs brings emotional and physical consequences that poses a serious threat for global public health, and may affect any individual, independent of race, creed or social class. Usually coaches seek to establish common healthy patterns of behavior among athletes, such as eating habits and lifestyles but few studies in developing countries evaluated the athletes use of illicit drugs during the adolescent period. Thus, the purpose of this study was to examine the use of illicit drugs by youth athletes in Paraná State, Brazil.
Methods
The study had a quantitative cross-sectional design and descriptive methodology. The population involved 4451 male and female athletes, in the age range from 10 to 18 years old, participating at The Youth Games of Parana State - 2010, Brazil. The Youth Risk Behavior Surveillance Questionnaire (YRBS), conceived by the Center for Disease Control and Prevention - CDC, translated and culturally adapted by Guedes and Lopes (2008) in Brazil was used to estimate the prevalence of illicit drug use. The sociodemographic indicators analyzed the type of school where the young athlete studied, grade, number of school failures, housing, paid working hours, level of education of parents or guardians of the young athlete, gender, educational level, age, ethnicity, foreign or Brazilian athlete, self-reported weight and height. Descriptive statistics was used to describe the subjects´ sociodemographic characteristics. The magnitude of gender differences was analyzed by the Chi-Square Test. The prevalence rates related to drug use of each item of the questionnaire used a 95% Confidence

Intervals. The extent to which sociodemographic indicators could be related to illicit drug use was calculated the Odds Ratio values through Binary Logistic Regression Analysis.
Results and discussion
The results indicated prevalence of the use of marijuana in the sport modalities (8,6%). Youth athletes belonging to Basketball, Cycling, Soccer, Futsal, Handball and Volleyball teams related the use of at least one type of illicit drug, and Handball and Volleyball presented higher rate. The Rhythmic Gymnastics was the only sport where the athletes indicated no use of illicit drug.

INACTION AS A FORM OF ACTION: THE BRITISH GOVERNMENT RESPONSES TO THE CALL TO BAN TACKLING IN SCHOOLS' RUGBY

WHITE, A.J.
OXFORD BROOKES UNIVERSITY

In 2016, the Sport Collision Injury Collective called upon the UK Government to remove and ban tackling from school physical education. This call was based upon the premise that tackling in rugby was the leading cause of injury, and particularly injurious in regard to concussion (Archbold et al., 2017). This is particularly worrying, given that rugby is delivered as an often compulsory element of the physical education curriculum for boys. Given that tackling is a structural element of rugby and that the injuries are often severe, this is an unacceptable level of risk for children (White et al., 2018).
This research explores the official responses from government officials to the call to remove and ban tackling from schools, focusing on the discursive mechanisms that they utilised to justify inaction. Government officials conflate the benefit of physical activity with the benefits of sport/rugby, they divert onto other issues (such as physical inactivity), they delay through substandard initiatives, they dismiss the evidence, they defame public health advocates and they devolve themselves of responsibility. This research identifies the mechanisms used to prevent public health intervention in order to reproduce and maintain sporting traditions and structures.

IS-PM04 Exercise-induced muscle damage: What is it, how is it detected, and why is it induced?

HISTOLOGICAL CHANGES IN MUSCLE FIBRES AND CONNECTIVE TISSUE AFTER ECCENTRIC EXERCISE: WHERE IS THE BORDER BETWEEN TOLERABLE DAMAGE AND RHABDOMYOLYSIS?

RAASTAD, T.
NORWEGIAN SCHOOL OF SPORT SCIENCES

There are characteristic changes in muscle ultrastructure observed after high-force exercise and ultra-endurance events that clearly demonstrate muscle damage in humans (1). The most frequently reported observations are minor to moderate changes in the myofibrillar structure involving disorganization of 1-20 adjacent sarcomeres (2). These changes are normally defined as muscle damage, but are also discussed as the first phase of a controlled remodelling process. More severe damage to muscle fibres involves segmental fibre necrosis and is related to more extreme exercise protocols involving unaccustomed maximal eccentric muscle actions (3). Segmental fibre necrosis is distinguished from the milder forms of damage and muscle fatigue by initiation of inflammation, slow recovery (> 2 weeks) and very high levels of circulating muscle enzymes (e.g., CK) the days after exercise, and the more severe form of this phenomena is termed rhabdomyolysis. Disturbances in Ca2+ homeostasis is involved in several of the processes leading to fatigue, myofibrillar disorganization and necrosis after high-force exercise. Elevated Ca2+ in resting muscles is supposed to change tissue stiffness and changes in share modulus measured by elastography has consequently been suggested as one possible non-invasive method for early detection of muscle damage (4). This presentation will show the different types of ultrastructural changes and suggest how the different types of muscle damage can be indicated without muscle biopsies.

NEURAL INHIBITION VERSUS DAMAGE EFFECTS: HOW CAN THEY BE DISTINGUISHED?

NICOL, C.
AIX MARSEILLE UNIV, CNRS

This presentation will focus on the neuromuscular fatigue effects of stretch-shortening cycle (SSC) type exercises, which characterize natural, but exhaustive activities such as short and intensive or prolonged running and jumping exercises. Exhaustive SSC performances serve for the purpose to characterize more specifically the effects of repeated eccentric muscle actions on various aspects of the neuromuscular function.
Intensive and/or unaccustomed SSC exercises induce impairments of the neuromuscular function that are usually bimodal is nature. The "acute phase" is characterised by large drops in maximal voluntary contraction, rate of force development, voluntary EMG activity and stretch-reflex response leading to reduced maximal isometric and maximal SSC performances. A "temporary recovery" occurs after a

couple of hours before the occurrence of large "secondary functional declines" and delayed onset muscle soreness (DOMS) that may last for a few days. Bimodal decrements are also reported in voluntary activation level and H/M reflex amplitude. Particularly important in terms of injury prevention is the timing of DOMS disappearance, as it occurs prior to complete structuro-functional recovery. It cannot therefore be used to reflect detailed recovery processes.
