The challenge lies in finding the origins and underlying mechanisms. The acute recovery within 2 hours supports a temporary metabolic failure rather than the influence of muscle damage. This is comforted by the limited acute but large delayed functional defects induced by intermittent exhaustive SSC protocols. A post-exercise decrease of the muscle-tendon compliance may occur as well. The delayed recovery phase is mostly attributed to the inflammation/remodelling processes within the damaged muscles. The parallelism of the neural and mechanical recoveries in maximal testing conditions suggests an attempt of the neuromuscular system to protect the muscle-tendon unit from additional damage.
Sensitization of group III and IV muscle afferents is proposed as an attractive factor to cause presynaptic inhibition, but also inhibition and/or facilitation at the supraspinal level. These afferents are mostly polymodal and sensitive to several parameters associated with either metabolic fatigue or tissue inflammation. Some of them are nociceptive and likely to contribute to the D.O.M.S. sensation. Variation in pain modulation at multiple levels in the nervous system could explain part of the inter-subject variability in soreness perception.
The cyclicity of the SSC task is expected to favour the interaction of such feedbacks with the feedforward control of the stretch-shortening cycle. Emphasizing the flexibility of the neural adjustments to the contractile failure, submaximal SSC tests reveal different central and reflex EMG adjustments in the acute and delayed recovery phases as well as in the preactivation, braking and push-off phases of the SSC.

SYMPTOMS AND MARKERS OF MUSCLE DAMAGE: WHAT CAUSES MUSCLE DAMAGE AND WHAT DETERMINES THE MAGNITUDE OF MUSCLE DAMAGE?

NOSAKA, K.

EDITH COWAN UNIVERSITY

Muscles become weak, sore, stiff and occasionally swollen after unaccustomed exercise consisting of eccentric (lengthening muscle) contractions. These are generally considered as symptoms of muscle damage. Since pain, loss of function and swelling are cardinal signs of inflammation, it is likely that the symptoms are more associated with inflammation than damage itself.
A loss of maximal voluntary contraction (MVC) strength is considered as the best indicator of muscle damage; however, it is also typical for neuromuscular fatigue. Thus, it is not possible to determine whether it is due to fatigue, damage or a combination of both from a decrease in MVC strength, especially at immediately after exercise. If it is necessary to diagnose muscle damage at immediately after exercise, it appears that resting twitch torque induced by supramaximal doublet twitches on the nerve by electrical stimulation is a good marker. It is also reported that the rate of force development at 100-200 ms slot can be used as a muscle damage marker.
It has been reported that the magnitude of decrease in MVC strength at 1 or 2 days post-exercise does not correlate well with the magnitude of delayed onset muscle soreness, increases in blood markers of muscle damage, muscle swelling and muscle stiffness changes. Histological alterations at least in muscle fibre level have been reported to be minimum after voluntary eccentric exercise. This may suggest that muscle fibre damage (injury) is not a main cause of muscle damage symptoms.
We have some evidence suggesting that damage and inflammation to connective tissue surrounding muscle fibres (endomysium), muscle bundles (perimysium) and muscle fascia (epimysium) are associated with muscle soreness and other symptoms of muscle damage. Our recent study showed that the magnitude of muscle damage was greater when muscle was stretched greater and muscle fascia movement was smaller. It is possible that this generates greater strain, resulting in damage and inflammation in the structure around the fascia.
We also found that muscle fascia became thicker after the first eccentric exercise bout and remained for 4 weeks, and the thicker the muscle fascia, the less the magnitude of muscle damage. One of the unique characteristics of eccentric exercise-induced muscle damage is that the magnitude of muscle damage is largely attenuated after the second bout of eccentric exercise that is performed within several weeks, even for the contralateral homologous muscle. This is referred to as the repeated bout effect, and when it is for the contralateral muscle, it is named as the contralateral repeated bout effect. The repeated bout gives us valuable information relating to the mechanisms underpinning muscle damage.
In the presentation, I will try to clarify what muscle damage is, and explain the possible mechanisms underpinning muscle damage and the repeated bout effect, and discuss why muscle damage is induced by unaccustomed eccentric exercise.

OP-PM23 Cardiac function and cardiovascular diseases

TOUR DE FRANCE CIRCUIT : EFFECTS ON CARDIAC FUNCTION IN WELL-TRAINED FEMALE CYCLISTS

LE DOUAIRON LAHAYE, S.

LABORATORY MOVEMENT SPORT AND HEALTH SCIENCES

INTRODUCTION: Prolonged and intense exercise induce a real challenge for the cardiovascular system. Very few studies have focused on multi-days events, and no have studied female athletes. This study aimed to analyze cardiac function in well-trained female cyclists during the Tour de France circuit.
METHODS: Seven healthy and well-trained female cyclists completed the 21 stages of the mens 2016 Tour de France. The event was performed without competition spirit. All underwent resting echocardiography on 5 differents times of the Tour de France circuit (3rd, 7th, 11th, 12th, 21st stage post-exercise echocardiography). Cardiac function was examined using two-dimensional M-mode, doppler. Ventricular and atrial longitudinal strain were also assessed. Pre-Tour baseline echocardiography was made. The heart rate was continuously monitored throughout the stages and daily load was assessed with the training impulse score.
RESULTS: No significant modification was observed on cardiac dimensions, whatever the cavity examined (left and right ventricles (LV, RV), left and right atria (LA, RA)) during the Tour de France circuit. This multi-stage event did not induce alteration on ventricular functions (LV, RV) nor on LA function. A significant alteration of the RA reservoir and conduit function was observed after the 3rd and 21st stage.

CONCLUSION: These results suggest that cycling multi-stage event, performed without competition spirit, was not associated with general cardiac fatigue in well-trained female cyclists. Nevertheless, this repeated and prolonged exercise appears sufficiently stressful to impair right atrial function. Although must be confirmed, these data are to be taken into consideration due to the link between long-term practice of strenuous endurance exercise and atrial fibrillation, the most common type of cardiac arrhythmia (1, 2).

THE RELATIVE IMPORTANCE OF PHYSICAL FRAILTY AND CARDIOVASCULAR FUNCTION AS EXERCISE-MODIFIABLE PREDICTORS OF FALLS IN HAEMODIALYSIS PATIENTS

ZANOTTO, T., MERCER, T.H., VAN DER LINDEN, M.L., RUSH, R., TRAYNOR, J.P., PETRIE, C.J., DOYLE, A., CHALMERS, K., ALLAN, N., SHILLIDAY, I., KOUFAKI, P.

QUEEN MARGARET UNIVERSITY

INTRODUCTION: Stage 5 chronic kidney disease (CKD-5) patients on haemodialysis (HD) are at higher risk of falls (1.18–1.6 falls/person-year) compared to non-uraemic, age-matched individuals (0.5 falls/person-year). Previous research has suggested that multiple risk factors such as older age, comorbidities, polypharmacy, and frailty contribute primarily to the increased risk of falling in the general population. In addition to these risk factors, HD patients are characterised by severe cardiovascular disease (CVD) burden that is often manifested with symptoms of orthostatic intolerance, impaired blood pressure (BP) control and syncope, all of which may be implicated in the aetiology of falling. Therefore, we aimed to explore the relative importance of frailty and cardiovascular function as potential exercise-modifiable predictors of falls.
METHODS: Ninety-three prevalent CKD-5 patients on HD were recruited from two Renal Units for this prospective cohort study, which was conducted between October 2015 and August 2018.
Frailty was assessed by means of the Fried's frailty phenotype. Additional physical function components were assessed using the: 1) timed up and go (TUG) test, 2) sit-to-stand 5 (STS-5) test, 3) ActivPal monitor for physical activity levels, 4) handgrip strength, and 5) knee extension isometric strength. Cardiovascular function was assessed using the Task Force monitor to determine baroreflex and haemodynamic function at rest and in response to a 60° head-up tilt test (HUT-60°). The number of falls experienced during a 12-month follow-up were recorded by a researcher on a monthly basis. The association between all potential predictors and number of falls was analysed using negative binomial regression modelling.
RESULTS: Sixty-nine out of 93 patients were included in the final analysis. A total number of 80 falls were recorded, resulting in an incidence of 1.16 falls/patient-year. Frailty, physical and cardiovascular function components were associated with a higher number of falls in univariate negative binomial regression analysis. In multivariate analysis adjusted for frailty and cardiovascular function, only baroreflex function (RR: 0.963, 95%CI: 0.939-0.987, p= 0.003), and the BP response to HUT-60° (RR: 0.920, 95%CI: 0.854-0.991, p= 0.028) remained significantly associated with a greater number of falls.
CONCLUSION: Results from this prospective study confirm previous research observations that physical frailty and cardiovascular function during a passive orthostatic challenge are implicated in the aetiology of a high number of falls in patients with CKD-5. Adding a baroreflex function variable implicated in the short-term regulation of BP to a frailty-only model significantly improved the prediction of number of falls. Moreover, baroreflex function showed a greater relative importance than frailty in predicting falls in this clinical population.

VENTILATORY EFFICIENCY IS A STRONGER PREDICTOR OF MORTALITY THAN PEAK OXYGEN UPTAKE AND BMI IN HEART FAILURE WITH REDUCED EJECTION FRACTION (HFREF)

MAIORANA, A.1,2, NAYLOR, L.H.1,3, DONGELMANS, S.5, JACQUES, A.2, THIJSSEN, D.H.J.4,5, DEMBO, L.1, O'DRISCOLL, G.6, GREEN, D.J.3

1. FIONA STANLEY HOSPITAL, 2. CURTIN UNIVERSITY, 3. UNIVERSITY OF WESTERN AUSTRALIA, 4. LIVERPOOL JOHN MOORES UNIVERSITY, 5. RADBOUD INSTITUTE FOR HEALTH SCIENCES, 6. PERTH CARDIOVASCULAR INSTITUTE

INTRODUCTION: Peak oxygen consumption (VO2peak) is a strong prognostic indicator in patients with heart failure (HF) (1). However, in some patients it is difficult to achieve a peak exercise test due to musculoskeletal co-morbidities, severe exercise intolerance, or a lack of confidence. In such cases, submaximal exercise parameters may be considered to guide prognosis (2). While higher body mass index (BMI) is generally associated with adverse clinical outcome, there is also a body of evidence in patients with HF that being overweight or obese may paradoxically confer 'protection' against cardiovascular and all-cause mortality (3). We hypothesised that patients with HF and reduced ejection fraction (HFrHF), with elevated submaximal ventilatory responses to exercise, would have impaired prognosis and that ventilatory inefficiency would outperform VO2peak and body mass index (BMI) as a predictor of all-cause mortality.
METHODS: Patients with HFrEF (n=312) who underwent cardiopulmonary exercise testing were characterized as 'fit' (VO2peak>14ml·kg-1·min-1) or 'unfit' (≤14). Fitness was further characterised based on a low (<35)('fit'), or high (≥35) ('unfit') VE/VCO2 regression slope, and finally as 'lean' (BMI 18.5-25.0kg·m-2) or 'overweight' (>25kg·m-2). This gave four classifications based on VO2peak or VE/VCO2 regression slope: 'lean and fit', 'overweight and fit', 'lean and unfit', or 'overweight and unfit'. All-cause mortality was documented from hospital records and a mortality database. Kaplan-Meier analysis was used to produce survival functions and curves which were compared using Log rank tests.
RESULTS: VO2peak and VE/VCO2 slope predicted mortality (P<0.01), whereas BMI was not an independent predictor. Elevated VE/VCO2 slope was the strongest independent predictor. Those who were fit (by any criteria) had better survival than their unfit counterparts, regardless of weight status (P<0.01). Weight status was not related to survival in fit subjects. Those who had VO2peak ≤14ml·kg-1·min-1 and were overweight had significantly higher survival compared with the normal BMI group, although this protective benefit of being overweight was not observed in the elevated VE/VCO2 slope group.
CONCLUSION: These data suggest that ventilatory efficiency provides a valid, robust and highly predictive assessment of risk in patients with HFrHF which may be superior to assessment of VO2peak. BMI was a poor prognostic measure in this cohort of patients with heart failure. Our study adds to the evolving view that assessment of outcomes from cardiopulmonary exercise testing are important to clinical decision making related to prognosis, including selecting patients for advanced therapies such as cardiac transplantation and left ventricular assist device implantation.

GAIT PATTERN AND MUSCLE OXYGEN SATURATION CHANGES ACT SYNERGISTICALLY TO IMPROVE EXERCISE TOLERANCE AFTER MULTIMODAL TRAINING IN PATIENTS WITH SYMPTOMATIC LOWER EXTREMITY ARTERY DISEASE

LANZI, S., BOICHAT, J., CALANCA, L., AUBERTIN, P., MALATESTA, D., MAZZOLAI, L.

DIVISION OF ANGIOLOGY, HEART AND VESSEL DEPARTMENT, LAUSANNE UNIVERSITY HOSPITAL; INSTITUTE OF SPORT SCIENCES, FACULTY OF BIOLOGY AND MEDICINE, UNIVERSITY OF LAUSANNE, LAUSANNE

INTRODUCTION: Patients with atherosclerotic lower extremity artery disease (LEAD) have impaired walking capacities leading to decreased quality of life. Previous studies showed that LEAD patients also have altered gait pattern (decrease speed, cadence and step length, and increased stance phase). Reduced strength and endurance of lower limb muscles play a major implication in these adaptations.
Supervised exercise training (SET) is effective in improving symptoms and walking performances in symptomatic LEAD patients. However, there is no clear consensus whether SET also influences gait pattern.
The aim of the present study was to investigate the effects of SET on gait pattern and calf muscle oxygen saturation (StO2) changes.
METHODS: Fontaine stage II LEAD's patients following a 3-month multimodal (Nordic walking and lower limbs strengthening) SET were investigated. Constant-load treadmill incline walking test (2.5-3.2 km/h at 12%) was used to determine pain-free walking distance (PFWD) and maximal walking distance (MWD). During the treadmill test, spatiotemporal parameters (Physilogs®, GaitUp, Switzerland) and calf StO2 (NIRS, PortaMon, Artinis, The Netherlands) were assessed at baseline, PFWD and MWD. Ankle-brachial Index (ABI) and toe-brachial index (TBI) were also measured. All assessments were performed prior and after SET.
RESULTS: Twenty stage II LEAD patients (62.7±2.4 yr, 80% men, 75% stage IIa) were included. Following SET, PFWD (98.5±10.0 pre- vs. 177.0±31.7m post-SET; P=0.012), and MWD (396.0±62.6 pre- vs. 633.0±107.4m post-SET; P=0.01) significantly increased. ABI (0.85±0.05 pre- vs. 0.85±0.03 post-SET; P=0.96) and TBI (0.61±0.03 pre- vs. 0.65±0.04 post-SET; P=0.07) did not change significantly. Following SET, patients had significantly shorter stride duration (-3%, P=0.05), higher cadence (+3%, P=0.04), longer double support (+10%, P=0.04), shorter swing (-3%, P=0.03), and longer stance duration phase (+2%, P=0.03). In addition, after SET patients also had significantly longer duration of the loading response (+9%, P=0.04) and foot-flat (+3%, P=0.04), and shorter duration of the push-off phase (-8%, P=0.01). Stride length was shorter although not significant (-2%, P=0.13). After SET, delta StO2 (baseline=0) was greater at PFWD (+33%) and at MWD (+68%; P=0.05, with no significant interaction effect).
CONCLUSION: These results confirm beneficial effects of SET on walking performances. After SET, the prolonged duration of loading response and foot-flat (stance sub-phases associated with limited calf muscles activation) may be a strategy to increase calf muscles oxygenation. The observed greater calf muscle oxygen desaturation (increased oxygen extraction) after SET may be related to an improved microvascular milieu leading to a better match between muscle oxygen delivery and utilization during exercise. Taken together, gait pattern and muscle oxygen desaturation changes may act synergistically to improve exercise tolerance in patients with LEAD.

THE EFFECT OF HIGH INTENSITY INTERVAL TRAINING ON CARDIAC AUTONOMIC ACTIVITY AFTER 4 WEEKS OF SUPERVISED CARDIAC REHABILITATION, AND 6 MONTHS OF HOME-BASED EXERCISE

TAYLOR, J.L., COOMBES, J.S., HOLLAND, D.J., KEATING, S.E., BAILEY, T.G.

THE UNIVERSITY OF QUEENSLAND

INTRODUCTION: Heart rate variability (HRV) is used to characterize autonomic nervous system (ANS) activity, in particular the balance between sympathetic and parasympathetic nervous systems. Reduced HRV is associated with increased risk of cardiovascular events in those with coronary artery disease (CAD) particularly following myocardial infarction (MI). While exercise training has been shown to positively affect the ANS in patients with CAD, research is needed to identify the type of exercise that produces optimal improvement in HRV. Furthermore, the long-term changes in HRV with home-based exercise are unknown. We compared the effect of High Intensity Interval Training (HIIT) and Moderate Intensity Continuous Training (MICT) on HRV in CAD patients with and without previous MI, commencing a 4-week cardiac rehabilitation program. We then also compared both protocols using home-based unsupervised exercise on longer-term changes in HRV at 3 and 6 months.
METHODS: Seventy-three patients with CAD (Aged: 64±8; 89% males, 27% post MI) completed 3 exercise sessions per week (2 supervised, 1 home-based) for 4 weeks, randomised to either 1) HIIT (n=36): 4x4 min intervals at a rating of perceived exertion (RPE) 15-18 interspersed with 3 min active recovery periods or 2) MICT usual care (n=37): 40 min moderate intensity continuous exercise at an RPE 11-13. This was followed by 3 unsupervised home-based sessions per week of their randomised training for 11 months. HRV was measured using 3-lead electrocardiography for 5 min following 10 min of supine rest. Using Kubios (V3.1.0), R-R intervals were used to calculate linear parameters in the time-domain (RMSSD, SDNN) and the AR spectrum frequency-domain (LF, HF, LF/HF). Data were analysed using a linear mixed model and ANOVA to assess group differences. Data are mean (95% CI).
RESULTS: After 4 weeks, the HIIT group increased RMSSD (ms) and SDNN (ms) from baseline with no change in the MICT group [RMSSD - HIIT: 8(4 to 12), p<0.001; MICT: 3(1 to 7), p=0.161] [SDNN – HIIT: 7(3 to 10), p=0.001; MICT: 2(1 to 5), p=0.162]. In patients post MI, we observed a group difference favouring HIIT [RMSSD - HIIT: 24(13 to 35) vs MICT: 2(-7 to 11), p=0.010] [SDNN – HIIT: 19(11 to 27) vs MICT: 0(-7 to 7), p=0.006]. Both groups increased RMSSD and SDNN from baseline at 3 months [RMSSD – HIIT: 6(2 to 10), p=0.008; MICT: 6(2 to 10), p=0.003] [SDNN – HIIT: 4(0 to 8), p=0.031; MICT: 6(2 to 9), p=0.001] and 6 months [RMSSD – HIIT: 8(4 to 13), p=0.001; MICT: 6(2 to 10), p=0.005] [SDNN – HIIT: 5(1 to 9), p=0.020; MICT: 5(2 to 8), p=0.003]. There were no changes in frequency-domain variables for either group.
CONCLUSION: In patients with CAD, particularly post MI, only HIIT improved HRV within a 4-week cardiac rehabilitation intervention. Both HIIT and MICT showed similar improvements in HRV with longer-term exercise at 3 and 6 months. HIIT may be more effective at improving ANS function over a short time period, typical of cardiac rehabilitation settings, in patients with CAD.

ENTRANCE AND EXIT EXERCISE STRESS TESTS IN INPATIENT CARDIAC REHABILITATION: WHAT DO THE NUMBERS TELL?

BIRKLBAUER, A.1,2,3, GEBETSBERGER, F.X.2, DIEM, G.

1DEPARTMENT OF SPORT AND EXERCISE SCIENCE, UNIVERSITY OF SALZBURG

INTRODUCTION: Cardiovascular disease is one of the biggest health risk factors (Powell et al, 2018). To reduce these risks, in- and outpatient cardiac rehabilitation (CR) with a multidisciplinary approach including medical treatment, nutritional counselling, smoking cessation, and exercise therapy, which is the essential component (Piepoli et al, 2012), has been commonly conducted (Sue et al, 2017). In many

international guidelines, an exercise stress test is recommended (Price et al, 2016), allowing for an individual and optimised patient-oriented exercise training. That is of major importance especially when starting CR. During a 4-week inpatient CR, exercise testing is usually performed twice in the form of an entrance and exit exercise stress test. To evaluate the effectiveness of exercise training within the 4-week CR, we analysed data from both entrance and exit exercise stress tests.
METHODS: We used data from a cohort of 2462 cardiac patients (18-89 yrs; 913 women). Our inpatient subjects were suffering from HFpEF, HFrEF, LVEF, CMP, hypertension, NSTEMI or STEMI, or participated in CR after bypass or stent surgery. Assessed were resting and maximum heart rate, blood pressure and maximal load and load per kilogram body weight (load/kg) and duration of tests.
RESULTS: ANOVA [Time(2)xAge(3)xSex(2)] showed statistically significant and meaningfully improvements in load and load/kg ($p<.01$; partial eta squared (ES)>.25) over the four weeks. Improvements did not correlate with entrance test performance ($r=-.257$), but varied between age groups: being larger in the younger patients (<50yrs; +16%; ES>.55), reduced in the 50-70 yr-olds (+11%; ES>.30) and again larger in the elderly (>70yrs; +14%; ES>.50) with the increase being stronger in female elderly (+15%) than in elderly males (+12%). The gain in load is supported by the longer exit exercise test time. We also found a slight reduction for resting heart rate and maximum heart rate (-2%; $p<.01$; ES>.01). For maximal blood pressure values, we obtained small positive effects of exercise on the systolic blood pressure in females (ES>.01; $p<.01$).
CONCLUSION: Our data confirm that exercise training during a 4-week inpatient CR helps expedite the development of an improved exercise tolerance and, thus, every-day living. This is an essential contribution to the scientific based evidence for CR, particularly as our rehabilitation program was found to be effective across age groups and improvements did not diminish with higher initial performance level. In due consideration of the comorbidities being higher in the elderly, it is of importance that even older age groups where rehabilitation is often underappreciated and underutilized benefit from CR. Particularly for the working population, the demonstrated physical improvements may be an excellent strategy for reducing hospital readmissions and to return to work.

OP-PM24 Recovery from sports and exercise

RECOVERY EFFECT OF A LOWER LIMB COMPRESSIVE GARMENT AFTER A TRAIL RUNNING COMPETITION ON BIOCHEMICAL MARKERS: A PRELIMINARY STUDY.

APARICIO, I.1,2, PRIEGO-QUESADA, J.I.1,3, MARTÍNEZ-NAVARRO, I.1, HERNANDO-DOMINGO, C.4, LLOPIS, J.2, PÉREZ-SORIANO, P.1

1. UNIVERSITY OF VALENCIA; 2. TEXTILE RESEARCH INSTITUTE; 3. UNIVERSITY OF VALENCIA; 4. UNIVERSITY JAIME I CASTELLÓN.

INTRODUCTION: Trail running is a discipline increasing in number of runners. This modality was associated with muscle damage due to some characteristics, such as this duration and succession of prolonged eccentric actions during downhill stretches (1,2). However, it is necessary more investigations about how can affect other physiological aspects such as renal or cardiovascular system. Compression garments could be an effective strategy to reduce muscle damage after competition (3). The objective of the study was to analyse the influence of wearing lower limb compressive garments (LLCG) during 24 h after trail running competition on biochemical markers.
METHODS: 10 runners participated in the study (age: 40±7 years; body mass index: 23±2 kg/m2; training volume: 60 ±23 km/week). Participants were randomized in two different recovery groups: 1) wearing LLCG during 24 hours after competition, and 2) control (without compressive garment). Competition was the 2018 Costa Blanca Trail (Alicante, Spain) with a distance of 65 km and 4200 meters of positive slope. The LLCG and control groups performed the competition in 668±95 min and 696±124 min, respectively. Composition of LLCG was 88% polyamide and 12% elastane, its weight was 200g, and it had graduated compression of 15-10 mmHg, according to manufacturer's specifications. Biochemical markers such as creatinine, creatine Kinase, troponin, and C reactive protein were measured using a blood analytical. Measurements were taken 24h before and 24h after the trail competition. Differences between groups were considered when Cohen's effect sizes (ES) was moderate (>0.5) or large (>0.8).
RESULTS: Similar values were found in all variables in both groups 24h before the competition (ES<0.5). 24h after competition, LLCG group presented lower values of creatinine than control group (0.95±0.17 vs 1.06±0.18 mg/dL; ES=0.6), creatine kinase (1157.25±470.06 vs 4468.2±7049.31 U/L; ES=0.9) and C reactive protein (1.23±0.52 vs 1.83±0.97 mg/dL; ES=0.8). Troponin variable was similar in both groups 24 h after competition (10.73±5.83 vs 11.3±2.89 ng/L; ES=0.1)
CONCLUSION: In this preliminary study, it was observed that runners who used LLCG during first 24 hours post-race showed lower values on muscle damage (creatine kinase), inflammation (C reactive protein) and renal function (creatinine). With these preliminary results, the use of LLCG could be suggested as an effective strategy to improve recovery. Result obtained on lower renal effort is interesting since there is a lack evidence on competition. On the other hand, no differences were observed on cardiac damage (troponin), and it could indicate that characteristics of trail competition produce higher muscle damage than cardiovascular damage.
Due to low sample, it is intended to carry out future studies with greater number of participants that confirm the results obtained.

CRYOTHERAPY AS A RECOVERY TECHNIQUE DURING CONSECUTIVE DAYS OF SIMULATED TENNIS MATCHES: COMPARISON OF WBC, CWI, PASSIVE RECOVERY

POIGNARD, M.

FRENCH INSTITUTE OF SPORT

INTRODUCTION: Professional tennis players are subject to large amounts of physiological and psychological stress during competition and inadequate recovery can result in accrued fatigue throughout the course of an ATP/WTA tour (1). One emerging recovery modality is

Cryotherapy, which increases in popularity despite the lack of evidence to show its benefits depending on the context. Literature supporting the use of such methods to improve recovery have focused on improvements in peripheral fatigue and neglect to investigate the effects of various recovery methods on central fatigue (2). The aim of this study was to investigate the effect of different recovery modalities (whole-body cryotherapy, WBC, cold-water immersion, CWI, passive recovery, PAS) on specific peripheral and central markers of the tennis recovery during consecutive days of simulated tennis matches.
METHODS: In a crossover design, thirteen competitive male tennis players completed 3 simulated tennis matches, on 3 consecutive days, each followed by a different recovery modality (WBC, CWI, PAS) in 3 different weeks. Perceptual measures (muscle soreness, general fatigue), blood parameters (Creatine kinase, CK), peripheral (Maximal voluntary contraction, MVC; M-wave characteristics) and central indicators (Maximal voluntary activation; EMG activity) have been recorded after every match and 24 hours following the 3rd match. Tennis specific indicators have also been measured (ball velocity, ball accuracy, and technical performance).
RESULTS: Regardless of recovery condition and days, MVC (Day 1: -16.4 ±23,4 N.M-1; Day 2: -10.3 ± 20,9 N.M-1; Day 3: -6.6 ±19 N.M-1) and CK (Day 1: 67.6 ±90.6 U.L-1; Day 2: 111.43 ±183.1 U.L-1; Day 3: 99.4±136.2 U.L-1) intraday variations have respectively decreased and increased significantly, consecutively after each of the three simulated matches ($p<.01$). There were no significant differences between days and recovery conditions, in the MVC and CK intraday variations, following simulated tennis matches. When we compared recovery conditions, we observed no differences on MVC, CK and perceptual scores before matches. Likewise, Tennis specific measures also showed no significant difference between days and conditions.
CONCLUSION: Our simulated tennis matches have induced, every day, a significant and reproducible fatigue similar to a real tennis match. Our preliminary results suggest that cryotherapy is not detrimental for tennis performance, however, it seems not efficient to accelerate recovery during consecutive days of simulated tennis matches.

INTRA-INDIVIDUAL VARIABILITY IN SLEEP AND NOCTURNAL HEART RATE VARIABILITY OF ELITE FEMALE SOCCER PLAYERS DURING AN INTERNATIONAL TOURNAMENT

COSTA, J.A.1, FIGUEIREDO, P.2,3, NAKAMURA, F.Y.4, RAGO, V.1,2, REBELO, A.1, BRITO, J.2

1UNIVERSITY OF PORTO, FACULTY OF SPORTS; 2PORTUGUESE FOOTBALL FEDERATION; 3UNIVERSITY INSTITUTE OF MAIA; 4PHYSICAL EDUCATION UPE/UFPB, JOÃO PESSOA;

INTRODUCTION: Research examining sleep and nocturnal heart rate variability (HRV) in athletes has typically averaged data across several nights, providing a mean estimate of usual sleep and HRV(1,2). While such approach is useful to provide basic insight into the recovery process, it lacks details of how individual sleep and HRV may vary across multiple nights. Moreover, individual variability can reflect differences within individuals over time. In fact, high intra-individual variability in sleep and HRV might indicate the potential value of individualising diagnostic approaches to promote appropriate recovery. Therefore, this study aimed to describe individual sleep and nocturnal HRV in elite female soccer players during an international tournament.
METHODS: Twenty elite female soccer players (aged 25.2±3.1 years) wore wrist actigraph units and heart rate monitors during night-sleep throughout 9 consecutive days (6 day-time trainings [DT; start ranged between 11:00AM–17:30 PM], 2 day-time matches [DM; both started at 3:00 PM] and 1 night-time match [NM; started at 6:00 PM) of an international tournament.
RESULTS: As a group, players presented appropriate total sleep time (TST) during the tournament (ranged between 7:41±0:44 and 8:26±0:41 h). However, a lower duration of TST was observed after NM compared to most of the other days of the tournament, including DM1 and DM2 (-1:32±0:19 hours and -1:37±0:11 hours, respectively; $p<0.001$). In addition, a lower sleep efficiency (SE) was found after NM compared with DM1 and DM2 (-7±3 % and -5±2 %, respectively; $p<0.001$). At the individual level, eight players slept less than 7 h at least for 2 out of the 9 days of the tournament. These players presented the higher coefficient of variation (CV) for TST than the remaining players (range between 11.1 to 18.7% and 3.0 to 9.2%, respectively). From the eight players that slept less than 7 h, five extended TST for ≥7 h on the days following matches. All players presented good SE (≥75%; individual range between 75-98%) across all days of the tournament. As a group, nocturnal HRV was not affected across the 9 days of the tournament ($p>0.05$) and ranged between 4.19±0.88 and 4.54±0.42 ln(ms). However, at the individual level, two players presented CV >10% (range between 11.4 and 11.5%) for nocturnal HRV, while most of the players had CV ranging between 3.0 and 9.0%.
CONCLUSION: The main finding of this study was that players generally accumulated adequate sleep quantity (TST ≥7h) and quality (SE ≥75%) throughout the tournament, during which no general disturbances in nocturnal HRV were observed. However, at the individual level, high intra-individual variability in TST and nocturnal HRV was observed, indicating the need for individualized sleep education strategies that could promote appropriate sleep and recovery of elite female soccer players, especially during periods of high congested fixtures.

THE STUDY OF DYNAMIC CHANGES IN FUNCTIONAL STATE OF RUSSIAN NATIONAL TEAM ATHLETES AFTER TRANSFER TO EAST REGION

ZHOLINSKY, A., PRISTANSKOV, A., FESCHENKO, V., FOMIN, A., KOMAREVTSEV, V., MITIN, I., OGANNISYAN, M., PIRUSHKIN, V., LITVINENKO, A.

FEDERAL MEDICAL BIOLOGICAL AGENCY

INTRODUCTION: Athletes of national teams are subject to constant stress associated with debilitating physical exertion and psychological stress during preparation and participation in competitions. This is multiplied by frequent travel across the world/ Flights with the intersection of three or more time zones lead to a displacement of the daily rhythms of the athletes body, which in turn leads to the appearance of pathological syndrome called circadian desynchronosis, also known as Jetlag. The purpose of this study was to assess the functional status of water polo athletes after the flight to the Eastern region.
METHODS: The study was conducted during the XXIX World Summer Universiade 2017 (August 16 – 26) in the Taiwanese city of Taipei. The study involved 8 athletes of the mens water polo team. The study was carrying in the morning, before breakfast, before training and competition loads. For the rapid diagnosis of the functional state of the body of athletes, heart rate variability analysis (HRV) was used. To

assess the state of the central nervous system was used simple visual-motor test (SVMT). SVMT allows to assess the speed of the nervous processes, the speed of occurrence and disappearance of the processes of excitation and inhibition in the nervous system.
RESULTS: The following parameters of HRV were studied: heart rate, stress index, spectral characteristics (Total power – TP, Low frequency – LF, High frequency – HF, Very low frequency – VLF), values of SVMT were determined during the first 11 days after the flight. The results of the study showed that TP has the highest value on the 6th day after arrival. Sympathetic type of regulation was dominating throughout the study. In the first 5 days there was a pronounced predominance of the sympathetic link. On days 6–7 LF / HF ratio remained relatively stable. On days 8–9, LF / HF increased, and by 10–11 days it returned to normal values. There were not any significant changes in heart rate values. The stress index had the highest value on the 6th day, meanwhile SVMT – the lowest. This allows us to conclude that at this point the maximum activation of the body's regulatory mechanisms is achieved.
CONCLUSION: Thus, it may be concluded that during the first 4-5 days the body's functional state changes under the new conditions (the acute phase of adaptation).On the 6th-8th day, the functional state of athletes stabilizes and adapts to the new environment. The optimal functional state for participation in competitions – 10th to 11th days after flight.

PARTIAL-BODY CRYOTHERAPY AND COLD-WATER IMMERSION AFTER MUSCLE-DAMAGE IN FEMALES: A RANDOMIZED CONTROLLED TRIAL

HOHENAUER, E.1,2,3, COSTELLO, T.J.4, DELIENS, T.3, CLARYS, P.3, STOOP, R.1, CLIJSEN, R.1,2,3

1: SUPSI , 2: THIM , 3: VUB , 4: UOP

INTRODUCTION: Partial-body cryotherapy (PBC) and cold-water immersion (CWI) are widely accepted recovery modalities and believed to improve recovery. However, direct comparisons between these favourite cold therapies have only been performed in a male population, demonstrating the significant under-represented female population in sport science. Accordingly, this study sought to examine (a) the physiological effects of CWI, PBC, and a passive control (CON) and (b) athletic recovery following exercise induced muscle damage (EIMD, 5 x 20 drop-jumps) in females.
METHODS: Twenty-eight females were randomly allocated into a PBC (30 sec at -60°C, 2 min at -135°C), CWI (10 min at 10°C) or CON (10 min resting) group. Muscle oxygen saturation (SmO2), cutaneous vascular conductance (CVC), mean arterial pressure (MAP) and mean skin temperature were assessed up to 60 min (10 min intervals) to quantify the physiological processes, while delayed-onset of muscle soreness (DOMS), muscle swelling, maximum-voluntary isometric contraction (MVIC) and vertical jump performance (VJP) were assessed up to 72 hrs (24 hrs intervals) following the treatments, as indicators for the recuperation.
RESULTS: Mean skin temperature was significantly lower after CWI vs. PBC up to 40 min following treatment ($p<0.05$). Mean skin temperature was significantly ($p<0.05$) higher in CON compared to CWI up to 60 min and compared to PBC up to 30 min. Despite reductions in mean skin temperature in PBC and CWI, no differences were observed for SmO2, CVC and MAP (all $p>0.05$). However, SmO2 was lower ($p<0.05$) in PBC and CWI compared to CON throughout the 60 min follow-up period. DOMS recovered quicker in the CWI compared to the PBC group. MVIC recovered after 24 hrs in the PBC group. However, it did not return to baseline after 72 hrs in CWI and the CON group. No differences between PBC and CWI were observed for muscle swelling and VJP.
CONCLUSION: Our study is the first one that directly compared the physiological responses and effects on muscle recovery between PBC and CWI in a female population after muscle damage, demonstrating that the physiological impact of CWI is only significantly greater than PBC in the skin but not in the muscle tissue (SmO2). Although CWI was superior compared to PBC to attenuate DOMS, PBC was superior compared to CWI for the recovery of MVIC. This study might show that the results from male participants cannot be transferred directly into a female population.

VALIDATION OF JUMP SIMULATION INPUT PARAMETERS FOR SLOPE STYLE AND BIG AIR: SNOW FRICTION AND AIR DRAG DURING IN-RUN

WOLFSPERGER, F., MEYER, F., GILGIEN, M.

NORWEGIAN SCHOOL FOR SPORT SCIENCES

INTRODUCTION: Ski- and Snowboard (SB) slopestyle (SS) and big air (BA) are new and progressive disciplines which are associated with high injury rates (Soligard et al., 2015). Jump design is considered as key injury risk factor. Although park designers have longstanding experience and remarkable research studies on jump designs are available (Scher et al., 2015; McNeil et al., 2012), the modelling of jumps still have considerable uncertainties including in-run, take-off and flight phase. Due to the variety of apparel and body postures used in SS / BA, the aerodynamic forces are largely unknown. This study aims to investigate air drag force during in-run and flight phase of ski and SB SS by wind tunnel experiments.
METHODS: Measurements were carried out in a closed loop wind tunnel with a closed test section of 7.5 x 11 m measuring dynamic pressure and temperature of the air flow as well as 3D forces. 4 skiers and 3 SBers performed 2 runs in typical low, mid, and extended postures at 35, 60 and 85 km/h wearing regular fit, tight fit and wide fit apparel.. The projected frontal areas AF were extracted from calibrated videos. Drag forces, cD and AF values were analysed using linear regression to describe their dependencies on position, clothing and speed.
RESULTS: cDAF values ranged from 0.3 to 0.95 and were dominated by posture and clothing, followed by subject and velocity. For example, wearing a baggy pant compared to a tight pant, increases cDAF as much, as extending the body from mid to upright posture (Fig. 1). Velocity dependency was found for the AF values, but not for the cD values confirming transcritical flow regime for SS / BA as expected for Reynolds Numbers of above 10^7.
CONCLUSION: The range of aerodynamic forces is large and the found variability due to posture and clothing causing challenge in jump simulations. The velocity dependency of AF is mostly attributed to adaptions of postures, counteracting the increasing air resistance at higher velocities. Considering the shown effect of apparel fitting and posture will help to simulate jumps within a more realistic range of parameters.

ANKLE JOINT MOMENT-ANGLE RELATIONSHIP IN THE FRONTAL PLANE DURING THE PUSH PHASE OF ELITE BOBSLEIGH

ZEDLER, M.1,2, SANNO, M.1,2, GROTHE, S.1,2, GÖLL, F.1, BRAUNSTEIN, B.1,2,3, GOLDMANN, J.P.1,2
GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: The push phase in bobsleigh is positively correlated with final race times [1] and the performance in this phase is limited by the athlete's ability to generate mechanical power with the ankle joint in the sagittal plane (SP) [2]. Therefore, the aim was to elaborate the understanding of the ankle's function by investigating the moment-angle relationship in the frontal plane (FP).
METHODS: Infrared cameras (250 Hz, Vicon, Oxford, UK) and force plates (1250 Hz, Kistler, Winterthur, Suisse) were used to conduct a 3D analysis of the ankle joint during the push start of the brakeman. Therefore, a rail system was installed on an athletics track, providing mechanical guidance of a sleigh (85 kg). 17 elite athletes (98,9 ± 6,9 kg; 185,8 ± 5,3 cm) of the german national squad were tested as follows: (1) initial acceleration (first and second step), (2) acceleration phase after 10 m and (3) 30 m. Statistics: four-level ANOVA.
RESULTS: Each condition showed a resulting external eversion moment (EM) during the entire stance phase, reaching its maximum at around 60-70 %. The peak moments ranged from (1) 42.3 ± 12.5 Nm to (3) 35.1 ± 10.2 Nm and declined with increasing speed ((2) and (3) significantly lower than (1), ($p < 0.05$)). The mean inversion angles at touchdown (TD) ranged from (1) -1.6 ± 3.0° to (3) -5.3 ± 3.4°. The eversion after TD and the subsequent inversion was highest for (3) 1.7 ± 1.9° and (3) -5.9 ± 2.5°. After maximum inversion a slight eversion until toe off was present.
CONCLUSION: Since the GRF increases with higher speed, the decline in peak EM must be due to a reduction in the moment arm of the GRF in the FP. This could be caused by an altered foot placement of the athlete. A wider step and an external rotation of the foot during the first and second step could enlarge the moment arm of the GRF in the FP while reducing the moment arm in the SP. A smaller external rotation after 10 and 30 m acceleration could explain the reduction in the moment arm in the FP and therefore the resulting decreased EM despite higher GRF. This pattern is consistent with elite sprinters who reduce their step width with increasing velocity [3]. Since a wide step is correlated with greater lateral impulse [4], it is still argued why this kinematic pattern could be advantageous for acceleration in anterior direction. Aside from greater muscle activation of adductor muscles during hip extension [5], a possible resulting reduction of the moment arm of the GRF in the SP could benefit the generation of mechanical power of the plantar flexors and therefore maximize propulsion. Strengthening the toe flexors and the m. tibialis posterior of the ankle joint complex could enhance the power contribution of the ankle joint and therefore lead to shorter push and final race times.

AERODYNAMICS SIMULATION FRAMEWORK FOR SKI-JUMPING TAKE-OFF AND ITS APPLICATION TO VARIOUS JUMPERS

KAJIMOTO, H., KOYAMA, S., BALE, R., IKEDA, J., YAMAMOTO, K., TSUBOKURA, M.
KOBE UNIVERSITY

INTRODUCTION: In this study, we have developed a simulation framework for predicting unsteady aerodynamic characteristics in ski jumping competition. The framework satisfies the following requirements: be quick enough to evaluate between trials, be able to consider the jumper's specific body shape, minimize athlete's direct involvement in data capture to avoid any inconvenience to the athlete, and be available at any time regardless of practice / games.
The ski jumping movement sequence can be divided into the following four phases: in-run, take-off, flight, and landing. Among these movement, take-off motion is the most important and difficult aspect of ski jumping. In order to shift from the approaching posture to the flight posture, a jumper rapidly extends the body in a short time of 0.25 to 0.30 seconds.
METHODS: In accordance with requirements we have formulated, the framework was constructed as follows. First, the shape of the jumper was obtained by 3D laser scanning technique (C90366; Hamamatsu Photonics K.K.). Second, in order to reduce jumpers' burden of being motion captured and to enable the usage of the framework even during a game, the posture change was assumed to be symmetrical with respect to the sagittal plane, and was obtained from video images. Finally, the aerodynamics simulations were performed using this posture reproduction technique.
Aerodynamics simulations were carried for two cases: Case A, here the posture change was obtained using framework described above, and Case B, where the posture change was obtained with three-dimensional motion capture. The results of aerodynamics simulation of Case A and Case B where compared to validate the methodology adopted in Case A, which is the main focus of this work.
For the aerodynamics simulations, equation of continuity and incompressible Navier-Stokes equations were solved as the governing equations. The governing equations were discretized based on a finite volume method with a hierarchical Cartesian grid system. We used the Constraint based Immersed Boundary Method (cIB) as the moving boundary method to incorporate the complex 3D motion of a ski jump.
RESULTS: From the simulation results, the flow structures and lift-drag ratio of Case A and Case B were compared. In the comparison of the flow structure, the flow of the rear part of the jumper obtained with Case A was very similar to that of Case B. In the comparison the lift-drag ratio, sudden drop due to the stall of the flow on the jumper's back was seen in both results. Accordingly, we concluded that it is reasonable to use a 2D video capture based posture reconstruction in the 3D aerodynamics simulation of the take-off motion of ski-jumping.
CONCLUSION: After examining the validity, we simulated aerodynamics of multiple jumpers using this framework. As a result of studying the relationship between the trunk angle of attack and lift-drag ratio, different trends were found between good-performing jumpers and poorly-performing jumpers.

SNOWBOARD GIANT SLALOM: 3D LOWER LIMB JOINT KINEMATICS USING WEARABLE INERTIAL SENSORS

FANTOZZI, S.1.2, MANGIA, A.L.1,2, FORNI, M.1, SIMSIG, M.3, NIGRO, F.3, CIACCI, S.3

UNIVERSITY OF BOLOGNA

INTRODUCTION: Recently, the use of wearable inertial and magnetic measurement units (IMMUs) has got increasing interest in winter outdoor sports applications like snowboard (1). IMMUs technology can monitored the action continuously without specified spatial limitation and does not require long-time post-processing and complex experimental setup (1). The kinematic analysis of a whole snowboard slope is fundamental to improve the knowledge of performance factors and to provide suggestions to athletes and coaches. The aim of the present study was to compare 3D lower limb joint kinematics of elite and experienced recreational snowboarders during giant slalom using IMMUs.
METHODS: Eight snowboarders were acquired: 4 males belonging to the Italian Snowboard National Team (age 27±3.2y, height 1.80±0.10 m, mass 83.4±4.3 kg) and 4 males were experienced recreational athletes (age 41.5±5.5 y, height 1.76±0.03 m, mass 89.0±12.2 kg). The athletes performed two trials on a snowboard slope (14 gates spaced at 21 m, 200m total descent). Eight IMMUs (APDM Opals, 128 Hz) were attached on sternum, sacrum, thighs, shanks, toe of ski boots (right and left). Outwalk protocol was implemented for the 3D kinematic analysis of trunk-pelvis, hip, knee and ankles joints (2). The motor task was divided in 2 phases: backside and frontside turns (BT, FT) using the change of ski edge for the identification of the beginning/end of a turn. Snowboarders were filmed for the first 4 gates using a video camera (JVC full HD, 250hz) to validate the algorithm for the automatic identification of the change of the ski edge using IMMU. Joint kinematics on sagittal and frontal planes were expressed in percentage of the duration of the BT and FT, mean and standard deviation curves were estimated for the two groups. Statistical parametric mapping was applied to investigated the differences between elite and recreational athletes (3).
RESULTS: The elite snowboarders showed an almost fixed value of flexion for the trunk-pelvis joint during both FT and BT (-7±9 deg), the recreational athletes exhibited a similar pattern for the BT while a more flexed trunk during the FT (24±18deg). Only during the BT, more flexed hip joint was found for the elite (105±9deg) with respect to the recreational (81±7deg) athletes. On the frontal plane, no differences were found.
CONCLUSION: The differences found for the trunk-pelvis and hip joints were consistent with the higher technical skills of the elite athletes. Furthermore, the higher variability of the kinematics patterns for the recreational athletes particularly during FT and for the knee identified this phase and joint as the most critical. Results indicated the IMMU technology as a viable option to analyse the joint kinematics of snowboard giant slalom. Further studies will be developed to investigate the joint kinematics variability of the turns execution during the whole slope.

MECHANICAL DETERMINANTS OF FORWARD SKATING SPRINT AND THEIR RELATIONSHIP WITH OFF-ICE MUSCULAR CAPACITIES

PEREZ, J., BROCHERIE, F., HAGER, R., GUILHEM, G.

FRENCH INSTITUTE OF SPORT

INTRODUCTION: Since its development (Samozino, Morin, Hintzy, & Belli, 2008; Samozino et al., 2016), the assessment of the force-velocity (F-V) relationship during functional movements has gained popularity. Recently, this method has been tested for reliability during on-ice forward sprint skating tasks in high-level women ice hockey players (Perez et al., under review). Because off-ice tests are often use to infer skating performance, the aim of this study was to quantify the magnitude of correlation between muscle capacities and performance measured during off- and on-ice F-V tests.
METHODS: Seventeen players from the French Ice hockey female national team were recruited. Performance and muscle capacities assessed on the lower limbs in the sagittal plane (F0: theoretical maximal force, V0: theoretical maximal velocity, Pmax: maximal power output, RFmax: maximal ratio of force applied in the horizontal component of the ground reaction force, DRF: minimal rate of decrease of this ratio and SFV: slope of the linear F–V relationship) were evaluated during squat jumps, 30-m running sprint and 40-m forward skating sprints. Pearson's product–moment correlation analysis were used to determine the F-V relationship for each testing modalities. Paired samples t-tests compared the magnitude of the F-V relationship parameters (F0rel, V0, SFVrel, Pmaxrel, DRF and F-V deficit) and performance (jump height and split times) measured during the squat jump, 30-m running sprint and 40-m forward skating sprint tasks.
RESULTS: On-ice muscle capacities (F0rel, Pmaxrel, RFmax and DRF) showed a large to very large correlation with the 40-m skating performance ($r = -0.89, -0.91, -0.89$ and 0.82, all $p < 0.001$, respectively). Pmaxrel was the most correlated variable for each specific performance task (i.e. with SJ height, $r = 0.92$; with 30-m running sprint split time, $r = -0.81$; and with 40-m skating sprint split time, $r = -0.91$, all $p < 0.001$). The F0rel and Pmaxrel were significantly higher for jumping ($p < 0.001$), while V0 was significantly higher for skating ($p < 0.001$). While F0rel was significantly higher ($p < 0.001$) for the running task than for the skating task, there was also a trend for a higher Pmaxrel parameter for the running task ($p = 0.06$).
CONCLUSION: The low (V0, SFVrel, DRF and F-V deficit) to strong (Pmaxrel) correlations between the same muscle mechanical properties inferred from off- and on-ice force-velocity tests confirm the force-velocity profile specificity previously reported between jumping and running sprint tasks (Jiménez-Reyes et al., 2018). Although ice hockey forward skating performance could be predicted using jump and/or running sprint performance, none of their force-velocity parameters appears indicative of on-ice performance. From the on-ice mechanical properties, it seems that the highest horizontal force applied and its minimal rate of decrease during 40-m skating sprint would be the main determinants for ice hockey forward sprint performance.

MOTOR SKILLS SPECIFIC TO FIELD ALPINE SKI RACING PHYSIOLOGICAL DEMANDS

BOTTOLLIER, V.

LABORATOIRE MOUVEMENT SPORT SANTÉ

INTRODUCTION: For climatic, organizational and financial reasons, off-snow alpine ski (AS) racing training is important. Moreover, for a given on-mountain training session, the effective time of skiing is particularly short. Consequently, coaches need to find ways to provide AS racers with race specific stimuli to further practice and enhance race specific skills and physiological profiles. Consequently, the purpose of this study was to compare the physiological demands and estimated contributions of energy metabolisms between field AS racing (slalom - SL - and giant slalom - GS) and different motor skills (Sliding, Tramp bouncing, Box bouncing, Running, Cycling) during same effort duration in highly trained AS racers.

METHODS: Eight highly trained AS racers (18.2 ± 0.8 years) performed two AS racing runs, each separated by at least 24-h rest, over an 8-day period during the winter competitive season. Subjects performed, in a random order of standardized runs, one GS and one SL of about 53s. After the warm-up, a portable gas exchange system (Metamax, Cortex, Germany) was attached to the subject's chest. All the tests were performed with International Ski Federation (FIS) approved and well-prepared skis on the same slope. Three to five days after the field test, subjects performed a lab-based maximal graded test on cycle ergometer (Erg 550, Bosch, Germany) to determine maximal oxygen uptake (o'O2max). Two days after the incremental test, subjects performed five all-out 53s tests of five different motor skills in a randomized order. The contribution of aerobic, glycolytic and phosphagen energy systems was estimated using Bertuzzi (1) method. Effect sizes (ES) were calculated using Cohen's d.
RESULTS: There was no significant difference (i) in aerobic system contribution between SL or GS and sliding, box bouncing or running, (ii) in glycolytic system contribution between SL or GS and sliding or trampoline bouncing and (iii) in phosphagen energy system contribution between SL and sliding or trampoline bouncing. There was no significant difference observed in total energy output between SL or GS and sliding. Total energy outputs in running ($p< 0.01$; ES: moderate) and cycling ($p<0.05$; ES: moderate) were higher than in SL. Total energy outputs in trampoline bouncing ($p<0.05$; ES: moderate), box bouncing ($p<0.01$; ES: large), running ($p<0.001$; ES: moderate) and cycling ($p<0.01$; ES: large) were higher than in GS.
CONCLUSION: This study has shown that sliding is more specific to GS and SL than the others motor skills tested regarding to physiological (aerobic and glycolytic energy contribution, total energy output, glycolytic energy output, aerobic energy output and phosphagen energy output) parameters. Sliding is a relevant technical AS racing specific motor skills for these AS racing specific parameters and because it is easily usable in the field, which is essential.

A SINGLE SESSION OF NEUROMUSCULAR ELECTRICALLY-EVOKED ISOMETRIC CONTRACTIONS GENERATES SUPERFICIAL ACTIVATION OF KNEE EXTENSOR MUSCLES AND LOCALIZED ALTERATIONS

FOURÉ, A., LE TROTER, A., OGIER, A.C., GUYE, M., GONDIN, J., BENDAHAN, D.

UNIVERSITY CLAUDE BERNARD LYON 1, AIX-MARSEILLE UNIVERSITY, CNRS, APHM, UNIVERSITY OF TOULON, INSERM

INTRODUCTION: Neuromuscular electrical stimulation (NMES)-induced isometric contractions can generate heterogeneous damage within activated muscles. Alterations in deep regions of the vastus lateralis (VL) and in superficial zones of the vastus medialis (VM) have been recently described within days following an isometric NMES exercise (Fouré et al., 2015). Although NMES has been reported to a superficial, synchronous and spatially fixed recruitment involving both fast and slow motor units (Maffiuletti, 2010), magnetic resonance imaging (MRI) observations have illustrated an heterogenous spatial muscle activation (Adams et al., 1993). The aim of the present study was to investigate the potential link between muscle activation and damage in response to a single session of isometric NMES. We assessed comparatively activated and damaged muscle areas using MRI.
METHODS: Thirteen subjects performed a single session of NMES-induced isometric contractions as previously described (Fouré et al., 2014). Such an activation has been linked to a maximal voluntary isometric contraction (MVC) reduction together with an increased muscle volume and a larger transverse relaxation time (T2). MVC, muscle volume and T2 were measured before, immediately after (POST), seven days (D7), fourteen days (D14) and twenty-one days (D21) after the NMES session. Changes in muscle T2 measured at POST were considered as illustrating muscle activation (Fouré et al., 2017) whereas delayed T2 changes (i.e., at D7, D14 and D21) were associated to muscle damage (Fleckenstein et al., 1989). A spatial normalization of T2 maps was performed in order to compare activated and damaged areas from statistical mapping analyses.
RESULTS: The significant MVC decrease found at POST (-26 ± 9%) was also observed at D7 (-20 ± 6%) and D14 (-12 ± 5%). At POST, T2 changes were quantified in the superficial part of the muscles located beneath the stimulation electrodes (VM: +14 ± 7%, VL: +17 ± 5%). However, long-lasting T2 changes were mainly identified in the deep part of the VL (+57 ± 24% at D7) and the superficial part of the VM (+24 ± 16% at D7).
CONCLUSION: Based on a genuine methodological approach, the present results disclosed a potential spatial independence between activated and damaged muscle areas following isometric NMES exercise. This apparent discrepancy might support a new result from an involvement of non-contractile tissues in the etiology of NMES-induced muscle damage.

NEUROMUSCULAR- AND TEMPERATURE-DEPENDENT FACTORS INFLUENCING MUSCLE FORCE POTENTIATION AFTER WARM-UPS WITH DIFFERENT FORCE-VELOCITY CHARACTERISTICS

BLAZEVICH, A.J., PINTO, M.D., BABAULT, N., WILSON, C.J.

EDITH COWAN UNIVERSITY

INTRODUCTION: Improvements in muscle force or power production subsequent to brief, high-intensity exercise (i.e. warm-up) are often ascribed to mechanisms related to "classic" post-activation potentiation (PAP), particularly changes in calcium sensitivity. The aim of this study was to broadly examine changes in neuromuscular function after both brief, task-specific practice and then a more intense warm-up activity, and to assess temporal relationships with changes in muscle force production.
METHODS: Two experiments (Exp) were performed with 19 subjects in each cohort. In Exp 1, total haemoglobin (near infra-red spectroscopy) and muscle stiffness (transverse strain) were examined in vastus lateralis before and after task-specific practice (TSP; maximal isokinetic knee extensions every 30 s at 180 deg/s until peak torque values were <3% for 3 consecutive reps). After TSP, conditioning activities (CAs) of either 5 isokinetic knee extensions at 60 deg/s or 25 extensions at 300 deg/s (i.e. same time under tension) were performed on

separate days in random order, and measurements were repeated 1-, 5- and 9-min post-CAs. In Exp 2, TSP and CA protocols were repeated however measurements of muscle temperature (Temp; needle thermometer), voluntary and electrically-evoked torques, muscle activity (electromyography; EMG) and M-wave amplitude were made.
RESULTS: Increases in total haemoglobin (i.e. blood content) were observed after TSP, and then further increases continued through to 9 min post-CA at both 60 and 300 deg/s. Trends towards increased stiffness did not reach significance. TSP also increased twitch torque, Temp and torque produced during knee extensions at 180 deg/s (T180). After CAs at 60 deg/s and 300 deg/s, increases in Temp and decreases in the ratio of torques produced during variable (train of 2 pulses 200 Hz, 9 pulses 20 Hz) vs. constant (20 Hz) frequency electrical muscle stimulation trains were observed. Small decreases in tetanic torques were observed post-CA at 60 deg/s only. T180 decreased at 1 and 5 min post-CA at 60 deg/s but increased above baseline by 9 min, but was elevated at all time points post-CA at 300 deg/s. EMG/M-waves were unchanged.
CONCLUSION: Task-specific practice improved dynamic knee extension performance with small increases in muscle temperature. Subsequent performance of maximal contractions at 60 or 300 deg/s further improved dynamic torque, although torque enhancement was not seen at 1 or 5 min post-CA in the 60 deg/s condition. This might have resulted from muscle fatigue or motor pattern interference. Clear improvements were seen after CA at 300 deg/s, which mirrored changes in muscle temperature. Changes in muscle calcium sensitivity (indicated by reduced variable:constant frequency torque ratio), often cited as causing PAP, were observed but changes were small and not temporally aligned with voluntary torque changes. Thus, PAP responses often reported after dynamic contractions in humans might be strongly influenced by muscle temperature changes.

MUSCLE-SPECIFIC MODULATION OF MOTOR EVOKED POTENTIALS AND SPINAL REFLEXES OF AGONIST AND ANTAGONIST MUSCLES DURING VOLUNTARY CONTRACTION

SAITO, A.1, NAKAGAWA, K.2, MASUGI, Y.1,3, NAKAZAWA, K.1

1. THE UNIVERSITY OF TOKYO; 2. TRONTO REHABILITATION INSTITUTE; 3. TOKYO INTERNATIONAL UNIVERSITY

INTRODUCTION: It is well known that voluntary contraction facilitates the excitability of corticospinal tract and monosynaptic reflex circuit in agonist muscles while this inhibits the monosynaptic reflex excitability in antagonist muscles through reciprocal inhibition (1). Although these neural effects have been studied for individual muscles, it remains unknown that modulations of the effects in multiple lower-limb muscles during voluntary contraction. The purpose of this study was to reveal the effects of voluntary contraction on the excitability of corticospinal tract and spinal reflex circuit in multiple lower-limb muscles.
METHODS: Eleven young males participated in this study. During rest and weak isometric voluntary contraction conditions (i.e., plantarflexion, dorsi-flexion, knee extension, and flexion), motor-evoked potentials (MEP) and spinal reflexes were evoked from lower-limb muscles by transcranial magnetic stimulation and transcutaneous spinal cord stimulation, respectively. These evoked responses were recorded from soleus (SOL), medial (MG) and lateral gastrocnemius (LG), tibialis anterior (TA), vastus lateralis (VL), rectus femoris (RF), and biceps femoris (BF) muscles. Peak-to-peak amplitudes of MEPs and spinal reflexes were calculated for each muscle.
RESULTS: MEP and spinal reflex amplitudes of each agonist muscle significantly increased with the contraction level, but not the spinal reflex of TA muscle. MEP amplitudes of each antagonist muscle were significantly increased with related to the agonistic torque level, but these of RF muscle was slightly depressed. The spinal reflexes amplitudes of antagonist muscles (SOL, MG, LG, and BF) significantly decreased with the contraction level, but these of VL and RF muscles significantly increased.
CONCLUSION: This study demonstrates that excitability of corticospinal tract and spinal reflex circuit of agonist muscles facilitated during voluntary contraction, whereas no facilitation of the spinal reflex circuit was observed in TA muscle. This may be caused by the primary components of the TA stretch reflex are transcortical pathway rather than spinal pathway (2). Furthermore, we suggest that spinal reflex circuit excitability of the quadriceps femoris is facilitated during their antagonist activation. It is suggested that the reciprocal inhibitory effects on the spinal reflexes of antagonist muscles are weaker in the quadriceps femoris than hamstrings muscles (3). Thus, we consider that the reciprocal inhibition of the spinal reflex circuit is counteracted by a descending drive during voluntary contraction. This study concludes that modulations of corticospinal tract and spinal reflex circuits excitability of agonist and antagonist muscles during voluntary contraction depend on the muscle.

ACUTE ADAPTATIONS IN SPINAL AND CORTICOSPINAL EXCITABILITY FOLLOWING VISUO-MOTOR SKILL LEARNING

HENRY, M., DUCHATEAU, J., BAUDRY, S.

UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: Previous work reported an increased excitability of the corticospinal pathway controlling the tibialis anterior (3) and a decreased excitability of the spinal pathway conveying muscle spindles signal onto the soleus motoneurones (2), in response to the acquisition of a visuo-motor task (VMT) that involved alternating activation of ankle plantarflexors and dorsiflexors. Whether similar adaptations occur following motor skill learning of a task that requires shortening and lengthening contractions of one muscle, however, remains an open question.
METHODS: 22 subjects (19-29 yrs) were randomly assigned to either a group that practiced a VMT (n=12) or a group that performed a control task (CT; n=10). In VMT group, subjects tracked a target that moved vertically on a screen by performing shortening and lengthening contractions of the ankle plantarflexor muscles against an inertial load corresponding to 15% of the maximum strength of the subject. The CT group had to perform the same task but without tracking a target. The total duration of practice was 20 min for both groups. Before and after practice, subjects maintained an ankle angle position of 90° against an inertial load of 15% of their maximal with the plantarflexor muscles (test task). The position fluctuations were measured during the test task by the standard deviation (SD) of the position signal. During the test task, maximal M wave and Hoffmann (H) reflex evoked by tibial nerve stimulation and motor evoked potential (MEP) induced by transcranial magnetic stimulation were recorded in the soleus.
RESULTS: During the test task, the SD of the position decreased after practice in VMT (before: 0.5±0.2°; after: 0.4±0.1°, $p<0.05$) but not in CT group ($p>0.05$). The H-reflex amplitude decreased after practice in VMT (35±15% Mmax vs. 27±18% Mmax, $p<0.05$) but not in CT group (42±15% Mmax vs. 44±8% Mmax, $p>0.05$). For VMT, correlation analysis revealed that the greater the decrease in H-reflex amplitude after practice, the greater the reduction in SD position ($r^2=0.39$, $p<0.05$). The MEP amplitude did not change significantly after practice regardless of the group ($p>0.05$). However, the amount of change in MEP amplitude was negatively associated with that of the SD position ($r^2=0.66$, $p<0.05$) in VMT group; the greater the increase in MEP, the greater the decrease in SD.

CONCLUSION: Our results suggest that practicing a VMT is associated with distinct changes in corticospinal and spinal excitability, although both sets of changes are associated with improved performance. These changes may reflect an increase in the controlled processing of sensorimotor integration as part of the motor learning process (1).

EFFECT OF ANODAL TRANSCRANIAL DIRECT CURRENT STIMULATION ON VOLUNTARY ACTIVATION LEVELS AND MAXIMAL VOLUNTARY CONTRACTIONS IN THE QUADRICEPS MUSCLE

KRISTIANSEN, M., NØRGAARD, J.E., THOMSEN, M.J., AAES, J.S., KNUDSEN, D., VOIGT, M.

AALBORG UNIVERSITY

INTRODUCTION: Anodal transcranial direct current stimulation (a-tDCS) has previously been investigated as a potential ergogenic aid in sports, capable of increasing cortical excitability as well as maximal voluntary contraction (MVC) (1,2). Changes in voluntary activation levels (VAL) have been suggested as a possible explanation for these increases (1). The aim of this study was therefore to investigate the effects of a-tDCS on cortical excitability, MVC, and VAL.
METHODS: Nine untrained male participants were recruited for this randomized sham-controlled experiment. The participants reported to the lab on two separate days, with at least seven days in between, where they received either a-tDCS or sham-stimulation. At each test day: baseline cortical excitability, MVC, and VAL were assessed prior to receiving either a-tDCS or sham-stimulation. Ten minutes post-stimulation cortical excitability, MVC and VAL were assessed again to evaluate the effects of the two types of stimulation. Transcranial magnetic stimulation was used to assess the cortical excitability of the cortical representation at M1 of the right rectus femoris, by averaging 20 motor evoked potentials elicited with 120% of the resting motor threshold stimulation intensity. Femoral nerve stimulation was applied to determine the VAL. Anodal-tDCS and sham-stimulation was applied through saline-soaked sponge electrodes (5x7 cm) with the anode placed over the motor representation of the right rectus femoris and the cathode centered over the contralateral deltoid muscle. During the a-tDCS condition, the electrical current amplitude was ramped up over 30 seconds to 2 mA and kept constant for 9 minutes and ramped down again over 30 seconds, this procedure was repeated three times separated by two 5-minute breaks. During the sham-stimulation the current was ramped up to 2 mA over 30 seconds, and then ramped down over 30 seconds to zero again followed by 9 min without stimulation. This procedure was repeated three times with two 5- minute breaks.
RESULTS: The results of the present study showed that the cortical excitability increased significantly following a-tDCS (54.8 ± 61.3 (%), $p = 0.03$), while no significant change occurred following sham stimulation (-4.0 ± 21.9%, $p > 0.05$). The increase in cortical excitability following a-tDCS did not lead to any significant changes in MVC (pre: 1000.7 ± 253.4 to post: 986.8 ± 271.9 (N) $p = 0.72$) or VAL (pre: 84.5 ± 8.7 to post: 84.8 ± 9.5 (%), $p = 0.33$). No significant changes occurred following sham stimulation in MVC (pre: 1043.7 ± 251.2 to post: 1016.4 ± 243.2 (N) $p > 0.05$) or VAL (pre: 87.0 ± 5.0 to post: 84.2 ± 9.6 (%), $p > 0.05$).
CONCLUSION: In conclusion, a total of 27 minutes of anodal transcranial direct current stimulation at 2mA applied to the cortical representation of M1 resulted in increased cortical excitability, but no significant changes in either MVC or VAL.

ENHANCED AVAILABILITY OF SEROTONIN EXACERBATES CENTRAL FATIGUE DURING MAXIMAL VOLUNTARY CONTRACTIONS

KAVANAGH, J.J., MCFARLAND, A.J., TAYLOR, J.L.

GRIFFITH UNIVERSITY

INTRODUCTION: Animal preparations have revealed that intense release of serotonin (5-HT) onto the spinal motoneurones causes spillover of 5-HT to extrasynaptic 5-HT1A receptors on the axon initial segment to reduce motoneurone activity (1). The release of 5-HT is believed to be related to motor activity, where enhanced levels of motor activity correspond to greater levels of serotonergic drive to motoneurones. We performed two experiments to determine how increased extracellular concentrations of 5-HT affect the ability to perform sustained maximal voluntary contractions (MVC) in humans.
METHODS: Each experiment was a double-blind, placebo-controlled, cross-over design. Paroxetine 20 mg was used to enhance 5-HT concentrations by inhibition of serotonin reuptake. In experiment 1, superimposed and resting twitches were obtained from biceps brachii via motor nerve stimulation during a fatigue protocol ($n = 11$). Four sustained maximal elbow flexions were each performed until torque declined to 60% MVC (4 contractions, 40 s rest between contractions). Within 6 s after each contraction, a resting twitch was elicited and then a superimposed twitch during a brief MVC. Voluntary activation was calculated by comparison of the amplitudes of these twitches. Experiment 2 used supramaximal ulnar nerve stimulation to elicit F-waves from adductor digiti minimi (ADM) following a 2 s and a 60 s MVC ($n = 8$). F-wave persistence and area were used as a measure of spinal motoneurone excitability.
RESULTS: Enhanced 5-HT availability did not affect twitch properties of the resting muscle, but decreased time-to-fatigue by 2.3 ± 3.8 s ($p = 0.038$) and voluntary activation of the biceps brachii by 2.6 ± 7.0% ($p = 0.048$) following repeated maximal elbow flexions. F-waves of the ADM were marginally affected following a brief 2 s MVC. However, F-wave area and persistence were significantly decreased by 19.0 ± 11.2% ($p = 0.032$) and 16.3 ± 9.1% ($p < 0.001$), respectively, following a prolonged 60 s MVC of the ADM.
CONCLUSION: Enhanced availability of 5-HT was associated with poorer motor performance as shown by shorter times for torque to drop to 60% MVC. The mechanisms underlying the decline in motor performance had neural origins as fatigue-related reductions in the resting twitch, which reflect peripheral fatigue, were unaffected by paroxetine, whereas reductions in voluntary activation were increased. Moreover, reductions in motoneurone excitability after a fatiguing MVC were also greater with paroxetine, which suggests a spinal mechanism by which 5-HT may contribute to central fatigue.

IS-BN03 Brain stimulation: An emerging phenomenon in sport and exercise

ENHANCING PHYSICAL PERFORMANCE WITH TRANSCRANIAL DIRECT CURRENT STIMULATION: STATE OF THE ART AND FUTURE PERSPECTIVES.

ANGIUS, L.

NORTHUMBRIA UNIVERSITY

The physical limits of human performance have traditionally been understood through a focus on the locomotor muscles, lungs and heart. However, greater attention is now given to mechanisms acting at brain level. A first step has been provided from studies involving neuroimaging techniques where the role of specific brain areas have been identified during isolated muscle and whole-body exercise. A new approach has been provided by studies involving non-invasive brain stimulation techniques where an electrical or magnetic field is used to specifically stimulate one or more brain areas in a controlled manner.
Among these techniques, transcranial direct current stimulation (tDCS) has been widely used in neuroscience research to understand and enhance brain function. tDCS modulates the targeted brain area by passing a weak electric current between two or more electrodes placed over the scalp. In this regard, a growing number of experimental studies explored the possibility to enhance exercise performance by tDCS in healthy people on a wide range of exercise paradigms. However, the current knowledge regarding the neurophysiological mechanism and perceptual response during exercise following tDCS is very limited.
This talk will review and discuss the current knowledge provided from experimental studies involving tDCS to enhance physical performance. In addition, some technical and theoretical research-based principles for future research, to promote a better understanding of potentials and caveats of this technique will be also included. Finally, a critical opinion for the usage of tDCS for exercise enhancement will be provided.

BRAIN STIMULATION: AN EMERGING PHENOMENON IN SPORT AND EXERCISE

HENDY, A.

DEAKIN UNIVERSITY

Increasing our understanding of the brain and neuromuscular pathway in motor control will enable practitioners to improve rehabilitation practices for patients suffering acute or chronic injury and pathophysiology. The use of innovative brain stimulation procedures allows researchers to examine and facilitate neuroplastic changes occurring as a result of physical therapy and motor practice. Cross-education is a well-documented phenomenon whereby single-limb resistance training or motor practice results in performance gains in the opposite (untrained) limb. An increase in neural drive, achieved by acute and chronic neuroplasticity in the 'untrained' motor cortex is believed to underpin the transfer effect. Anodal transcranial direct current stimulation (a-tDCS) can be used to modulate motor cortical excitability, and potentially facilitate performance. Recently, studies have investigated the application of a-tDCS to the inactive cortex during resistance training in an attempt to enhance the cross-education effect, with mixed success. Beyond its use in cross-education, there is also a growing body of literature investigating the potential to utilise tDCS in conjunction with physical therapy in conditions such as Parkinson's disease and stroke. For example, both anodal and cathodal stimulation can be used to adjust hemispheric imbalance following stroke, which may enable more effective outcomes when used in conjunction with standard motor rehabilitation. The duration, frequency and intensity of stimulation is likely to influence the outcomes of combined treatment. This presentation will critically examine the current evidence and future directions for the use of tDCS to facilitate cross-transfer, and other forms of physical therapy and rehabilitation.

NEURODOPING: GAINING THE EDGE THROUGH NON-INVASIVE BRAIN STIMULATION

MAUGER, A.

UNIVERSITY OF KENT

For a substance to be included on the prohibited list, WADA states that the technique/substance must have the potential to enhance performance, represent a potential health risk and violate the spirit of the sport. There are now several studies demonstrating that tDCS is capable of improving both single limb and whole body endurance exercise performance, but the landscape of the literature is more complex than this. Whilst acute tDCS applied according to the recommended guidelines is relatively safe, little is known regarding the chronic use of tDCS in healthy populations, and it is this repeated use that is most applicable to athletic populations. Finally, there is limited justification for using tDCS prior to or during sporting activity other than to improve performance, which may violate the concept of fair competition.
Although tDCS is a relatively new technique, its (perhaps exaggerated) potential as an ergogenic aid has quickly spread from the research laboratory to the public. This is concerning because a tDCS system can be purchased commercially for as little as £200, or even constructed at home with basic equipment and expertise. This means the technique is widely available to both the well-funded professional athlete and the amateur using a DIY tDCS set-up. This sudden interest and accessibility has led to dramatic increases in the use of tDCS by athletes, which as yet, has not been addressed by governing bodies. This talk will discuss the current evidence relevant to the classification of tDCS as neurodoping, and discuss how such a technique may already be being used in sport to enhance performance.

OP-PM43 Nutrition: Supplements and dietary regimens

IS TAKING SULFORAPHANE EFFECTIVE FOR ECCENTRIC EXERCISE-INDUCED MUSCLE SORENESS AND MUSCLE DAMAGE IN HUMANS?

MIURA, I.1, KOMINE, S.1, MIYASHITA, N.1, TOKINOYA, K.1,2, KONNO, M.1, KAWAZU, S.1, OHMORI, H.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Eccentric exercise is effective in increasing skeletal muscle mass, but on the other hand it may cause muscle soreness and muscle damage after exercise. Involvement of oxidative stress has been reported as one of causes of exercise-induced muscle soreness and muscle damage [1]. The nuclear factor erythroid 2-related factor 2 (Nrf2) plays a role as a defense mechanism in vivo against oxidative stress. Sulforaphane (SFN) activates Nrf2 and induces a protective effect against oxidative stress. It has been reported that administration of SFN to mice suppresses exercise-induced oxidative stress and muscle damage [2]. However, it is still unclear whether SFN supplement is useful in humans. Therefore, in this study, we investigated the effect of SFN supplement in humans to suppress eccentric exercise-induced muscle soreness and muscle damage.
METHODS: The subjects were 16 young men. Subjects were randomly divided into SFN intake group (SFN group) and control group (CON group). In the SFN group, a supplement containing 10 mg of sulforaphane glucosinolate (SGS), a precursor of SFN, was taken three times a day. The exercise load was an eccentric exercise of the brachial flexor muscle group of non-dominant arm and supplements were taken from 2 weeks before exercise load to 4 days after exercise. Subjective muscle soreness (Visual analogue scale : VAS) and range of motion (ROM) were measured before and after exercise load, and 1, 2, 3 ,4 days after exercise. Blood samples were taken at the same time as measurement, and skeletal muscle damage markers (Creatine Kinase: CK, lactate dehydrogenase: LDH, aldolase: ALD, aspartate aminotransferase: AST) were measured.
RESULTS: In the SFN group, VAS 2days after exercise was significantly lower than the CON group. And restrictions on ROM were suppressed 2 days after exercise.
In addition, CK, a muscle damage marker, showed a tendency to suppress 2days after exercise ($p = 0.081$).
CONCLUSION: We demonstrated that Nrf2 activation by ingestion of SFN suppresses muscle soreness and muscle damage. The mechanism might be the suppression of eccentric exercise induced oxidative stress in muscles. This study first revealed the usefulness of SFN intake in humans. This result not only contributes to maintaining and improving performance of athletes but also suggests the possibility of improving health and improving quality of life in ordinary people.

MAKING WEIGHT COULD BE SAFE AND EFFECTIVE

CANNATARO, R., MARZULLO, N., CIONE, E.

UNIVERSITY OF CALABRIA

INTRODUCTION: In various sports, athletes are grouped in weight classes, even if the body weight is important for many athletes such runners, skaters, jumpers, jockeys, the tecnique colloqually called "making weight" (MW) (or "weight cutting"), is about exclusive of combat sport, it consist in a very rapid weight loss (RWL) (2-3 days) and subsequent rapid weight gain (RWG) in the days preceding competition (achieved in 4-16 hours depending on sport practicede). This practice is often carried out without a scientific background but just anecdotally and sometime athletes use drugs (i.e. diuretics). Regrettably, this practice is common in several sports, even Olympic, such as boxing, wrestling, taekwondo, MMA and muay thai/kick boxing. Here we tried to standardize the MW appling it in 24 muay thai athletes (8 females and 16 males). 3 days of rapid weight loss (RWL) and 8 hours of rapid weight gain (RWG) were achieved by a diet program (i.e: glycogen depletion).
METHODS: Peripheral blood samples were collected at the beginnign, after RWL and after RWG. TSH was evaluated by ELISA with CENTAUR XP and biochemical parameters with ADVIA 1800. Bioelectrical Impedance Vector Analysis (BIVA) was performed using a single-frequency BIA analyser (ImpediMED DF50), which applies a 50 kHz oscillating electrical current.
RESULTS: Results highlited a drop of the TSH of about 1/3 that was restored after RWG. Concomitantly with peripheral blood, we performed antropometric parameters and BIVA analysis. This latter pointed out that Active Tissutal Mass (ATM), good indicator of the overall body health status and atheltic performance, in some subjects, reached a better value respect to the beginning, hydratation (checked via BIVA) too was restored after RWL
CONCLUSION: It is our opinion that the desired weight should reached and kept during all the season, and if needed have a weight loss in reasonable time (ie: weeks at least) but if carried out scientifically MW could be effective and safe (as data on TSH and ATM demonstrate), in effect it is not MW per se to be dangerous, buti it could strongly become if applied in wrong way and in any way if applied too often (several time in season)

TIME-RESTRICTED FEEDING, A ZEITGEBER FOR MUSCLE RESPONSE, LIPID PROFILE, AND MUSCLE DAMAGE-RELATED BIOMARKERS IN YOUNG AND OLDER ADULT MEN

SELLAMI, M.

QATAR UNIVERSITY

INTRODUCTION: The present study examined the effect of a three month time-restricted feeding program (TRF) on serum glucose, lipids, C-reactive protein (CRP), Alanine transaminase (ALT), Aspartate transaminase (AST), uric acid, and creatine. A secondary aim was to determine the effects of TRF on skeletal muscle in healthy men.
METHODS: Forty active men were recruited for this study. Young and elderly participants were randomly assigned into a young experimental group (YE: 26.27±1.95 years, n=11), a young control group (YC: 24.64±1.21 years, n=11), an aged experimental group (AE: 52.36±6.65 years, n=11), and an aged control group (AC: 53.00±5.18 years; n=11). YE and AE participated in 12-weeks of TRF (2 days per week). Before (P1) and after (P2) intervention, participants performed a repeated sprint exercise to determine maximal power. Before exercise, 10 mL antecubital venous blood samples were collected.

RESULTS: Our results showed that TRF had no detrimental impact on glycemia, lipid profile (except from a change in HDL) and muscle damage biomarkers. Furthermore, no changes were observed in muscle performance.
CONCLUSION: TRF seems to be a safe dietary intervention.

ASSOCIATIONS BETWEEN NUTRITION AND BODY COMPOSITION WITH CARDIOVASCULAR DISEASE RISK FACTORS AND PRO-INFLAMMATORY BIOMARKERS DURING A 6-MONTH MILITARY DEPLOYMENT

NYKÄNEN, T.1, PIHLAINEN, K.1, VASANKARI, T.2, KYRÖLÄINEN, H.3,4, FOGELHOLM, M.5

1: FINNISH DEFENCE FORCES, 2: UKK INSTITUTE FOR HEALTH PROMOTION RESEARCH, 3: UNIVERSITY OF JYVÄSKYLÄ, 4: NATIONAL DEFENCE UNIVERSITY, 5: UNIVERSITY OF HELSINKI

INTRODUCTION: Globally increasing overweight and obesity also exist in military service persons. Risk factors that induce cardiovascular diseases (CVD) such as obesity may be detected in soldiers; especially diet, smoking and other behavioral habits may facilitate CVD development in this population. Furthermore, stressful military tasks tend to be associated with low-grade inflammation, which also affects CVD risk. This study investigated the associations between nutrition and body composition with CVD risk factors and pro-inflammatory markers in soldiers during a 6-month military deployment in South Lebanon.
METHODS: Altogether 35 male soldiers (age 30.0 ± 8.7 yrs., height 178.6 ± 6.3 cm, BMI 24.2 ± 2.5 kg/m2) were observed three times (PRE, MID, POST) during their 6-month military deployment. Three-day food diaries were kept and analyzed to assess the macronutrient intake. Bioelectrical impedance analysis was used to estimate body composition. Blood samples for lipid profile and pro-inflammatory markers as well as blood pressure were measured after an overnight fast.
RESULTS: The carbohydrate intake increased from PRE (39.4 E%) to MID (42.6 E%; p=0.034) and the protein intake first decreased (21.7 E%, 18.7 E%; p<0.001) but then recovered (22.5 E%; p<0.001). Fiber intake decreased 22 % from PRE to POST (p=0.002). Body composition remained stable during the deployment. Blood lipids, glucose and pro-inflammatory markers remained within the reference values during the deployment, but systolic blood pressure increased above the level of 120 mmHg in POST. Fat mass and body fat percent were associated positively with the total and LDL cholesterol at all measurement points. A negative association was found between the change in fiber intake and the total and LDL cholesterol values (R=-0.362, p=0.033; R=-0.394, p=0.019).
CONCLUSION: A low fiber intake and greater amount of body fat had an impact on total and LDL cholesterol. Nevertheless, the measured CVD risk factors remained within the reference values except for the higher value of systolic blood pressure measured at POST. The responses for pro-inflammatory markers while conducting military missions need to be clarified in future studies. A regular screening of body composition and encouraging the consumption of fiber-rich foods may promote cardiometabolic health in soldiers.

METABOLIC AND HORMONAL RESPONSES TO SHORT-TERM KETOGENIC DIET AND EXERCISE

CHO, W., JUNG, H., YANG, H.I., PARK, D.H., HONG, S., MIN, J.H., YOO, S., CHOE, Y.S., LEE, W., JEON, J.Y.

YONSEI UNIVERSITY

INTRODUCTION: Short-term effects of ketogenic diet with and without acute exercise on energy utilization and metabolic and hormonal changes have not been fully studied. Therefore, we aimed to explore the effects of a 3-day ketogenic diet on energy expenditure, substrate utilization, glucose and lipid metabolism, and hormones in healthy young participants at rest and during acute exercise.
METHODS: Fourteen healthy adults (8 men and 6 women) volunteered for the current study. Participants were asked to consume a mixed diet (25% protein, 15% fat, and 60% carbohydrate) followed by a 3-day ketogenic diet (20% protein, 75% fat, and 5% carbohydrate). After measurement of resting energy expenditure (REE) participants ran on a treadmill until they spent 100 kcal at each exercise intensity: low, moderate and high intensity.
RESULTS: The 3-day ketogenic diet significantly increased REE with decreased the respiratory exchange ratio. During 3-day ketogenic diet, glucose, insulin triiodothyronine, fibroblast growth factor (FGF) 21 significantly decreased, while total and low density lipoprotein, thyroxine, and uric acid significantly increased. Energy expenditure and fat oxidation was significantly higher throughout exercise and recovery when participants were on the ketogenic diet. FGF-21 significantly increased with acute exercise during the ketogenic diet while no change was observed in response to exercise when consumed mixed diet.
CONCLUSION: We observed metabolic and endocrine response to ketogenic diet similar to fasting, except marked increase in REE during ketogenic diet.

THE RELATIONSHIP BETWEEN DIETARY INTAKE, MEAL TIMING AND SLEEP IN ELITE AUSTRALIAN FOOTBALL PLAYERS

CONDO, D.1,2, FALKENBERG, E.1, LASTELLA, M.3, ROBERTS, S.2, AISBETT, B.2

1: CENTRE OF SPORTS RESEACH , DEAKIN UNIVERSITY; 2: INSTITUTE OF PHYISCAL ACTIVITY AND NUTRITION DEAKIN UNIVERSITY. 3: APPLETON INSTITUTE, CQUNIVERSITY

INTRODUCTION: The recovery from training and competition is paramount to athletic success (1). Fundamental to recovery and performance is sleep (1, 2). Thus optimizing sleep is critical for athletes, especially professional Australian Football League (AFL) players who routinely report inadequate sleep (2). Emerging evidence in non-athletic populations suggests that dietary factors including calorie intake, macronutrient composition and meal timing, can influence sleep (3). However, the mechanisms explaining how these factors impact sleep is unclear, and the purported nutrition-sleep relationship has not been investigated in elite athletes. The aim of this study was to investigate the relationship between total daily and evening dietary intake, meal timing and sleep in elite male AFL players.
METHODS: Sleep behaviour and dietary intake were assessed in 36 elite male AFL players for 10 consecutive days in pre-season. Wrist activity monitors and self-reported sleep diaries were used to assess sleep. Photo food diaries were used to assess dietary intake via the smartphone application MealLogger and analysed using the dietary analysis program FoodWorks. Generalised linear mixed models were used to assess the associations (β score represents the change in sleep variable for every one unit increase in dietary variable) between diet [total daily and evening (>6pm) energy, protein, carbohydrate, sugar and fat intake] and sleep [total sleep time (TST), sleep efficiency (SE), wake time (WT) and sleep onset latency (SOL)]. All data presented as mean ± SD, unless stated otherwise.
RESULTS: The daily intake of energy, carbohydrate, protein and fat was 14.3 ± 4.5MJ, 298.0 ± 117.3g (3.4 ± 1.4g·kg-1), 191.1 ± 66.3g (2.2 ± 0.8g·kg-1) and 150.8 ± 62.3g (1.7 ± 0.7g·kg-1), respectively. The TST, WT, SE and SOL was 7.9 ± 1.1 h, 45 ± 20 min, 91 ± 3 % and 5 ± 9 min, respectively. Total daily energy intake (MJ) increased WT [β=3, 95%CI: 0.2-5; p=0.03] and lengthened SOL [β =5, 95%CI:1-9; p=0.01]. Total daily protein intake (g·kg-1) increased WT [β =4, 95%CI:0.8-7; p=0.01], while evening (>6pm) protein intake (g·kg-1) shortened SOL [β =-2,

95%CI:-4 to -0.4), p=0.02). Evening sugar intake (g·kg-1) reduced TST (β =-5, 95%CI:-10 to -0.6; p=0.03) and decreased WT (β =-1, 95%CI:-2 to -0.3; p=0.005. A longer period between the evening meal consumption and bedtime reduced TST (β =-8, 95%CI:-16 to -0.3; p=0.04).
CONCLUSION: Dietary factors including the timing of evening meals, daily energy and protein intake and evening sugar intake can influence TST, WT and SOL in elite AFL players. Future research should investigate experimental manipulation of these dietary to determine their cause-and-effect relationship with sleep. The current findings and future research may help guide dietary recommendations to improve sleep in athletes, promoting improved recovery, athlete well-being and subsequent performance in training and competition.

INTRODUCTION: Peripheral arterial disease (PAD) is characterised by impaired blood flow to the lower limbs caused by atherosclerotic lesions in the conduit arteries. PAD also has a negative impact on skeletal muscle capillary density and structure. Using contrast enhanced ultrasound (CEU), it has previously been shown that leg muscle microvascular blood flow (perfusion) is impaired in response to high intensity exercise (1), but not submaximal intensity exercise (2), in patients with PAD. It is unclear whether these perfusion responses are due to a microvascular impairment or merely reflect the limited conduit artery flow. Therefore, in a group of PAD patients (n=9, 59±7 years) undergoing lower limb revascularisation, we aimed to determine the effect of conduit artery blood flow restoration on muscle microvascular perfusion in response to submaximal leg exercise.
METHODS: Microvascular perfusion (microvascular volume x flow velocity) of the medial gastrocnemius muscle was measured before and immediately after a 5-min bout of submaximal, intermittent isometric plantar-flexion exercise (300N) using contrast-enhanced ultrasound imaging. Contraction-by-contraction whole-leg blood flow was also measured using strain-gauge plethysmography. Assessments were performed at baseline prior to revascularisation, then repeated following full recovery (44±11 days) after revascularisation.
RESULTS: With revascularisation there was a significant improvement in the resting ankle-to-brachial blood pressure index (ABI: pre: 0.71±0.13, post: 0.96±0.13; p=0.011), and an increase in whole-leg blood flow during leg exercise (p<0.05). The rise in muscle microvascular perfusion with leg exercise did not change significantly after revascularisation (pre: 3.50±2.49, post: 3.86±1.50 aU.s-1; p=0.711). However, the parameters that determine perfusion changed following revascularisation with a reduction in the microvascular volume response (pre: 7.16±3.76, post: 2.38±0.70 aU; p=0.016), and a tendency for microvascular flow velocity to increase (pre: 0.27±0.15, post: 0.58±0.27 aU.s-1; p=0.067) in response to exercise.
CONCLUSION: Improvements in conduit artery blood flow with revascularisation were not accompanied by changes in the muscle microvascular perfusion response to exercise. The changes observed in microvascular flow volume suggest that alterations in microvascular flow distribution may compensate for the limited conduit artery flow, and thereby maintain perfusion, during submaximal leg exercise in patients with PAD.

THE INFLUENCE OF MATURATIONAL STATUS ON INTRA-CRANIAL VELOCITY AND NEUROVASCULAR COUPLING IN PRE AND POST-PUBERTAL BOYS

TALBOT, J.S.1, PERKINS, D.1, OLIVER, J.L., LLOYD, R.S., MCMANUS, A.M.2, AINSLIE, P.N.2, PUGH, C.A.1, STEMBRIDGE, M.1

1CARDIFF SCHOOL OF SPORT & HEALTH SCIENCES, CARDIFF METROPOLITAN UNIVERSITY, CARDIFF, UK. 2CENTRE FOR HEART, LUNG & VASCULAR HEALTH, UNIVERSITY OF BRITISH COLUMBIA, KELOWNA, BC, CANADA

INTRODUCTION: Neurovascular coupling (NVC) describes the regulation of cerebral blood flow in relation to increased synaptic activity and metabolic demand at active neurovascular units. Cerebrovascular tone is influenced by changes in estrogen and testosterone (1); however, it is not known whether biological maturation modulates NVC (2). Therefore, the aim of this study was to quantify the NVC response in pre and post-pubertal boys.
METHODS: 12 pre-pubertal (10.8 ± 1.7 yrs, 142.2 ± 8.9 cm and 32.6 ± 5.0 kg) and 10 post-pubertal (15.6 ± 0.8 yrs, 177.0 ± 8.6 cm and 68.1 ± 12.6 kg) physically active boys were recruited from the local community. Pubertal status was categorised by an estimation of somatic maturity (3). Middle and posterior cerebral artery intra-cranial blood velocities (MCAv and PCAv respectively) were recorded continuously using trans-cranial Doppler. Baseline measures were recorded following 15 minutes of supine rest. The NVC was assessed over five cycles of visual stimuli and normalised post-hoc for changes in arterial blood pressure (photoplethysmography) and end-tidal CO2. A progressive exercise test to exhaustion was carried out to assess cardiorespiratory fitness following the NVC assessment. Data are reported as the group mean ± SD. Between-group differences were determined by independent t-tests and the relationship between cardiorespiratory fitness and NVC examined via Pearson's correlation.
RESULTS: Pre-pubertal boys were 2.7 ± 0.8 years pre, and post-pubertal boys were 1.8 ± 0.4 years post predicted peak height velocity respectively. At baseline, there were no differences in MCAv (59.9 ± 13.4 vs 53.1 ± 11.9 cm·s-1; P = 0.24) or PCAv (39.8 ± 10.1 vs 39.1 ± 7.9 cm·s-1; P = 0.86) in pre and post-pubertal boys, and VO2peak (57.0 ± 8.3 vs 55.5 ± 10.8 ml·min·kg-1; P = 0.72) was also similar. The peak PCAv response during the NVC stimulus was not different between pre and post-pubertal boys (29.4 ± 8.0 vs 27.9 ± 8.2%; P = 0.69) and the NVC response was not related to cardiorespiratory fitness in our moderate-to-high fit group (r = 0.25; P = 0.36).
CONCLUSION: In summary, our data indicate that pubertal development does not modulate the regulation of blood flow to active neurovascular units in boys. However, further research is required in both sexes and with a greater heterogeneity of fitness that employs more

comprehensive assessments of cerebrovascular function to understand how maturation and cardiorespiratory fitness influences the regulation of brain blood flow throughout adolescence.

INVESTIGATING THE POTENTIAL FUNCTIONAL EFFECTS OF POLYMORPHISMS WITHIN THE PROTEOGLYCAN AND ANGIOGENESIS GENES IN A GENETIC SUSCEPTIBILITY MODEL FOR ACHILLES TENDINOPATHY

RAHIM, M., WILLARD, K., LAGUETTE, M.J., LUHANGA, G., BALLIM, R.D., COLLINS, M., SEPTEMBER, A.V.
DEPARTMENT OF HUMAN BIOLOGY, UNIVERSITY OF CAPE TOWN

INTRODUCTION: Polymorphisms within genes encoding proteoglycans such as biglycan (BGN), decorin (DCN) and the angiogenesis protein vascular endothelial growth factor A (VEGFA), were previously implicated in susceptibility to Achilles tendinopathy. However, the biological mechanism through which these polymorphisms may influence susceptibility remains to be elucidated. Therefore, this study aimed to investigate the potential functional effects of these genetic loci on relative gene and protein expression levels at a) baseline and b) in response to treatment with TGF-β1, using an ex vivo model.
METHODS: Fourteen healthy participants were classified according to their genetic risk profile as being reduced, unknown or increased susceptibility based on previous genotype data. Each participant donated a skin biopsy from which primary fibroblast cell lines were established. Messenger RNA expression and protein levels for the genes of interest were measured at baseline and after TGF-1β treatment, using RT-PCR and Western blot, respectively.
RESULTS: Interestingly, the growth rates of cells in the different genetic risk groups varied; with cells in the reduced susceptibility group showing a faster growth rate compared to the increased susceptibility group. Significant differences were noted at baseline and after TGF-1β treatment. At baseline, mRNA expression was significantly higher in the reduced susceptibility group compared to the increased susceptibility group for both BGN [reduced: 1.13 arbitrary units (AU), n=8; increased: 0.46AU, n=10; p<0.001] and VEGFA [reduced: 1.02AU, n=8; increased: 0.52AU, n=10; p=0.001]. Additionally, relative VEGFA expression was significantly higher in the reduced risk group in response to TGF-1β treatment (reduced: 3.43AU, n=8; increased: 2.45AU, n=10; p=0.001). Preliminary Western blot analyses showed an increase in biglycan mRNA expression in response to TGF-β1 treatment in the reduced susceptibility group.
CONCLUSION: These novel findings provide preliminary evidence highlighting a working hypothesis on the biological significance of these genes on injury risk. Further analysis of the protein expression levels and correlation to the relative gene expression is currently underway.

CHANGES IN P-WAVE AND PQ-INTERVAL OF THE ELECTROCARDIOGRAM IN MALE MIDDLE-LONG RUNNERS OVER A THREE-YEAR TRAINING PERIOD*

NIE, J., MA, S.S., SHI, Q.
MACAO POLYTECHNIC INSTITUTE

INTRODUCTION: Electrocardiogram (ECG) changes in athletes have been found and usually, reflect structural and electrical remodelling of the heart as an adaptation to regular physical training (athlete's heart). However, these findings may be limited by cross-sectional observation. By the longitudinal observation, the study evaluated the P-Wave and PQ-interval pattern alterations caused by three years endurance training in middle-long runners.
METHODS: Resting computerized 12-lead ECGs were obtained in 19 male middle-long runners (aged 26.0±6.4 years; years of training for competitive races 9.8±5.5 years) before and after three-year endurance training. The analysis focused on the voltage and duration of T-wave and PQ-interval.
RESULTS: The athletes had significantly reduced the duration of P-wave in V5 lead, compared with the pre-training (71.1±11.3 vs. 82.5±16.6 ms, $P < 0.05$). After three-years training, the voltage and duration of P-wave in other leads were similar to pretraining values ($P>0.05$). Besides, there was no significant difference in PQ interval over a three-year training period ($P >0.05$).
CONCLUSION: The findings from the present study show that, for the middle-long runner with training experiences, endurance training of three years might reduce P-Wave duration in V5 lead but didn't influence atrioventricular nodal conduction time. The result of the study can facilitate resting ECG interpretation for the middle-long distance runners.

SKELETAL MUSCLE MICROVASCULAR BLOOD FLOW AND POSTPRANDIAL GLYCAEMIC RESPONSES TO A HIGH-GLUCOSE MIXED MEAL INGESTED 3 HOURS AFTER EXERCISE.

PARKER, L., MORRISON, D., BETIK, A., ROBERTS-THOMSON, K., WADLEY, G., SHAW, C., KESKE, M.
DEAKIN UNIVERSITY

INTRODUCTION: Skeletal muscle microvascular blood flow increases in the post-prandial state to augment glucose disposal. However, high-glucose meals impair muscle microvascular blood flow which can contribute to elevated postprandial glycaemia. In contrast, insulin-mediated glucose uptake in skeletal muscle is enhanced post-exercise, in part via increased responsiveness of the microvasculature to insulin. The aims of this study were to determine whether prior exercise could protect the microvasculature from a high-glucose meal and improve postprandial glycaemia.
METHODS: Six young healthy males (Age: 27 ± 1 years [mean ± SEM]; Weight: 77 ± 3 kg) ingested a high-glucose mixed meal (10 kcal.kg-1; 45% carbohydrate [1.1g/kg glucose], 20% protein, and 35% fat) in the morning after an overnight fast (control trial), and on a separate day three hours after aerobic cycling exercise (1 hr at 75% VO2peak). Skeletal muscle microvascular blood flow was measured via con-

trast enhanced ultrasound prior to meal ingestion, and 1 hr and 2 hrs postprandial. Blood glucose and plasma insulin were measured every 15 minutes throughout the 2 hr postprandial period.
RESULTS: Compared to baseline (pre-meal), the high-glucose meal impaired muscle microvascular blood flow at 1 hr (~-48%; p = 0.012) and 2 hrs post-prandial (~-66%; p = 0.009). Compared to the control trial, microvascular blood flow was elevated 3 hrs post-exercise (pre-meal), and remained elevated during the 2 hr postprandial period (main effect between control and exercise trial of ~104%; p = 0.005). Despite post-exercise microvascular blood flow being elevated before and during the meal, microvascular blood flow was impaired by a similar extent as the control trial (main time effect p = 0.004; interaction effect p = 0.211) at 1 hr (~-51%; p = 0.012) and 2 hrs post-prandial (~-37%; p = 0.009). Acute exercise did not significantly alter the 2 hr postprandial area under the curve for blood glucose (Control: 724 ± 150 mmol/Lx2hr; Exercise: 782 ± 57 mmol/Lx2hr, p = 0.49) or plasma insulin (Control: 6398 ± 2757 μU/mLx2hr; Exercise: 5228 ± 1735 μU/mLx2hr, p = 0.35). Interestingly, three out of six participants exhibited significantly lower postprandial glucose after exercise (Control: 869 ± 40 mmol/Lx2hr; Exercise: 760 ± 48 mmol/Lx2hr, p = 0.05), whereas the remaining three participants exhibited significantly elevated postprandial glucose after exercise (Control: 579 ± 37 mmol/Lx2hr; Exercise: 805 ± 56 mmol/Lx2hr, p = 0.03).
CONCLUSION: Acute aerobic cycling exercise increases skeletal muscle microvascular blood flow 3 hrs after exercise, which persists during the 2 hr period after consumption of a high-glucose meal. Postprandial glycaemic responses to the meal after exercise were highly divergent in healthy men and were not linked to changes in muscle microvascular blood flow. Further research is required to understand the relationship between skeletal muscle microvascular blood flow and divergent postprandial glycaemic responses after exercise.

POST-EXERCISE MALONDIALDEHYDE ELEVATION AND EXERCISE INTENSITY ARE ASSOCIATED WITH TROPONIN ELEVATION: THE INDONESIAN NORTH COAST AND TOUR DE BOROBUDUR 2017 TROPONIN STUDY

AZAM, M., RAHAYU, S.R., FIBRIANA, A.I.

UNIVERSITAS NEGERI SEMARANG

INTRODUCTION: Post-exercise cardiac-troponin elevation was related to the decreased of cardiac function, however, the mechanism remains unclear. Studies also reported oxidative stress occurs after prolonged exercise. Present study aimed to explore the relationship between malondialdehyde (MDA) and cardiac troponin I (cTnI) elevations after prolonged cycling.
METHODS: Ninety-two male participants of long-distance cycling tour were agreed to participate in this study. Baseline and post-exercise blood samples were collected to determine MDA and cTnI levels. Biochemical parameters were measured at baseline. Exercise intensity was examined by recording heart rate (HR) and was determined as the percentage of peak HR to maximal predicted HR. MDA and cTnI elevations were defined as a positive difference of post-exercise to baseline MDA and cTnI levels, respectively.
RESULTS: Eighty-eight participants (age, 45.3 ± 11.47; body mass index (BMI), 24.2 ± 3.03) completed cycling tour and involved in the analysis. Subjects characteristics were comparable based on touring category, except HDL-cholesterol levels. MDA levels were increased significantly from 190.18 μmol/mL at baseline to 210.90 μmol/mL post-exercise. cTnI levels were increased from 5.16 ng/dL to 13.65 ng/dL as well. Alongside this increase, MDA elevations are associated with cTnI elevations after prolonged cycling. Binary regression logistic analysis concluded that MDA elevation and exercise intensity were related to cTnI elevations after prolonged cycling.
CONCLUSION: The current findings add to evidence that cTnI elevations after prolonged exercise are associated with oxidative stress condition, defined by MDA elevations. However, previous study concluded contrary condition i.e. oxidative stress did not relate to the cTn elevation after strenuous exercise(1). Oxidative stress involved in the pathological mechanism of coronary artery diseases(2). Although the cTn release after exercise is not evidentiary for myocardial injury(3), current study proved the association between oxidative stress process and cTn elevations after prolonged cycling.

OP-SH15 Sociology: Children and gender

TOO YOUNG FOR SPORT: AN ANALYSIS OF ORGANIZED SPORT ACTIVITIES FOR YOUNG CHILDREN IN NORWAY AND SWEDEN

SOLENES, O., HEDENBORG, S.

MOLDE UNIVERSITY COLLEGE / MALMÖ UNIVERSITY

Introduction
The aim of this presentation is to map out and analyse sport activities for pre-school children in Sweden and Norway. Over time, sport has followed a general pattern of childification – in which sports associations and agents in the commercial sports sector increasingly offer activities for (younger) children (Lindroth 1991; Goksøyr 2008; Solenes 2009; Carlsson & Fransson 2006:2). In this presentation equestrian sports will be given special attention, although a general mapping out of activities for pre-school children in other federations will be presented and analysed too.
Theory and method
Perspectives derived from the sociology of childhood will be used (Hedenborg 2006; James & James 2004, 2012; Prout 2005; Qvortrup 2009), arguing that childhood are socially constructed, as well as historically and socially contingent. The dominant construction of childhood in modern educational theory is that of the competent child (Samuelsson & Carlsson 2003). The paper discusses this as a possible explanation to why sport activities are offered to pre-school children.
In this study, we conduct a mapping out of activities for pre-school children in the 51 Norwegian, and 71 Swedish specialized sport federations, using registered activities/memberships, information from the federation's official webpages and structured telephone interviews with representatives from the federations with the highest number of pre-school children.

Results
Gymnastics, Football and Swimming are among the biggest federations in relation to pre-school children in both Sweden and Norway. In Sweden equestrian sports is the 7th biggest. In Norway, equestrian sport is registered as the 14th biggest federation in relation to number of pre-school children. This number is, however, possibly higher as many private riding schools (not members of the Equestrian Federation) offer and organize activities for this group.
A study of the federations indicate that special activities organized for the pre-school children, prepare them for latter sporting activities. It seems plausible to conclude that pre-school children are seen as competent enough to take part of these activities. Programs designed for pre-school children in some of the specialized sports federations are constructed around the idea of learning even complex skills through playing. In equestrian sports, another pattern is seen too, as the children have to respect the well-being and welfare of the horses.

YOUNGER CHILDREN AND OLDER HORSES, EQUESTRIAN SPORT FOR PRE-SCHOOL CHILDREN

ROSÉN, A., THORELL PALMQUIST, G., HEDENBORG, S.

FACULTY OF EDUCATION AND SOCIETY

Younger Children and Older Horses, Equestrian Sport for Pre-school Children
Annika Rosén
Gabriella Thorell Palmquist
Susanna Hedenborg
Introduction & aim
Equestrian sport is one of the largest sports for girls/women in Sweden. It´s offered by riding schools and gather riders from all social groups/geographical areas. Riders attend lessons once a week in groups of 5–12 lead by an instructor. Many riding schools offer riding for pre-school children and equestrian sport has gone through childification – a process in which younger children are offered sport activities by associations/agents in the commercial sector (Lindroth 1991). Yet, there are few studies of sport activities for young children (Hedenborg & Fransson 2011). The aim of this project is to increase knowledge about activities for young children in equestrian sport. How are activities for young children presented and carried out; how are safety aspects considered; what kind of equipment and horses are used in these activities; how are horses kept and cared for?
Theory & Method
The material consists of nine semi-structured interviews with Swedish riding school managers. The interviews are transcribed and analyzed using content analysis (Neuendorf 2019) and concepts to explain the characterization of equestrian sports/stable environments (Henderson 2018; Thorell & Hedenborg 2015); the sociology of childhood; learning and educational perspectives (Dewey 2004; Piaget 1952).
Results & discussion
The managers discussed the importance of reaching children from 2-¬3 years, with activities stressing the role of play in learning and relationships. This prepares them with horse/stable/communication knowledge for further riding. The activities and instructors' education vary, and many of them are not trained in early childhood development which may have impact on safety. The managers pointed to the importance of using safe horses for young children. The horses used were older, experienced, well-educated and horses living outdoors. The outcomes of this study are useful for instructors, the Equestrian Federation and for pedagogical content in education of future riding instructors.

VALIDATION OF THREE WIDELY USED QUESTIONNAIRE ITEMS INTENDED TO ASSESS ACTIVE COMMUTING AMONG ADOLESCENTS

MALNES, L.1, HAUGEN, T.1, HANSEN, B.H.1, KOLLE, E.2, BERNTSEN, S.1

1:UNIVERSITY OF AGDER 2:NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Active commuting (cycling or walking to school) may increase the level of physical activity in adolescents. Self-reported transport mode and commuting time through questionnaire have been the most applied method; however, validity and reliability of the instruments are rarely reported. This study aim was to investigate agreement between a travel diary and three questionnaire items on travel mode to and from school, and travel time to school.
METHODS: The present study was a part of the School In Motion (ScIM) project. Students (n = 50) in the 9th grade (14 to 15 years of age, 67 % girls) from seven different schools in Norway participated in this part of the study. In spring 2018, transport habits were reported using items based on the Health Behaviour in School-aged Children (HBSC) questionnaire and a five-day travel diary, to and from school. Level of agreement between the HBSC and the travel diary were analysed using Cohens Kappa, and Spearman correlation for mode and commuting time, respectively.
RESULTS: Data from the travel diary showed that the most common reported travel mode was public transport to and from school (32 and 38 %, respectively), followed by walking (24 and 28 %), bicycling (24 and 26 %) and car (20 and 8 %). Agreement between the HBSC and the travel diary for travel mode to and from school were $\kappa = 0.65$ ($P < 0.001$) and $\kappa = 0.72$ ($P < 0.001$), respectively. However, percentage of participants that measured the same mode in the diary as in the HBSC was higher for walking (92 and 85 %) and bicycling (92 and 92%), than for motorised transport (58 and 73 %) to and from school, respectively. There was a positive correlation between the HBSC and the travel diary for travel time ($\rho = 0.60$, $P < 0.001$).
Discussion:

The findings indicated a higher agreement in students walking and bicycling compared to motorised transport. Also, compared to the diary, the questionnaire items showed a tendency towards underestimating travel time. The present study provides a measure of construct validity on three highly used questionnaire items in research focusing on active commuting, which may enable researchers to more accurately and critically interpret findings based on these instruments.

THE ADAPTATION AND DEVELOPMENT OF STUDENT-ATHLETES: A PERSPECTIVE FROM THE CONCEPT OF MEANING

YANG, C., LIAO, C.

NATIONAL TAIWAN SPORT UNIVERSITY

The Adaptation and Development of Student-Athletes: A Perspective from the Concept of Meaning
Yang, C-H., Liao, C-M.
National Taiwan Sport University
Introduction
Student-athletes play two roles at the same time. They are expected to fulfill both the duties of a student and an athlete and tend to suffer from the conflicts of these two roles. How student-athletes perceive and make reasonable associations among things, relationships, and events in and across the academic and sport domains may be the foundation of an adaptive development of student-athletes. The purpose of this study was exploring in nature, attempting to describe the adaptation and psychological development of student-athletes based on the theoretical framework of meaning. Specifically, the validity of the concepts of meaning (Mackenzie & Baumeister, 2014), the meaning in life (George & Park, 2016; Martela & Steger, 2016), and meaning-making model (Park, 2010) was examined.
Methods
Ten collegiate student-athletes (male=6, female=4; Age M= 21, SD= 0.67) from 7 different sports were interviewed based on the principles of narrative inquiry and visual narrative methods (Busanich, McGannon, & Schinke, 2016). They were asked to create a visual image regarding the relationships of their school work, sports, and other activities with a circle which represented themselves. Interviews were conducted and analyzed based on the concepts of meaning, the meaning of life, and meaning-making model.
Results and discussion
The results of content analysis of the interview data showed that student-athletes' perception and description of their academic, athletic, and interpersonal experience were in line with the concepts and theories of meaning. The findings of this study provide a theoretical as well as an empirical basis for future investigations of a more systematic understanding to the adaptation and psychological development of student-athletes.

SUBCLINICAL DISORDERED EATING AND BODY DISSATISFACTION IN NORMAL WEIGHT CHILDREN - THE ROLE OF SPORTS ACTIVITY

GRIMMINGER-SEIDENSTICKER, E.

TU DORTMUND UNIVERSITY

INTRODUCTION: Body dissatisfaction is considered as "one of the most robust risk factors for eating disturbances" (Stice, 2001, p. 55). Sports activity is one of the discussed factors in the context of disordered eating and body dissatisfaction, even if its role remains contradictory or ambivalent. Although, 45% of 8 to 14 years old children are affected by body dissatisfaction and 20% of them report disordered eating attitudes, most of the existing studies are focused on adolescents (or young adults), and the relationships between sports activity, body dissatisfaction and eating disorders in children remain unclear. Thus, the presented study explores which role sports activity play in the context of subclinical disordered eating in relation with body dissatisfaction among normal weight children.
METHODS: In total, a sample of 824 children aged 7 to 12 years filled in a questionnaire, containing the Body Esteem Scale (weight and shape concerns; Bender, 2011) and the Muscularity Concern Scale (Bender, 2011) . Subclinical disordered eating was examined by the subscale "restraint intake" of the Dutch Eating Behavior Questionnaire for children (Franzen, & Florin, 1997). Children´s sport activity level was derived from their motor abilities, tested with the German Motor Ability Test (Bös et al., 2009) which integrated height and weight measurement.
RESULTS: In normal weight boys, a stepwise multiple linear regression analysis showed that weight and shape concerns enhance restraint intake. The interaction of weight and shape concerns with sports activity decreases significantly restraint intake ($R2 = .15$, $F(1, 270) = 5.20$, $p = 0.023$). Muscularity concerns enhances and the interaction of muscularity concerns with sport activity decreases restraint intake ($R2 = .10$, $F(1, 279) = 3.94$, $p = 0.048$). In normal weight girls, a stepwise multiple linear regression model showed that weight and shape concerns enhance restraint intake ($R2 = .19$, $F(1, 238) = 55.89$, $p < 0.001$). Furthermore, we can state that muscularity concerns increase restraint intake, and that sports activity decreases restraint intake ($R2 = .12$, $F(1, 259) = 6.54$, $p = 0.011$).
Discussion:
A significant moderator effect between weight and shape concerns and sports activity as well as muscularity concerns and sports activity was shown for boys. In contrast, no significant interaction effect between weight and shape concerns and sports activity as well as mus-

cularity concerns and sports activity was shown for girls. The findings might implicate that - at least for boys - sports activity could be considered as a protective factor in the context of childish body dissatisfaction. For girls, the findings remain puzzling. As shown for adolescent girls, shape and weight concerns enhance significantly restraint intake. Whereas sports actvitity decreases restraint intake, however not in the interplay with body dissatisfaction. In this context, sports activity does not have a buffering effect for girls.

IMPACT OF THE TALENT DEVELOPMENT ENVIRONMENT ON THE WELLBEING AND BURNOUT OF CARIBBEAN YOUTH TRACK AND FIELD ATHLETES

INTRODUCTION: To optimize the process of developing young athletes, it is important that the critical environmental factors that facilitate athlete performance and impact athlete wellbeing are understood. This study examines the talent development environment of youth track and field athletes within the Caribbean region and explores the relationship with their subjective wellbeing and burnout levels.
Design and method:
Cross-sectional study. 400 talented Caribbean youth track and field athletes (male = 198 and females = 202) between the ages 13 and 20 years participated in this study. Athletes responded to a survey which included the Talent Development Environment Questionnaire (TDEQ-5), the World Health Organization Wellbeing Index (WHO-5) and the Athlete Burnout Questionnaire (ABQ).
RESULTS: Linear regression models indicated that a positive and supportive talent development environment was associated with better athlete wellbeing and reduced athlete burnout. More specifically, the talent development environment factors of long-term development focus, alignment of expectations and support network were positively associated with athlete wellbeing, while holistic quality preparation was inversely associated with athlete burnout. Moreover, training more than 7 hours per week negatively moderated the relationship between the athletes' perceptions of their development environment and burnout levels.
CONCLUSION: Talent development environments that were perceived as supportive, with clearly outlined goals, and a long-term development focus were associated with better athlete wellbeing and lower reported burnout. Findings can be used to improve talent development practices in youth athletes as well as influence the formulation and implementation of effective youth sporting policies in the Caribbean region.

THE IMPACT OF THE MENSTRUAL CYCLE ON PERFORMANCE: ELITE ATHLETES' PERCEPTIONS

FORREST, L.J.1, FINDLAY, R.J.1, MACRAE, E.1, EASTON, C.1, WHYTE, I.Y.2

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: In recent times, there has been an increased interest in the female athlete. Traditionally, studies have generally focussed on hormonal changes associated with the menstrual cycle (MC) and their associated effects on physiological outcomes. However, the perceived impact of the MC on sporting performance from an athlete's perspective is unknown. Therefore, through an investigation of the athletes' past and current experiences, this study aimed to identify the perceived impact of the MC on general well-being, training and competition performance in a group of international team sport athletes.
METHODS: Using an inductive approach, fifteen elite female players participated in semi-structured interviews (age: 24.5 +/- 6.2 years). Interviews were conducted individually to elicit experiences and perceptions of the MC and impact on their lives, including key areas of training and competitive performances. All interviews were recorded and transcribed verbatim, resulting in 87 A4 pages of text for thematic analysis. Inter-rater reliability checks were conducted with a concordance of agreement of 83%.
RESULTS: Two hundred and sixty two meaning units, 38 sub-themes, 10 themes, and 4 general dimensions emerged from a thematic analysis. The 4 general dimensions were derived and categorised as: 1. Indicators: physiological and psychological MC related symptoms such as dysmenorrhoea, flooding, reduced energy levels, worry, distraction, fluctuating emotions and reduced motivation; 2. Impact: perceived impact of the MC on different aspects of daily lives and performance including negative and neutral responses; 3. Resolution: the methods/approaches in dealing with MC related concerns including self-medication or expert treatment and 4. Support: available advice or treatment from expert and non-expert individuals. Almost half of all athletes (47%) reported current or historical irregular MC whilst 33% perceived heavy menstrual bleeding. Ninety-three percent of athletes reported MC related symptoms, with 68% perceiving these symptoms as negatively affecting their daily life, training and/or competition performances, resulting in worries and fears. Two-thirds of athletes self-medicated to alleviate symptoms. Athletes also reported a perceived lack of awareness of their symptoms and associated potential issues from the coaching and support team and had a general concern about what advice can be given to them and by whom.
CONCLUSION: This study provides the first insight into the symptoms experienced and the perceived impact that the MC can have on training and competition performance. Significantly, it highlights the requirement of expert support mechanisms for athletes. Further consideration of a variety of both team and individual sports of different levels of performance could provide a greater understanding of the female athlete.

OPERATION OF SPORTS FACILITIES. IS THERE A HEALTH-PROMOTION FUNCTION? 25 CASES FROM HUNGARY AND THE WORLD

GYÖMÖREI, T., MÁTÉ, T.

SZÉCHENYI ISTVÁN UNIVERSITY

Placing sports facilities (within a given city) is always a risky decision. The host city and the sport company - with a parallel to the corporate site selection - should choose a location where, in addition to settlement development considerations, the expected revenue from the sport economy will exceed the expected maintenance and operating costs as much as possible, furthermore from a social point of view, the desired effects are realized, their functions are fulfilled (community building, health care, entertainment).
In the case of sports facilities, market-oriented placement is a rational decision. A company that follows such a strategy will be established to its customers, trying to minimize the "delivery" distance. The functions of the sports facilities are different, including customers, sports consumers. We can basically differentiate active and passive sports consumers (András, 2003). The sport and thus the health-

preservation and health promotion function of sports facilities, like the more active and active display of active sports among the general population in Hungary, has been felt since the late 1990s (Gyömörei, 2012), the international community, Sport For All, preceded this.
The aim of the research is such analytical research method which targeting consumer behavior and organizational effectiveness, „health-sport", economic and social effects of health development area of sport. In case of our research, the operating environment and operation model of the sport facilities were investigated in 20 Hungarian and 5 international cities (Sindelfingen, Ingolstadt, N. Novgorod, Colmar, Wuhan) including 8 different sport facilities (swimming pool, multifunctional sports hall, ice rink, football stadium, athletic center, tennis court, gymnasium, outdoor sports park).
Our research question is, how do the goals related to the health-preservation and health-promotion of the community appear during the investment of the sports facilities and during the utilization and operation?
In the framework of quantitative research, the comparative analysis was carried out in pairs based on the following aspects: financing, primary function, the range of services, occupancy, residential sports, health-preservation and health-promotion, and related motivation tools.
The results indicate, which ownership and operation models are the most common in 2019. Is the health-promotion and health-preservation of the population a determinable factor in the installation and operation of sports facilities? How is the distribution of capacities distributed across different types of facilities?
The research is supported by the European Union and realized with joining to the project of sport, recreation, and health-economics cooperation research network.

IS-SH04 Motivation in physical education: A focus on teachers role through self-determination theory

AUTONOMY-SUPPORTIVE TEACHERS IN PHYSICAL EDUCATION. UNDERSTANDING DISPOSITIONAL AND CONTEXTUAL DETERMINANTS.

COTERON, J.
UNIVERSIDAD POLITÉCNICA DE MADRID

Self-Determination Theory distinguishes three basic psychological needs that, applied to the educational field, appear as required conditions for the students to get optimally involved into their learning process. Teachers must support these three needs (competence, autonomy and relatedness) to enhance intrinsic motivation and promote positive behaviour and effective learning in physical practice.
Autonomy need satisfaction has long been recognized as a fundamental factor in the promotion of optimal motivation. The subjective experience of autonomy in PE students depends on the conditions created in the learning environment by teachers through the motivational styles implemented.
Nevertheless, does this autonomy-supportive style depends on the personal teacher´s characteristics or can be easily defined and taught to them?
In this lecture, research carried out in three different countries in the last years will be exposed in order to give clues on the path to improve the teachers training, design new interventions and generate pedagogical materials according to the actual teaching and learning scenario.
The session could be of interest to abroad audience including physical education teachers, sport psychologists and researchers.

A MULTILEVEL APPROACH TO UNDERSTAND STUDENTS' MOTIVATION TAKING INTO ACCOUNT TEACHERS' ANTECEDENTS

FRANCO, E.
UNIVERSIDAD PONTIFICIA COMILLAS

Self-Determination Theory has enjoyed increasing popularity in physical education research during the past decade and have generated insights into the motives underlying learners' behavior related to adaptive physical activity outcomes. The target population of research has been primarily comprised of students. Countless studies have confirmed the relationships of a motivational sequence among different samples of students consisting on need support in physical education > student need satisfaction > motivation > outcomes in physical education and leisure time.
Moving line of research forward is needed in order to gain some more knowledge and understanding of those gaps which remain unclear. In the last years it has been suggested that this motivational sequence might be affected by the teachers. Thus, a research line is being focused on teachers in order to complete the model.
In this lecture, a large study is presented in which teachers' antecedents as predictors of subsequent factors are analysed using multilevel modelling.
The study will be the first step to design a training programme for teachers focusing on strategies which are effective and are not found easy to implement by the teachers.
The lecture could be of interest to abroad audience including physical education teachers, sport psychologists and researchers.

IMPORTANCE AND FEASIBILITY PERCEIVED IN MOTIVATIONAL STRATEGIES BY PHYSICAL EDUCATION TEACHERS

HESS, C.M.
UNIVERSIDADE ESTADUAL DE CAMPINAS

All teachers face the universal challenge to motivate their students so that they can engage in and benefit from the learning activities they provide. Several studies in the physical education context have proven that teacher-provided motivational strategies (e.g., providing autonomy support, offering different levels of difficulty for the activities they design,…) foster greater engagement, self-regulation, learning, achievement and well-being. Despite evidence, there are several teachers who do not implement this kind of strategies during their

lessons. Previous studies have suggested that beliefs which might underlie teacher's performance are the belief of effectiveness (how important different strategies are to make their lessons effective) and feasibility (how easy is to implement a particular strategy during everyday instruction). In this lecture, a study is presented in which a large sample of Brazilian physical teachers reported their beliefs about certain motivational strategies. The study will be the first step to design a training programme for teachers focusing on strategies which are effective and are not found easy to implement by the teachers.

IS-PM06 The lungs during exercise: often overlooked, often misunderstood [Clinical track]

RESPIRATORY RESPONSES TO EXERCISE IN ATHLETES WITH SPINAL CORD INJURY

ROMER, L.M.

BRUNEL UNIVERSITY LONDON

Individuals with spinal cord injury (SCI) exhibit restrictive pulmonary dysfunction, characterised by a lesion-dependent reduction in lung volumes. During exercise, individuals with cervical SCI demonstrate an immediate and sustained rise in operating lung volumes. This so-called dynamic hyperinflation increases the elastic work of breathing, impairs the capacity of the inspiratory muscles to generate pressure, and reduces the contribution of the diaphragm to inspiration. In individuals with complete cervical SCI, maximal heart rate is usually limited to ~120-130 b/min and vasomotor tone is impaired. Consequently, blood cannot be redistributed effectively during exercise. This has been associated with venous pooling in non-active vascular beds and may, in turn, restrict O2 transport to working muscles by compromising venous return and stroke volume. Previous studies have attempted to increase O2 transport by using a supine position during arm exercise, electrical stimulation of lower-limb muscles, and application of lower-body positive pressure. The effects of these interventions on exercise responses have been variable. An alternative method has been to apply external compression to the abdomen using an elastic binder. Using this approach, binding-induced changes in respiratory mechanics have been shown to improve the circulatory function of the diaphragm, thereby enhancing the overall exercise response through an increase in venous return, cardiac output and O2 transport.

SEX DIFFERENCES IN THE VENTILATORY RESPONSE TO EXERCISE

SHEEL, A.W.

UNIVERSITY OF BRITISH COLUMBIA

Studies examining the pulmonary physiology of exercise have primarily focused on young healthy men, whereas the response in women has received limited attention. Evidence is accumulating that the response of the lungs, airways and/or respiratory muscles to exercise is less than ideal and this may significantly compromise oxygen transport and exercise performance in certain groups of otherwise healthy subjects. For example, using high resolution computed tomography we have shown that when men and women are matched for lung size, the airway luminal areas of the larger conducting airways in women are significantly smaller than in men, which becomes physiologically relevant under conditions of high ventilation. The proposed session will present a summary of recent findings linking sex-based differences in airways to the integrated ventilatory response to exercise. A focus will be on new findings which show that young athletic women experience expiratory flow limitation more frequently and at a lower level of ventilation than men and that the oxygen cost of breathing is higher in women. Despite a higher work of breathing and mechanical constraint to the ventilatory response, women appear to be resistant to diaphragm fatigue. The mechanistic basis of this physiological paradox will be discussed.

ASTHMA IN ELITE ATHLETES: CAUSES AND CONSEQUENCES

KIPPELEN, P.

BRUNEL UNIVERSITY LONDON

With an overall prevalence of 8%, asthma/airway hyper-responsiveness (AHR) is the most common chronic medical condition in elite sport. The distribution of asthma/AHR is however skewed, with endurance-trained athletes being most at risk. Emerging evidence suggests that late onset of asthma/AHR in endurance athletes is driven by repeated osmotic changes within the airways as a result of the increased ventilatory demand of exercise. Using the latest available evidence, the author of the proposed session will explain how hyperpnoea-induced dehydration of the small airways and ensuing injury to the airway epithelium are thought to contribute to the development of asthma/AHR in elite athletes. The inflammatory basis of the respiratory condition will be discussed, and pharmacological and non-pharmacologic interventions to limit osmotic-driven airway perturbations will be evaluated. Finally, the consequences of asthma/AHR will be assessed, with a particular focus on its impact on airway calibre fluctuations during exercise and on exercise performance indicators.

Oral presentations

OP-PM26 High intensity interval training

EFFECTS OF SCHOOL-BASED HIGH-INTENSITY INTERMITTENT EXERCISE ON HEART RATE VARIABILITY AND ARTERIAL COMPLIANCE

KETELHUT, S., KIRCHER, E., KETELHUT, S.R., WEHLAN, E., HOTTENROTT, K., KETELHUT, K.

MARTIN-LUTHER-UNIVERSITY HALLE-WITTENBERG

INTRODUCTION: In the last years research has discovered that the relative intensity and not the duration of exercise is of more importance in relation to all-cause mortality (1). In this concern high-intensity interval training (HIIT) has been purposed as an effective alternative to traditional moderate intensity continuous exercise (MICE) inducing similar or even superior changes in cardio respiratory fitness and health-related markers in adults (2). Regardless of the positive effects evidence supporting the effectiveness of HIIT in children and adolescents are sparse. Thus the present study aimed to evaluate the effects of a school based high-intensity intermittent exercise intervention on heart rate variability (HRV) and established markers of arterial compliance in children.
METHODS: 40 students (mean age 10.7 ± 0.7 yr; 57% girls; BMI 19.8 ± 4.4 kg/m2) were randomized into intervention (INT) (N = 20) and control (CON) (N = 20) group. Throughout a 3 month experimental period both INT and CON took part in the regular physical education lessons (PE) 2 times a week. Only the INT received a HIIT during the first 20 minutes of the PE. Time and frequency domain measures of HRV were obtained using RS800CX (Polar, Finnland). Additionally, central blood pressure (BP), augmentation index (AIx), and aortic pulse wave velocity (aPWV) were assessed non-invasively using Mobil-O-Graph (IEM Stolberg, Germany).
RESULTS: After the intervention, INT showed a significant improvement in central systolic BP (-2,51 mmHG, p = 0.025), AIx (-3,88 mmHG, p=0,05), aPWV (-0,19 m/s, p < 0,001), RMSSD (10,58 ms, p = 0.004), pNN50 (7,52 %, p = 0.013), Low Frequency-Power (LF-Power) (-4,67 %, p < 0.001), High Frequency-Power (HF-Power) (5,96 %, p < 0.001) and LF/HF ratio (0.34, p < 0.001). No significant changes were observed for CON. Significant difference in the mean improvement could be detected for central systolic BP (-5.19 mmHg, p = 0.041), aPWV (-0.19 m/sec, p = 0.031), LF-Power (-5.13%, p = 0.014), HF-Power (-8,07%, p = 0.002) and LF/HF ratio (-0,439, p < 0.001) favoring INT.
CONCLUSION: A school-based and child specific HIIT induces meaningful improvements in arterial compliance, and HRV parameters in 11-year old children. These results highlight the potential of embedding HIIT within school setting, offering a time-efficient strategy for the strict school time table. Furthermore, short bouts of high-intensity exercise especially when applied in a child specific manor may be more natural, appealing and easier to adhere to than traditionally recommended MICE. This may aid in the development of self-directed physical activity in later life and thus reduces the burden of future cardiovascular disease.

CARDIORRESPIRATORY RESPONSE COMPARISON BETWEEN RESISTED AND ENDURANCE HIIT PROTOCOLS.

FERNANDEZ-ELIAS, V.E., ITURRIAGA, T., SANCHEZ-LORENTE, I.M., AYUSO, M., JIMENEZ, A.

UNIVERSIDAD EUROPEA DE MADRID

INTRODUCTION: High Intensity Interval Training (HIIT) has been proposed as an effective training method to improve cardiorespiratory fitness in general population. However, HIIT training can be performed under different protocols that could involve different cardiovascular adaptations. Resisted (RHIIT) and endurance (EHIIT) are the most common protocols presented in sports centers, being interval strength training for RHIIT or indoor cycling for EHIIT the most representatives and populars. We compared the two different protocols in order to analyze which exercise elicit a greater cardiorespiratory fitness response.
METHODS: 35 subjects, age 34.11±3.87 yo, weight 73.19±12.52 kg and height 165.72±24.28 cm, were divided into 2 groups, EHHIT (N=15) and RHIIT (N=20). All subjects performed a session of each of these group exercise modes, measuring the following: lactate level (Lac) before and after session, Rating of Perceived Exertion (RPE) with Borg scale (10 point) at the end, and heart rate (HR) during the session. Sessions were divided into zones of HR intensity (1) <70; 2) 70-80; 3) 80-90; 4) >90 %HRmax). The EHIIT mode consisted of 10 minutes of warm-up (85-95RPM) and cool down, main part of 25 minutes (65-100RPM). RHHIT included 10 minutes of warm-up (treadmill) and cool down, main part: metabolic training (6 burpees), weightlifting (3 PushPress), and gymnastic exercises (9 hanging knee raise).
RESULTS: The T test showed HRmean was higher in EHIIT compared to RHIIT (148.80±16.23 vs 134.90±19.150ppm respectively, p=0.027). Percentage of exercise time was lower in zone 1 and higher in zone 3 during EHIIT (15.50±22.10%) compared to RHIIT (15.50±22.10% vs 30.24±17.92%, p=0.037 and 32.19±20.17% vs. 19.57±11.54%, p=0.025 respectively). There were no significant differences in HRmax, Kcal, Lac, time in zone 2 and zone 4 between EHIIT and RHIIT.
CONCLUSION: Greater HRmean and longer exercise time in higher intensity zones observed during EHIIT indicate that this type of protocols (i.e. indoor cycling) have a greater exercise cardiorespiratory load than RHIIT protocols (i.e. interval strength training). Thus, in order to improve cardirrespiratory fitness, EHIIT exercise are more recommendable.

THE EFFECT OF ISCHEMIC PRECONDITIONING ON CENTRAL MOTOR OUTPUT AND MUSCLE CONTRACTILITY AFTER A REPEATED SPRINT EXERCISE

KROGH, M., RASMUSSEN, S.

AALBORG UNIVERSITET

INTRODUCTION: Ischemic preconditioning (IPC) is found to reduce the development of fatigue during exercise and it is suggested that this could be caused by changes in the central motor output (Barbosa et al., 2015; Cruz et al., 2015). However, no studies have investigated the effect of IPC on the central motor output with direct measures. The present study investigated the effect of IPC on the fatigue and recovery after a repeated sprint exercise (RSE) on a bike ergometer. We hypothesised that IPC would attenuate the declines in RFD experienced during RSE explained by smaller decreases in measures of central motor output.
METHODS: Eight trained men participated in this study. The study was performed as a cross-over study, were the participants went through two protocols: IPC and sham, with a cuff pressure of 220 mmHg and 20 mmHg, respectively. The participants had to perform RSE protocol consisting of five sets of five sprints each sprint of 5 seconds duration, with 30 seconds rest between sprints and 2 minutes

rest between sets. The fatigue and recovery were measured before (BL), immediately after (IP), one hour (1H) and 24 hours (24H) after the RSE protocol. The measurements included maximal voluntary force, rate of force development (RFD), central motor output (quadriceps muscle activation, voluntary activation, H-reflexes and V-waves) and muscle contractility (evoked twitch response). Oxygenation was measured with a near infrared spectroscopy device during the IPC/sham protocol and through the RSE. Repeated measures ANOVAs was used for statistical analysis.
RESULTS: The maximal force and RFD declined from BL to IP and 1H, but no differences between conditions were observed. All measures were returned to BL levels after 24 hours. No differences were found between conditions or time in any of the central motor output measures. Increased oxygenation through the RSE was observed after the IPC protocol compared to sham.
CONCLUSION: IPC did not have an effect on the central motor output or muscle contractility after RSE. The findings showed that IPC enhances oxygenation to the working muscles during RSE. After RSE, the recovery profile showed that the participants were fully recovered after 24 hours. The results are relevant in training contexts where repeated sprints are an important aspect. To date, this is the first study to investigate the effect of IPC on central motor output, and further research is needed in this area.

EFFECTS OF TRAINING INTENSITY ON THE VO2 AND MUSCLE DEOXYGENATION KINETICS

REIS, J.F.1,2, CURTO, D.2, ALMEIDA, N.2, ESPADA, M.3, INFANTE, J.2, ALVES, F.B.2

1UNIVERSIDADE EUROPEIA, LISBON, PORTUGAL, 2FACULTY OF HUMAN KINETICS, UNIVERSITY OF LISBON, PORTUGAL, 3SCHOOL OF EDUCATION OF POLYTECHNIC INSTITUTE OF SETÚBAL, PORTUGAL

INTRODUCTION: Faster oxygen uptake kinetics (VO2k) have been related to better fatigue tolerance and performance, reflecting an increased oxidative contribution to energy transfer, which decreases the disruption caused by greater levels of anaerobiosis (Jones & Burnley, 2009). Endurance training induces a speeding of the initial VO2 and muscular oxygen extraction kinetics. However, the characteristics of training that optimizes said parameters is not yet clearly established.
We aimed to compare the effects of 4 weeks of low volume continuous (CT) and high intensity interval training (HIIT) on VO2k and muscle deoxygenation kinetics in transitions from rest to moderate intensity running.
METHODS: Twenty seven active subjects, with no endurance training background were randomly assigned to complete 12 sessions of CT (24–32 min in the heavy domain) or HIIT (6-8 x 30 s running at 120-2% of maximal aerobic velocity, interval rest of 30s) over a 4-wk period (CT n=13; mean ± SD; 24.0 ± 4.3 yr.; 62.8 ± 10.5 kg; height 1.68 ± 0.08 m and HIIT n=14; 25.1 ± 5.6 yrs; 66.7 ± 9.8 kg; 1.71 ± 0.07 m). Before (PRE) and after (POST) the intervention period, subjects completed on the treadmill an incremental test and four 6 min square wave transitions to 80% of the first ventilatory threshold. In all tests, pulmonary oxygen uptake was collected breath-by-breath (Metamax3b, Cortex, Germany) and deoxy-hemoglobin [HHb] data of the vastus lateralis was determined by near-infrared spectroscopy (NIMO, Nirox srl, Brescia, Italy). The parameters of the VO2k and [HHb] kinetics were determined using a monoexponential model.
A two-way (time by group) ANOVA with repeated measures for time determined the effects of the interventions on the physiological variables. When the analysis revealed a significant effect, paired-samples t-tests with Bonferroni correction was used.
RESULTS: The time constant of the VO2k was not affected by either training modalities (CT: 32.6 ± 4.4 vs 31.4 ± 6.6s; HIIT: 28.2 ± 8.1 vs 26.7 ± 7.0 s, for PRE and POST, respectively). Similar responses were obtained for the effective time constant of [HHb] kinetics (CT: 25.0 ± 15.4 vs 30.3 ± 14.4 s; HIIT: 27.3 ± 10.8 vs 25.8 ± 13.4 s, for PRE and POST, respectively).
However, only HIIT induced a decrease in the HHb/VO2 ratio (1.08 ± 0.1 vs 1.00 ± 0.1) and an increase of relative peak oxygen uptake (VO2peak) after training (49.4 ± 6.6 vs 54.6 ± 5.3 ml.kg-1min-1).
CONCLUSION: Four weeks of low volume HIIT and CT were not sufficient to induce changes in the VO2 and HHb kinetics in transitions to moderate running. However, HIIT, unlike CT, was able to induce improvements in the HHb/VO2 ratio and VO2peak, suggesting the need of a higher intensity training to induce improvements in these parameters. The decrease in HHb/VO2 values suggests a better matching of the oxygen microvascular distribution and utilization by the muscles.

COMPARISON BETWEEN SKELETAL MUSCLE ADAPTATIONS TO FREE-RUNNING WHEEL AND HIGH-INTENSITY INTERVAL TRAINING

BELEZA, J., ALBUQUERQUE, J., STEVANOVIC, J., SANTOCILDES, G., ASCENSÃO, A., TORRELLA, J.R., MAGALHÃES, J.

FACULTY OF SPORT, UNIVERSITY OF PORTO

INTRODUCTION: Free-running wheel (FRW) is an exercise model that mimics low-intensity daily-life behavior in animals. However, some FRW bouts rely on high-intensity interval moments interspersed with low-intensity or pauses similar to those performed in high-intensity interval training (HIIT). The aim of this study was to analyze and compare morphological skeletal muscle adaptations induced by FWR and HIIT.
METHODS: Wistar rats (n=18) with 7-8 weeks old were assigned into Sedentary (SED), FRW and HIIT groups (n=6/group). FRW animals had free access to running wheel throughout the entire protocol. The animals from the HIIT group were exercised 5 days a week during 12weeks. The HIIT protocol started with 5 minutes at low speed (60% of VO2max) for warm up, thereafter the rats were submitted to 4 bouts of 4 minutes at 85-90 % of VO2max with 2 minutes of active recovery at 60% of VO2max. Histochemical analyzes were performed in tibialis anterior (TA) and soleus (SOL).
RESULTS: Histochemical analyzes performed in TA and SOL muscles showed a general adaptation towards a more oxidative phenotype in both FRW and HIIT. Exercise increased the percentage of fast oxidative glycolytic (FOG) fibers in the lateral and medial fields of TA ($P<0.05$) and slow oxidative (SO) in the posterior field of TA and in SOL ($P<0.05$) with a concomitant decrease in fiber cross-sectional area (FCSA) of FOG and SO ($P<0.05$). Fast glycolytic fibers were bigger across all the TA muscle in FRW and HIIT groups ($P<0.05$). The FCSA decrease in FOG fibers was accompanied by a circularity decrease of SO from SOL fibers, and a fiber and global field capillarization increase in both FRW and HIIT protocols ($P<0.05$).
CONCLUSION: This study suggests that FRW induces significant morphological adaptations on skeletal muscle similar to those obtained under a forced exercise regimen, such as HIIT.

FUNCTIONAL VS. RUNNING LOW-VOLUME HIIT: EFFECTS ON VO2MAX AND MUSCULAR ENDURANCE

MENZ, V., MARTERER, N., FAULHABER, M., LAWLEY, J.S.
UNIVERSITY OF INNSBRUCK

INTRODUCTION: High-intensity interval training (HIIT) has become a popular, time efficient training method for improving maximal oxygen consumption (VO2max). Classically, HIIT is performed using exercise modalities as running, swimming, cycling or rowing. In terms of improving competitive performance, it is reasonable to design the training in a sport specific manner. However, for recreationally active individuals these monotonous exercise modalities may be perceived as boring due to little or no variation, which could have a negative impact on training adherence, as "lack of enjoyment" is a commonly cited barrier for engaging in regular exercise (1). Thus, our aim was to assess if a functional HIIT regime incorporating multiple calisthenics exercises is as effective as a traditional running HIIT regarding the improvement of VO2max and muscular endurance.
METHODS: Fifteen healthy, trained female and male participants (age 25.6 ± 2.6 years) were assigned, stratified by VO2max and gender to either running HIIT (HIIT-R; n= 8) or functional HIIT (HIIT-F; n= 7). Over a four-week period, both groups had to perform 14 exercise sessions of either running (HIIT-R) or functional (HIIT-F) HIIT consisting of 3-4 sets of low-volume HIIT (8x 20 s, 10 s rest; set rest: 5 min). HIIT-F contained various calisthenic exercises as e.g. burpees, mountain climbers, push-ups and crunches. Training intensity during the HIIT sessions was controlled by continuous heart rate (HR) monitoring.
RESULTS: Mean and maximal HR during the training sessions were significantly different (p=0.018 and p=0.022, respectively) between training groups, with HIIT-F eliciting lower HR responses than the HIIT-R. However, despite these differences in exercise HR, VO2max improved similarly (~13% for the HIIT-R versus ~11% for the HIIT-F, p=0.300). Muscular endurance (burpees and toes to bar) significantly improved (p=0.004 and p= 0.001, respectively) independent of training modality.
CONCLUSION: These findings suggest that classic running HIIT and functional HIIT both improve cardiorespiratory fitness (VO2max) and affect functional muscular endurance to the same extent despite a lower cardiovascular strain in the functional protocol. Hence, the exercise modality seems not to affect the training responses regarding CRF and functional muscular endurance. For enhancing CRF, high-intensity functional training seems to be an effective alternative to traditional endurance training modalities.

OP-PM25 Metabolic syndrome and diabetes II

HEMODYNAMIC ABNORMALITIES AND CEREBRAL OXYGENATION DURING CONTEMPORARY MENTAL TASK AND METABOREFLEX ACTIVATION IN PATIENTS WITH METABOLIC SYNDROME

CRISAFULLI, A., ROBERTO, S., MILIA, R., PINNA, V., MAGNANI, S., GHIANI, G., LECIS, R., GUICCIARDI, M., DONEDDU, A.
UNIVERSITY OF CAGLIARI

INTRODUCTION: Metabolic syndrome (MS) is associated with an elevate incidence of circulatory abnormalities and cardiovascular events. Previous research showed that hemodynamic response to exercise is significantly altered by MS, with exaggerated vasoconstriction in response to sympathetic nervous system activation 1,2. Another important phenomenon reported in patients with MS is that cerebral blood auto-regulation is impaired during exercise. The "muscle metaboreflex" (MM) appears to be one of the mechanisms by which sympathetic activity is increased in these patients. Thus, we wondered whether sympathetic activation during contemporary mental task (MT) and MM activation would result in a reduced cerebral oxygenation (COX) in these patients.
METHODS: Two different groups of subjects participated in this investigation: 13 patients (5 women, age 52.9±11.2 yrs) with MS, and 14 age-matched control healthy subjects (CTL, 50.8±8.1 yrs). They underwent 5 different tests, each lasting 12 min: post-exercise muscle ischemia (PEMI) to activate the MM, control exercise recovery (CER), PEMI+MT, CER+MT, and MT alone. During each sessions, COX was detected by near infrared spectroscopy with sensors applied in the forehead. Hemodynamic parameters were assessed by impedance cardiography.
RESULTS: Data analysis found that, when MT was added to PEMI, CTL increased their COX with respect to baseline (+3.46%±3.14), whereas this capacity was impaired in MS patients (+2.37%±2.46%). Moreover, significant hemodynamic differences between groups were found, with MS patients showing higher level of systemic vascular resistance and lower cardiac output than CTL.
CONCLUSION: Results indicated that the capacity to increase COX in response to MT during the MM was reduced in patients with MS in comparison with CTL. This was accompanied by an exaggerated systemic vascular resistance response and by an incapacity to increase cardiac output. It was concluded that MS suffered from significant hemodynamic dysregulation during manoeuvres able to activate sympathetic nervous system. Moreover, they could not properly increase COX during MT. This phenomenon may provide a potential physio-pathological basis of the bad predisposition to exercise often reported in patients with MS.

EFFICACY OF COMBINED AEROBIC AND RESISTANCE HIGH-INTENSITY INTERVAL TRAINING FOR IMPROVING CARDIORESPIRATORY FITNESS AND MUSCULAR STRENGTH IN ADULTS WITH TYPE 2 DIABETES: A RANDOMIZED CONTROLLED TRIAL

COX, E.R., GAJANAND, T., KEATING, S.E., BROWN, W.J., HORDERN, M.D., BURTON, N.W., FASSETT, R.G., COOMBES, J.S.
UNIVERSITY OF QUEENSLAND

INTRODUCTION: High-intensity interval training (HIIT) shows promise to improve exercise and physical activity participation in people with type 2 diabetes (T2D). We aimed to compare the effects of low-volume combined aerobic and resistance HIIT (C-HIIT), combined moder-

ate-intensity continuous training (C-MICT) and usual care control (CON) on markers of cardiorespiratory fitness and muscular strength in people with T2D.
METHODS: 57 individuals diagnosed with T2D (63.2% male, age 61±9yrs, HbA1c 7.7±1.2%) were randomised to either 8-weeks of supervised C-HIIT (1x4min HIIT @ 85-95% HRpeak plus 8x1min resistance training, 3times/week = 78mins/week), supervised C-MICT (52.5min @ 55-65% HRpeak, 2times/week; 22.5min @ 55-65% HRpeak plus 30min resistance training, 2times/week = 210mins/week) or CON (usual care). Cardiorespiratory fitness (VO2peak), exercise capacity (test duration) and muscular strength (1 repetition maximum [1-RM; chest and leg press], grip strength, isometric knee extensor strength, 30sec sit to stand, 30sec arm curl, floor rise to stand) were evaluated pre- and post-intervention. Adverse events (AEs) were also recorded throughout the intervention period. Data are presented as mean ± standard deviation.
RESULTS: Although there were no significant group differences in post-intervention VO2 peak (p=0.075), maximal exercise test duration was significantly greater in C-HIIT than in C-MICT and CON (118.4±91.6sec vs. 24.8±67.5sec vs. -17.7±88.5sec; 95% confidence interval [CI]=15.9, 162.65, p=0.012; 95% CI=62.31, 214.71, p=0.000 respectively). Compared with CON, only C-MICT resulted in significant improvements in 30sec arm curl (95% CI=0.59, 6.57, p=0.014) and gait speed (95% CI=-0.98, -0.73, p=0.018). Both C-HIIT (-0.4±0.5sec) and C-MICT (-0.5±0.7sec) significantly reduced floor rise to stand time compared with CON (0.3±1.2sec; 95% CI=-1.52, -0.11, p=0.019; 95% CI=-1.79, -0.37, p=0.001 respectively). Only C-HIIT significantly increased leg press 1-RM compared with CON (22.9±26.8kg vs. -12.6±46.4kg; 95% CI=5.18, 51.7, p=0.012). There were no group differences in post-intervention isometric knee extensor strength (p=0.185), 30sec sit to stand (p=0.109), chest press 1-RM (p=0.783) and grip strength (p=0.556). No serious adverse events were recorded in any intervention.
CONCLUSION: C-HIIT improved markers of exercise capacity and muscular strength in people with T2D. C-HIIT therefore offers an effective exercise option for this population, that is well tolerated and more time efficient.

EXTRA SCHOOL BASED PHYSICAL EDUCATION REDUCES RISK OF DEVELOPMENT OF METABOLIC SYNDROME IN 9-10 YEAR OLD CHILDREN

REIHMANE, D., OZOLINA-MOLL, L., JUSTAMENTE, I., SLEZINA, L., RAUDENIECE, J., TREIJA, E.M., SILINA, L., PIRAGS, V.
UNIVERSITY OF LATVIA

INTRODUCTION: Cardio-metabolic risk factors like hypertension, dyslipidemia and insulin resistance among others tend to cluster not only in adults, but also in children, leading to early development of metabolic syndrome (MS). Effective solutions for prevention of increasing levels of childhood obesity are of high importance, as well as finding easily accessible tools to evaluate cardio-metabolic risk factors. The aim of the PACH-study is to clarify whether extra school based physical education (ExPE) can reduce risk of MS development.
METHODS: 97 3rd grade students were enrolled in the study and were assigned to ExPE group (N=52) and control (CON) group (N=45) having 5 vs. 2 weekly PE lessons, respectively. Additionally, subgroups of normal weigt (NOR) and overweight/obese (OB) children based on WHO BMI percentile scale were analyzed. In school year 2017/2018 body mass index (BMI), waist circumference (WC), fitness level (FL) (3-min Kasch Pulse Recovery Test) and self reported Physical Activity Questionnaire (PAQ-C) of children were collected twice. Lipid profile (TAG, LDL, HDL), glucose, insulin and hs-CRP levels were determined by E.Gulbis clinical laboratory. Two way ANOVA for comparison of delta values (mean±SEM) were used. Data were analyzed with SigmaPlot12.5.
RESULTS: There was a significantly greater increase (Δ) in WC in CON vs. ExEP group, 3.13±0.52 cm vs. 0.83±0.44 cm, respectively. Furthermore, Δ WC was significantly higher in obese children only in control group: CON/NOR 2.30±0.39 vs. CON/OB 5.40±1.50 cm. There was a significant effect of ExEP on LDL levels in normal weight children (ExEP/NOR Δ -0.20±0.06 vs. CON/NOR Δ -0.03±0.05 mmol/l) while no effect in children with excess weight. There were significant differences between the groups in Δ TAG values; however, main effects cannot be properly interpreted as significant interaction between factors was determined. Δ values for other measured anthropometric or blood parameters did not vary significantly after half a year. Significant difference also was observed between normal and overweight/obese children in baseline TAG, LDL and hs-CRP levels. There were significant ($p < 0.05$) positive correlations between WC and FL, hs-CRP, glucose, HOMA-IR, TAG and LDL levels, while negative correlation with HDL levels.
CONCLUSION: Children with obesity have increased HOMA-IR index, lipid profile and hs-CRP levels in comparison to children with normal weight. Daily physical education lesson in school can promote general health of 9-10 year old children by reducing levels of LDL and visceral obesity. Measurement of WC (main parameter used to determine risk for development of MS in children by International Diabetes Federation) is simple tool which can be used in school setting to determine children at risk developing chronic cardio-metabolic diseases.

OP-PM29 Team sports: Soccer

ANALYSIS OF GOAL SCORING OPPORTUNITIES FROM ORGANIZED OFFENSIVE PATTERNS IN THE FIFA WORLD CUP RUSSIA 2018

MITROTASIOS, M., MOCHLAS, S., PIPERAS, S., CHRISTOFILAKIS, O., ARMATAS, V.
UNIVERSITY OF ATHENS

INTRODUCTION: Performance in soccer is a multifactorial and complicated issue and it is depended on technical, tactical, physiological and psychological characteristics of the sport. Offensive and defensive tactical patterns can be monitored through performance analysis, in order to increase the efficiency of either goal – scoring or the interception of the opponents' attack (Lago-Ballesteros et al., 2010). Aim of this study was to record and analyze the offensive goal-scoring opportunities from organized offensive patterns in the previous World Cup and discriminate the most effective of them, concerning the structure of this competition.
METHODS: The goal-scoring opportunities (n=183) from the sixteen matches of the FIFA World Cup Russia 2018 were analyzed from two well-educated in analysis coaches for this purpose. Cohen's kappa was then calculated to check the degree of agreement between them. The data for the analysis were available from the WyScout platform. Analysis referred to the variables of 1) the result of the match, 2) the formations used, 3) the time period of the match, in which teams scored, 4) the way the offensive pattern initiated, 5) the kind and the direction of the offensive pattern, 6) the kind of technical and tactical action before the execution of the offensive opportunity, 7) the technical skill and the outcome of the execution. Statistical analysis conducted with descriptive statistics (f, %f), chi-square tests and r-Pearson tests ($p<0.05$).

RESULTS: The majority of the offensive goal-scoring opportunities were developed in the time period 61-75 (18,58%) and 76-90+ (18,03%) of the match and originated from shooting attempts (84,70%). These scoring opportunities were allocated to goals-scored (10.38%), shots off target (40.98%) and shots saved by the goalkeeper (33.33%). The most frequent technical action before the opportunity was passing (29.19%). Significant statistical difference was found between the most effective teams that won the games and the teams were mostly defeated or drawed ($p<0.001$).
CONCLUSION: Take into account the above results we reach to the conclusion that teams that thrive and compete in high level tournaments with the structure of the World Cup create more organized goal-scoring opportunities during the last 30 min of the match, of which the technical action preceded is shooting.

WORK RATE PATTERNS DURING THE 2010, 2014 AND 2018 FIFA WORLD CUP: EFFECT OF SUBSTITUTIONS AND EXTRA-TIME

RAGO, V.

PORTUGUESE FOOTBALL FEDERATION

INTRODUCTION: In top-level football matches, the rate of intense activities (e.g. number of sprints) performed decreases towards the end of the match [1] but increases when a player enters as substitute [2]. However, there is still lack of evidence describing the work rate patterns during the extra-time (ET). The present retrospective study investigated whether substitutions and the ET affected work rate patterns during the FIFA World Cup (FWC).
METHODS: Total distance covered (TD), number of sprints (number of occurrences >25 km·h-1), peak speed (Vpeak) and individual playing time were collected for each player from the official FIFA website. Only teams involved at least in one match with ET during the 2010, 2014 and 2018 FWC were considered. Data were collected independently of the tournament stage (group or knock-out phase) separately for the 1st half, 2nd half and ET, and normalised by individual match playing time. Once excluding goalkeepers, the final sample comprised 453 outfield players (n=3238 individual records). Players' were classified according to their starting status as starters (initial line-up or substitutes up to the 45 min match-play; n=2818), 2nd half substitutes (during the half-time break or up to 90 min match-play; n=380), and ET substitutes (between the 2nd half and the ET or up to 120 min match-play; n=40). Data were analysed using mixed effect models.
RESULTS: In matches without ET, starters decreased TD/min from the 1st to the 2nd half (Median ± 95% confidence intervals; group stage, 110 vs 104 m; ES=0.38 [0.28; 0.48]; knock out stage, 110 vs 104; ES=0.48 [0.29; 0.67]; $P<0.001$), whereas no substantial differences between halves were observed in the number of sprints/min and Vpeak ($P>0.05$). During knock-out matches with ET, starters presented small to moderate decreases in TD/min (109 vs 101 vs 100 m), number of sprints/min (0.44 vs 0.36 vs 0.33 counts) and Vpeak (26.8 vs 26.1 vs 25.0 km·h-1) from the 1st half towards the ET ($P<0.05$; ES=0.20 to 0.74), but no substantial differences were detected between the 2nd half and ET ($P>0.05$). However, TD/min increased in 2nd half substitutes from the 2nd half to the ET (110 vs 112 m; ES=0.58 [0.23; 0.93]; $P=0.001$), with no substantial differences in the number of sprints/min and Vpeak ($P>0.05$). 2nd half substitutes players showed higher TD/min and number of sprints/min during the 2nd half compared to starters (110 vs 101 m; ES=0.34 to 0.96; $P<0.05$). Likewise, ET substitutes covered higher TD/min compared to starters during the ET (112 vs 100 m; ES=0.38 [0.04; 0.72]; $P<0.05$).
CONCLUSION: Irrespective of the ET occurrence, work rate pattern appears to decrease towards the end of the matches. These declines were more evident in TD/min than in the number of sprints/min. Moreover, substitutions seem to contribute to counteract the decrease in work rate patterns during either the 2nd half and ET during FWC matches.

COMPARISON OF IN-SEASON EXTERNAL AND INTERNAL LOAD ACROSS A PROFESSIONAL JUNIOR SOCCER ACADEMY.

JULIAN, R., BOOTH, A., HELMS, M., PAGE, R.M.

UNIVERSITY OF MÜNSTER

INTRODUCTION: To enhance athletic development, coaches and practitioners are required to manipulate training load to induce effective adaptive responses (1). Therefore, it is logical to systematically progress load across an academy to ensure levels of adequate physical performance are apparent prior to qualifying to the first team alongside reducing the risks of potential overtraining and injury. However, there is currently limited information regarding internal and external load of training across academy age groups. Therefore, the purpose of this investigation was to observe the differences in internal load and external load across differing age groups of a high-levelled soccer academy.
METHODS: Thirty eight players (16±1 y, 176.1±5.8 cm, 65.1±5.7 kg) were recruited from one academy and represented the age groups U16 and U18's. Moreover, players were further separated from year 1 and year 2 of each academy age group. For analysis 367 training observations were recorded across the U15, U16, U17 and U18 players. External load was measured using 10Hz GPS technology and accelerometery (Polar Team Pro, Kempele, Finland), and were normalised to remove the variations of session length (e.g. meters per minute). Internal load measures comprised relative and absolute heart rate (HR), and session rating of perceived exertion (sRPE). Comparisons across age groups training data for each internal and external load measure were analysed using a linear mixed model (fixed effect: age group, random effect: player ID). Where appropriate, Bonferroni corrected pair wise comparisons were used to assess differences between age groups
RESULTS: For external load measurements, there were significant main effects for relative total distance and low intensity distance covered (both, $p<0.01$) and relative number of sprints ($p<0.01$). However, there was no significant differences across age groups for relative moderate intensity, high intensity, very high intensity or sprinting distance ($p=0.06$, $p=0.76$, $p=0.13$, $p=0.15$). For internal load measures there were no significant main effect for age group in HR indices (HRaverage, $p=0.06$; HRmax, $p=0.18$; HRaverage%, $p=0.06$; HRmax%, $p=0.10$). However, there was a significant main effect for sRPE ($p<0.01$).
CONCLUSION: Overall, the results suggest no consistent systematic increases in the measured metrics; however, there were observed differences in certain load parameters across age categories. Although it has been previously regarded as an important factor for

coaches and practitioners to use training load to monitor and prescribe training for their players (2), it would appear the current data does not demonstrate the prescription of developmental specific load.

LOCOMOTOR CHARACTERISTICS, INTERNAL LOAD AND TECHNICAL ATTRIBUTES DURING BIOLOGICAL VS. CHRONOLOGICAL AGE BANDED SMALL-SIDED GAMES IN ELITE YOUTH SOCCER PLAYERS

SMITH, J.A., MCNARRY, M.A., UNNITHAN, V.

SWANSEA UNIVERSITY

INTRODUCTION: In many team sports, including soccer, youth teams are banded into chronologically-matched age groups for both training and competition. However, chronological and biological age can be significantly dissociated as biological maturation does not progress linearly or at the same tempo between individuals, potentially resulting in considerable maturational differences between players within a single chronological age group. A potential strategy to resolve this issue is the use of biological-banding (bio-banding), where individuals are grouped on characteristics associated with growth or maturation. Bio-banding is therefore suggested to normalise maturity-associated differences in size, strength and skill, resulting in a decreased risk of injury and greater competitive equity. The aim of the study was to compare locomotor characteristics, internal load and technical skills in biologically-banded (BB) and chronological age-group (CA) small-sided matches.
METHODS: Twelve elite youth male soccer players from an English Premier League Academy (U12s to U15s) were categorised into maturity-based groups based on predicted adult height (PAH) (85-90%; 90-95% and 95-100%PAH). All players took part in 5, 5-minute 4 vs 4 small-sided games in both their chronological age group and their maturity-based groups. Internal load was quantified as time spent in heart rate bands (HRB) 1-4 obtained by heart rate telemetry, locomotor characteristics (Total Distance Covered (TDC), High Speed Running distance (HSR) and Total Player Load (TPL)) were obtained using GPS whilst key technical attributes that matched the game model of the club were obtained using video analyses (1 vs 1; beat passes; defending 1 vs 1; finishing and passes in behind).
RESULTS: There were no significant differences according to group for TDC (BB: 104.6 ± 18.6 vs CA: 105.8 ± 14.1m), HSR (BB: 12.2 ± 5.6 vs CA: 13.3 ± 5.5m) and TPL (BB: 13.6 ± 3.0 vs CA: 13.9 ± 2.8 AU). Whilst more time was spent in HRB2 (BB: 23 ± 16% vs CA: 12 ± 13%) and HRB3 (BB: 27 ± 11% vs CA: 15 ± 10%) in the BB compared to CA games, more time was spent in HRB4 during CA games (BB: 41 ± 28% vs CA: 62 ± 27%). No statistically significant between group differences were noted for any of the technical actions.
CONCLUSION: The lack of differences between BB and CA across the locomotor and technical variables and the greater time spent in the lower HRB zones suggests that, while physical precocity differences may be normalised by BB, the challenge point may become too low for the players. This results in an environment (BB) that may not stimulate the enhancement of physical outputs and technical attributes. Based on our findings, more work is required on BB small-sided games to optimise their suitability for physical and technical enhancements in elite youth soccer players.

THE EFFECT OF MATCH STANDARD ON THE POST-MATCH PERCEIVED EXERTION AND WELLNESS OF PROFESSIONAL SOCCER REFEREES

FIGUEIREDO, P.1,2, PERES, P.1, BRITO, J.1

1: PORTUGAL FOOTBALL SCHOOL, PORTUGUESE FOOTBALL FEDERATION, PORTUGAL, 2: RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT, CIDESD, UNIVERSITY INSTITUTE OF MAIA, ISMAI, PT

INTRODUCTION: Soccer is a psychophysiological demanding sport. Changes in load and strain influence physiological and psychological variables in addition to wellness, affecting not only players, but also referees. Considering that the competition standard may influence the intensity of the matches, it may also have impact on referees' match workload and wellness responses when refereeing at different levels of competition.
Therefore, this study aimed to assess post-match perceived exertion and wellness according to the match standard in professional soccer referees.
METHODS: Data were collected from 8 professional field referees in Portugal, during the 2017-18 season. The referees recorded their rating of perceived exertion (RPE) after the match on a 0-10 rating scale (1). The sleep duration and rating of the perceived sleep quality, as well as the quantity of stress, fatigue, muscle soreness, and motivation were collected in the morning following each match using a 1-7 rating scale psychometric questionnaire (2).
Differences between match standard (1st League vs 2nd League) were analyzed with a linear mixed model. Competitive leagues were modelled as fixed effects and referee ID as a random effect. The t statistics were converted to effect size correlations (3). An α-level of 0.05 was used as the level of significance for statistical comparisons. The results are presented as marginal means and 95% confidence interval.
RESULTS: No significant differences in RPE were observed between 1st and 2nd League matches (6.5 [5.6; 7.4] vs 6.1 [5.1; 7.0] AU; $p>0.05$, $r=0.14$). Also, perceived stress (2.6 [1.7; 3.4] vs 2.4 [1.5; 3.2] AU) and motivation (4.5 [3.9; 5.1] vs 4.5 [4.0; 5.1] AU) were similar between the two league matches ($p>0.05$, $r=0.03$-0.12). Referees' perception of sleep quality was moderately lower following 1st League matches (3.9 [3.4; 4.4] vs 4.5 [3.9; 5.0] AU; $p=0.002$, $r=0.3$). Concomitantly, sleep duration during the night after 1st League matches was also lower (-75 min, $p<0.001$, $r=0.41$). Referees reported small, but significantly higher values of fatigue (3.9 [2.8; 5.1] vs 3.6 [2.4; 4.8] AU) and muscle soreness (4.0 [3.1; 4.9] vs 3.6 [2.7; 4.5] AU) after 1st League matches ($p<0.05$, $r=0.19$-0.21).
CONCLUSION: Match standard seems to affect perceived sleep quality, fatigue, muscle soreness and sleep duration in professional soccer referees, whereas perceived stress, motivation and RPE were similar regardless of match standard. Considering the reduced sleep duration after 1st League matches, data suggests that both sleep duration and quality could affect the perception of physical recovery, despite similar perceived match load on both competitive leagues. These findings have implications for recovery strategies after the match in soccer referees.

RELATIONSHIPS BETWEEN DIFFERENT ACUTE:CHRONIC WORK LOAD RATIO CALCULATIONS AND INJURIES IN ELITE SOCCER PLAYERS

GUALTIERI, A.1, CONNOLLY, D.1, RIGGI, E.2, RAMPININI, E.3, SASSI, R.1

(1) SPORT SCIENCE DEPARTMENT, JUVENTUS FOOTBALL CLUB, TORINO, ITALY (2) UNIVERSAL HOSPITAL, "CITTÀ DELLA SALUTE E DELLA SCIENZA", TORINO, ITALY (3) MAPEI SPORT RESEARCH CENTER, OLGIATE OLONA, ITALY

INTRODUCTION: In the last decade a number of different approaches have been utilized to monitor players acute:chronic workload ratio (ACWR): this was originally calculated using week by week data (WbW) and more recently using day by day data (DbD) (Gabbett 2010, Delecroix 2018). The methods applied evaluate players injury risk (IR) on a daily or weekly basis. In the present study we aim to compare these two approaches, as well as the different ratios proposed, in order to verify their ability to predict injuries.
METHODS: Thirty-five elite Italian football players (age 28 ± 6 y, height 184 ± 5 cm, body mass 81 ± 7 kg) participated in a 3-season prospective study during which 13,265 single day and single player observations were collected and 96 non-contact injuries were recorded. Session rate of perceived exertion (sRPE-TL) was used to calculate different workload parameters: cumulative 1, 3 and 4 weekly load (last 7, last 21, last 28), acute:chronic 7:21 (ACWR 7:21) and 7:28 (ACWR 7:28) work load ratios. Each parameter was calculated with both approaches, week by week and day by day. A Generalized Estimating Equation analysis was used to examine the association of a single marker with a non-contact injury in the subsequent week or following day. P-values and confidence intervals are based on robust standard error. Prediction was examined with receiver operating characteristic curve, area under the curve (AUC).
RESULTS: Using WbW analysis the IR of the following week increased when an ACWR 7:21 value exceeded a 1.2 ratio (odds ratio (OR), 90% confidence interval (CI): 5.2, 2.6-10.5; p<0.001); AUC was 0.55 (CI: 0.5-0.6) and sensitivity was 65%. All the other WbW parameters were not significant.
Using DbD analysis the IR in the following week significantly increased (p<0.001) with higher sRPE-TL in the last 7 days (OR, 90% CI: 0.9989, 0.9986-0.9994), but no prediction was found (AUC=0.50).
CONCLUSION: No association was found between the majority of workload parameters and injuries. Significant association was found only for last 7 days sRPE-TL (DbD) and ACWR 7:21 (WbW). Furthermore, no injury prediction or low levels of prediction were detected. The results of this study confirm that non-contact injury is a multifactorial phenomenon in which several factors in addition to workload are implicated (e.g. injury history, age, fitness level, fatigue, psychosocial conditions and strength imbalances).

OP-BN17 Sports physiotherapy: Foot and ankle

EFFECT OF 12-WEEK EVERTOR AND INVERTOR STRENGTH TRAINING ON MEDIAL AND LATERAL INCLINED WALK

BAVDEK, R., DOLENEC, A.

SECONDARY SCHOOL OF TECHNICAL PROFESSIONS, FACULTY OF SPORT, UNIVERSITY OF LJUBLJANA

INTRODUCTION: Lateral and medial ankle sprains are generally considered to be one of the most frequent injuries [1]. As medio-lateral stability is mostly managed by the evertor and invertor muscles it is crucial that neuro-muscular activation of these muscles is optimal. For that reason, researchers suggest different types of training methods, such as elastic bands [2] or isokinetic exercise [3]. However, foot eversion and inversion movements occur in the subtalar joint. Since the precise subtalar axis of rotation is difficult to achieve in previous mentioned studies, a special evertor/invertor strength training device was made. The purpose of the study was to observe how a 12-week strength training exercise influences walking on a medially and laterally inclined ramp, while subjects tried to keep the lateral and medial part of the foot in the air.
METHODS: The study included 32 subjects, which were randomly assigned to a training or control group. Training group participated in a 12-week strength-training protocol using evertor/invertor strength training device while the control group did not participate in the strength-training protocol. Subject in both groups were pre- and post- tested for evertor and invertor isometric strength with an isometric device. Subject also performed walking on a flat surface, walking at lateral inclination of 15° with an inverted foot, and walking at medial inclination of 30° with an everted foot. While performing different types of walking, foot position was monitored by IMU. To identify pre- and post-test differences between the training and the control group, ANCOVA was used.
RESULTS: After the 12-week training programme, statistically significantly higher torque production in eversion ($F = 9.24$, $p = 0.005$) and inversion ($F = 12.13$, $p = 0.002$) were observed on the test subjects in the training group. The same test subjects performed higher foot eversion ($F = 4.52$; $p = 0.043$) and inversion ($F = 9.64$; $p = 0.004$) while walking on a medially and laterally inclined ramp.
CONCLUSION: The study showed, that the 12-week strength training improved the strength of evertor and invertor muscles. That had an effect on foot position, which, consequently, resulted in a more stable walking on uneven medio-lateral surface. This fact could be of great interest for people who suffer from ankle instability or for other subjects for whom optimal evertor and invertor strength is crucial.

EFFECT OF FOOTWEAR ON ANKLE PROPRIOCEPTION TESTED DURING LANDING IN PROFESSIONAL BADMINTON PLAYERS AND PARTICIPANTS WITHOUT SPECIFIC TRAINING EXPERIENCE

YU, R.1, YANG, Z.1, XU, Z.1, YAN, K.1, WADDINGTON, G.2, WITCHALLS, J.2, ADAMS, R.2, WU, S.3, HAN, J.1,2

[1]SHANGHAI UNIVERSITY OF SPORT, [2]UNIVERSITY OF CANBERRA, [3]SWINBURNE UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Ankle sprains are the most common injuries in the lower extremity during jumping and landing activities. Ankle joint proprioception plays a significant role in such movements. To date, the effects of footwear on ankle proprioception during landing have not been investigated.
METHODS: Ten professional badminton players (PBP), 5 National first class and 5 National second class (6 M, 4 F; Age = 20.5±1.4 years; Height = 175.6±9.9 cm; Weight = 63.9±10.3 Kg) and twelve young healthy participants (YHP) without specific sport training experience (8 M, 4 F; Age = 24.3±3 years; Height = 174.2±8.5 cm; Weight = 65.8±13.6 Kg) volunteered. All participants completed the ankle proprioceptive tests after a 10cm drop on the Ankle Inversion Discrimination Apparatus for Landing (AIDAL). The participants were required to identify the difference between 4 angles of inversion (8°, 10°, 12° and 14°). The testing order of wearing shoes and barefoot was randomized. The interval between the two testing conditions was approximately 30 minutes. Each participant wore their training shoes and was tested on their dominant leg, determined by using the Chinese version Waterloo footedness questionnaire. Ankle proprioceptive discrimination sensitivity scores as mean pair-wise Area Under the Curve (AUC) values were obtained using SPSS ROC software. Repeated measures analysis of variance (ANOVA) was conducted to analyze the data, and t-tests used to examine the difference between factor levels.
RESULTS: Although the footwear or sport experience main effect was not statistically significant ($F = 0.818$, $p = 0.389$; $F = 0.264$, $p = 0.620$, respectively), there was a significant interaction between footwear and sport experience ($F = 10.930$, $P = 0.009$). The paired-samples t-tests showed that wearing training shoes significantly worsened ankle inversion proprioception in PBP (95% CI = -0.098, -0.012, $t(9) = -2.906$, $P = 0.017$), while the improvement in YHP was not statistically significant (95% CI = -0.024, 0.073, $t(11) = 1.105$, $P = 0.293$).
CONCLUSION: Consistent with previous studies on ankle taping, the findings here suggest that footwear may improve proprioceptive sensitivity in those with poor proprioception but impair proprioceptive sensitivity in those with superior proprioception. This crossover effect warrants further investigation in sport footwear innovation and personalized sport footwear design to better prevent ankle injuries in landing.

CRITERIA-BASED RETURN TO SPORT DECISION-MAKING FOLLOWING LATERAL ANKLE SPRAIN INJURY: A SYSTEMATIC REVIEW AND NARRATIVE SYNTHESIS.

TASSIGNON, B.1, VERSCHUEREN, J.1, DELAHUNT, E.2, SMITH, M.3, VICENZINO, B.3, VERHAGEN, E.4, MEEUSEN, R.1

1,2, 3,4

INTRODUCTION: Lateral ankle sprain (LAS) injury is one of the most frequently incurred musculoskeletal injuries and shows high recurrence rates in individuals participating in sports [1, 2]. This high recurrence rate is hypothesised to be mainly caused by an increased re-injury risk due to previous LAS injury, the persistence of sensorimotor impairments and premature return to sport (RTS) clearance [3]. Therefore, it is indicated to develop and implement evidence-based criteria to guide RTS decisions for individuals with LAS injury. The aim of this systematic review was to identify prospective studies that used a criteria-based RTS decision-making process for patients with LAS injury.
METHODS: The PubMed (MEDLINE), Web of Science, PEDro, Cochrane Library, SPORTDiscus (EBSCO), ScienceDirect, and Scopus databases were searched till 23 November 2018. Studies were included if they prospectively applied a criteria-based RTS decision-making process for patients with LAS injury. Studies were excluded if they merely gathered outcome measures at the RTS time-point. Studies were also excluded if patients were recovering from ankle fracture, high ankle sprain, medial ankle sprain, chronic ankle instability or complex ankle injury.
RESULTS: No studies were identified that used a criteria-based RTS decision-making process for patients with LAS injury. We were unable to conduct a quantitative synthesis or meta-analysis, so we provided a narrative synthesis of 47 relevant questionnaires, as well as 45 clinical and functional assessments commonly used in studies retrieved in the search.
CONCLUSION: There are currently no published evidence-based criteria to inform RTS decisions for patients with a LAS injury. It seems that RTS decisions following LAS injury are still generally time-based. Therefore, we propose the following variables that could be used to develop a criteria-based RTS decision paradigm: (1) predisposing factors increasing the (re-)injury risk and prognostic factors increasing the risk of developing CAI, (2) ligament healing, ankle laxity and arthrokinematics, (3) clinical tests and patient reported outcomes, (4) functional and sport-specific performance tests (a. quantitative performance analysis, b. movement quality assessment, and c. acute fatigue as a constraint and extra criterion), (5) load monitoring, (6) psychological and psychosocial factors, (7) decision modifying variables. Future research should aim to reach consensus on these variables and apply them to actual RTS decisions within prospective study designs. Furthermore, we suggest that complex systems theory and the RTS continuum [4] could be used to inform the development of a RTS decision-making paradigm for individuals with LAS injury.

IS NEW PLANTAR FOOT INTRINSIC MUSCLE TRAINING MORE EFFECTIVE FOR THE MORPHOLOGY OF MEDIAL LONGITUDINAL ARCH AND MUSCLE STRENGTH?

TSAO, T.L., YANG, C.H., CHEN, P.T., LIU, K.L.

COLLEGE OF MEDICINE, TZU-CHI UNIVERSITY

INTRODUCTION: Plantar foot intrinsic muscle training (1) is commonly used for athletes with plantar heel pain (PHP). More importantly, recent evidence (2) demonstrated the association between PHP and the weakness of intrinsic foot muscles (IFMs), a group of muscles which provides static and dynamic stability to medial longitudinal arch and controls the foot movements. Currently, tools that are utilized

to measure the strength of IFMs were unable to eliminate the contribution of muscle strength from the extrinsic foot muscles. Clinically, traditional foot exercises have problems with no clear feedback and difficulties to learn. Therefore, a clear-informed and easy-to-learn foot intrinsic muscle exercise is necessary for athletes with PHP. We aimed to investigate the intrinsic and extrinsic foot muscle characteristics (strength, activation and cross-sectional area) of the IFMs and foot arch after IFMs strengthening training using the novel foot plantar dynamometer (NFPD) and compare it with the effect of conventional short foot exercises.
METHODS: A total of 23 participants were enrolled in this study, comprising 12 participants who performed the short foot exercise (SFE) on the NFPD (EN group) and 11 participants who performed conventional SFE (EC group). All subjects in both groups underwent the 4-week training program. Muscle characteristics (strength, activation, and cross-sectional area) of the IFMs and foot arch (arch height index) were measured before and after the four-week intervention. Mann-Whitney U test was used to compare the differences of variables between groups in the pre-intervention evaluation. Wilcoxon signed-rank test was used to compare the differences of variables between pre-intervention and post-intervention evaluation in both groups.
RESULTS: There was a significant increase in muscle activation ($p<0.05$) and the CSA ($p<0.05$) of the IFMs after 4 weeks of SFE training in both groups. The abductor digiti minimi muscle (Abd*M*) during NFPD SFE could be activated more than that of conventional SFE. There was no significance in the strength of IFMs ($p>0.05$) in the EN group and the arch height of the foot ($p>0.05$) after 4 weeks of SFE training in both groups.
CONCLUSION: The activation of Abd*M* increased while learning SFE on NFPD with EMG biofeedback. The morphology and activation of the IFMs increased after the 4-week progressive SFE training with the NFPD. However, the training effects in the morphology and activation of the IFMs were the same between performing SFE on NFPD and conventional SFE in healthy subjects.

PROGRESSIVE EXERCISE SERIES FOR PATIENTS WITH CHRONIC ANKLE INSTABILITY: A CASE CONTROL STUDY.

BOSSARD, D.S.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Lateral ankle sprains (LAS) are especially prevalent in court and field sports due to the exposure to high-risk movements such as jump landing and side-cutting. Following LAS injuries there is a high prevalence of chronic persistent symptoms such as pain, swelling, impaired function, "giving-way", and sprain recurrence; these characterize what is referred to as chronic ankle instability (CAI). The aim of the present study is to determine a progressively challenging sequence of static postural stability exercises using biomechanical analysis for patients with CAI and to determine whether patients with CAI perform differently to healthy controls.
METHODS: 30 Participants with CAI and 30 matched healthy Controls performed 4 static postural balance exercises (Double Limb Stance [DLS], Tandem Stance [TS], Single Limb Stance [SLS], Squat Stance [SS]) in 4 Different Variations (Hands Free Eyes Open [HF EO], Hands Free Eyes Closed [HF EC], Hands Hips Eyes Open [HH EO], Hands Hips Eyes Closed [HH EC]). All Participants were engaged in court or field sports. Measurements included EMG measures (Biopac) of 5 lower limb muscles, kinetic data (AMTI Forceplate) and kinematic data (CODA Motion Analysis). Outcome measures that are analysed to date is the count of balance errors according to the Balance Error Scoring System (BESS).
RESULTS: According to the BESS score significantly more balance errors were found in the CAI group in the HH EC variation of both SLS and SS when compared to the control group.
Also HF EC and HH EC both showed a statistically significant difference from HF EO and HH EO in the CAI group when performing tandem stance, single limb stance and squat stance. There were no differences between the 4 different variations of the DLS within the CAI group.
CONCLUSION: This study is one of the first to determine a sequence of progressively challenging static balance exercises for individuals with CAI. The primary hypothesis was partially confirmed, as several differences in BESS scores were observed between the exercise variations when the CAI group was compared to the control group. However, the observed differences were small, interestingly showing that only two exercise variations (SS HH EC and SLS HH EC) had significantly different scores upon comparison of the two groups. The overall aim of the study was to develop a sequence of progressively challenging balance exercises, based on the hypothesis that there would be significant differences in BESS scores within the CAI group, when the variations of each exercise were compared.
Despite the proven efficacy of balance training programs, there is still lack of recommendations regarding the exact dosage and progressive sequence of exercises. This study fills this gap in the literature by comparing four variations of three separate balance exercises and ranking them in order of difficulty for individuals with CAI.

LOWER EXTREMITY JOINT MOMENTS DURING THE ACCELERATION PHASE OF BEND SPRINTING

JUDSON, L.J., CHURCHILL, S.M., BARNES, A., STONE, J.A., WHEAT, J.

SHEFFIELD HALLAM UNIVERSITY

INTRODUCTION: Biomechanical adaptations during bend sprinting result in decreased velocity compared with the straight (1). This decrease in performance is hypothesised to be attributed to non-sagittal plane adaptations restricting the capacity of muscles to generate force in the sagittal plane (2). However, this is yet to be confirmed empirically in conditions representative of competitive athletics. Therefore, the aim was to evaluate lower limb joint moments during the acceleration phase of sprinting on the bend and straight.
METHODS: Seven male sprinters (200 m personal best 22.70 ± 0.52 s) volunteered to participate. Bend trials were collected on a standard flat indoor track surface with a reconstructed bend (radius: 36.5 m, lane 1) and straight trials on a 30 m section of straight track. Data were collected 12 m from the start line using a 15-camera optoelectronic motion capture system and a force plate embedded into the track surface. Joint moments were calculated using Visual 3D and expressed in the joint coordinate system (3). Joint moments were normalised to body mass, gravitational acceleration (3/2) and height (1/2) resulting in dimensionless units (4). Two way repeated measures ANOVAs were used to assess differences between condition (bend vs. straight) and limb (left vs. right). Effect sizes (d) were also calculated.
RESULTS: An increase in ankle plantarflexor moment was observed during the left step on the bend (0.38 ± 0.05) compared with the straight (0.31 ± 0.07, d = 0.96, P = 0.27). Furthermore, an increase in left metatarsophalangeal (MTP) joint plantarflexion was seen on the bend (-0.04 ± 0.01) compared with the straight (-0.02 ± 0.02, d = 1.61, P = 0.02). Moderate increases in non-sagittal plane peak moments were observed on the bend compared with the straight for the left step: peak ankle (d = 0.68, P = 0.05) and midfoot eversion (d = 0.74, P = 0.10). There was a moderate decrease in peak flexion moment on the bend at the left hip (0.07 ± 0.06, d = 0.65, P = 0.31) and large decrease in left knee peak flexion moment (-0.02 ± 0.02, d = 1.14, P = 0.07). This was combined with a large increase in left hip adduction

moment on the bend (0.23 ± 0.14) compared with the straight (0.14 ± 0.06, d = 0.80, P = 0.07). In contrast, the right step was mostly unaffected by the bend.
CONCLUSION: Increased left step ankle and MTP joint sagittal plane moments suggest the capacity to produce high peak moments in the sagittal plane is not restricted on the bend. However, decreases in sagittal plane moments at the left hip and knee suggest bend sprinting does restrict the ability of these joints. Thus, the hypothesis of Chang and Kram (2) is only applicable at certain joints.

PHYSICAL, PERCEPTUAL AND MENTAL DEMANDS OF BASKETBALL SMALL-SIDED GAMES: INFLUENCE OF TACTICAL TASKS AND TRAINING REGIMES

SANSONE, P.1, TESSITORE, A.1, PAULAUSKAS, H.2, LUKONAITIENE, I.2, TSCHAN, H.3, CONTE, D.2
1: UNIVERSITY OF ROME FORO ITALICO; 2: LITHUANIAN SPORTS UNIVERSITY; 3: UNIVERSITY OF VIENNA

INTRODUCTION: Performance in team sports is determined by the interaction between physical, physiological, technical-tactical and cognitive factors. Therefore, this study evaluated the effects of different tactical tasks and training regimes on physical, perceptual and mental demands of basketball small-sided games (SSGs).
METHODS: Twelve male semi-professional basketball players (age: 21 ± 2 y; stature: 194 ± 7 cm) participated to four half-court 3vs3 SSGs designed with two different tactical tasks (offense; defense) and training regimes (long: three 4-min bouts with 2' of rest in between; short: six 2-min bouts with 1' of rest in between), respectively. Thus, four experimental conditions were played, on separate days in a randomized order: offense-long; defense-long; offense-short; defense-short. Players wore Catapult S5 devices, to measure PlayerLoad per minute (PL·min-1). Perceived exertion (RPE, centiMax scale) and perceived mental effort (ME, 0-100 mm visual-analogue scale) scores were collected after each SSG. Additionally, before and after the SSGs players reported their level of perceived fatigue (F) and muscle soreness (S) (0-5 Likert scales); for each indicator, the differences between post and pre-SSG scores were calculated (ΔF; ΔS) and considered for analysis. Statistical analysis was performed via two-way (tactical task; training regime) repeated-measures ANOVA (Bonferroni post-hoc).
RESULTS: PL·min-1 was higher in the offensive task [12.2 ± 0.4 arbitrary units (AU)] compared to defensive (11.3 ± 0.3 AU) (p= 0.006, ES: moderate), and short regime (12.1 ± 0.4 AU) compared to long (11.4 ± 0.3 AU) (p= 0.022, ES: moderate); no interaction (task*regime) effect was found (p= 0.615, ES: no effect). RPE did not differ between tasks (offense: 85.8 ± 2.9 AU; defense: 79.3 ± 3.4 AU) (p= 0.072, ES: moderate) or regimes (long: 80.1 ± 3.3 AU; short: 85.1 ± 2.8 AU) (p= 0.102, ES: minimum), while a combined (task*regime) effect was found (p= 0.011, ES: moderate). ME was higher in the offensive task (47.5 ± 5.5 AU) compared to defensive (38.8 ± 4.4 AU) (p= 0.042, ES: moderate), while it did not differ between regimes (long: 45.4 ± 5.7 AU; short: 40.8 ± 4.4 AU) (p= 0.317, ES: minimum); also, no interaction was found (task*regime: p= 0.897, ES: no effect). ΔF did not differ between tasks (offense: -0.8 ± 0.2 AU; defense: -0.3 ± 0.2 AU) or regimes (long: -0.4 ± 0.2 AU; short: -0.7 ± 0.1 AU), and no interaction was found (all p> 0.05). ΔS differed between tasks (offense: -0.8 ± 0.2 AU; defense: -0.3 ± 0.2 AU) (p= 0.042, ES: moderate) but not regimes (long -0.6 ± 0.3 AU; short -0.5 ± 0.2 AU) (p= 0.555, ES: no effect); also, no combined effect was found (task*regime: p= 0.056, ES: moderate).
CONCLUSION: This study evaluated that, in basketball SSGs, physical load and perceived exertion are influenced by tactical tasks and training regimes. Furthermore, this study offers an initial insight on the mental demands of basketball training.

EXTERNAL LOAD BETWEEN PLAYING POSITIONS AND QUARTERS IN COMPETITIVE ELITE BASKETBALL

GARCIA, F.1, CASTELLANO, J.2, VÁZQUEZ, J.1, RECHE, X.1, TARRAGÓ, J.R.1
1: FC BARCELONA; 2: UNIVERSITY OF THE BASQUE COUNTRY

INTRODUCTION: In order to prescribe training accordingly, it is essential to understand beforehand the specific demands of basketball during competition. To date, there is no research published using micro-technology in official basketball games due to multiple restrictions in the principal European leagues. The aim of this investigation is, therefore, to analyse possible differences between positions and quarters during elite level basketball competition.
METHODS: Thirteen professional basketball athletes competing with FC Barcelona in the second Spanish division (Leb gold) were monitored during 5 official matches with a local positioning system (WIMU PRO®, Realtrack Systems SL, Almería, Spain). To allow comparisons, all data was divided between minutes played per player. Two-way Anova and Bonferroni post-hoc were used to contrast differences between positions and quarters in six main variables: Distance (DIS), Player Load (PL), number of Accelerations (ACC) and Decelerations (DEC), Distance over 18 km/h (D18) and Jumps over 5G (JUM). In addition, Cohen's effect size (ES) and 90% confidence intervals (90% CI) were also calculated.
RESULTS: After analysing differences between quarters, it can be seen that only DIS was found significantly dissimilar between 1st and 4th period (p = 0.04; ES = 0.61; 90% CI = 0.25, 0.97). On the contrary, some meaningful changes (p < 0.05) were identified between positions. Firstly, guards covered greater DIS (p < .001; ES = 0.87; 90% CI = 0.59, 1.15) than centers; and accumulated greater PL (p = 0.004; ES = 0.61; 90% CI = 0.36, 0.86) than forwards. Secondly, forwards covered greater D18 (p = 0.017; ES = 0.55; 90% CI = 0.30, 0.80) than guards and larger DIS (p = 0.01; ES = 0.67; 90% CI = 0.36, 0.98) than centers. To end, centers had higher JUM than both guards (p = 0.48; ES = 0.39; 90% CI = 0.12, 0.67) and forwards (p = 0.004; ES = 0.61; 90% CI = 0.30, 0.91). Regarding ACC and DEC, it can be said that these variables did not show significant variations between any of the two factors studied.
CONCLUSION: This research shows almost no significant differences between values across quarters in the six variables studied. Nevertheless, DIS was found to exhibit a moderate increase in the last period of the game, where the majority of matches are decided in pro-

fessional basketball. In regards of the differences between positions, some significant differences were detected. As an example, PL tends to be higher in guards compared with forwards and centers. Moreover, this investigation also found that the position that performs the highest number of jumps were the centers. A possible explanation for this is the fact that they are the tallest athletes in the team and normally play around the ring performing vertical actions such as rebounding and blocking shots, for instance. To sum up, enhanced understanding of the differences between quarters and, specially, positions will allow practitioners to prescribe training in a much more individualised manner.

IS LANDING IMPACT ASSESSED IN BIOMECHANICAL-BASED LABORATORY TESTS FIT FOR PURPOSE?

MORAN, K., MACMAHON, N., OCONNOR, S., WHYTE, E.

DUBLIN CITY UNIVERSITY

INTRODUCTION: Lab-based landing tests are commonly used to assess injury risk. However, it is unclear if these are reflective of landing during a training session, where injuries actually occur, and therefore may lack ecological validity and discriminative power.
METHODS: Sixteen female basketball athletes completed two lab-based landing tests [drop vertical jump (DVJ), stop-jump (STJ)] and lay-ups in a simulated training session. Peak impact acceleration (PIA) was measured at both the tibia and sacrum using wireless accelerometers (Shimmer, Ireland). Bland-Altman analyses [1] and intra-class correlations (ICC) were used to determine if the DVJ and STJ were in agreement with the Lay-up. For the Bland-Altman analysis, agreement was acceptable when the difference in the Outer Limits of Agreement (OLOA) [upper CI95% for the upper Limits of Agreement – lower CI95% for the lower Limits of Agreement] was smaller than the clinical acceptance range (CAR) [2], which was set a priori as ±10% of the average for each paired comparison.
RESULTS: For the TibiaPIA there was a lack of agreement between the Lay-up and both the DVJ [OLOA: 26.7g, CAR: 3.5g; bias: 3.7g] and the STJ (OLOA: 15.1g , CAR: 4.1g; bias: 2.4g). The ICC was not significant between the Lay-up and the DVJ (r = 0.26, CI95%: -1.11, 0.74; P>0.05). While the ICC was significant between the Lay-up and the STJ (r = 0.69, CI95%: 0.13, 0.89; P=0.013), the relationship ranged from little to strong. Paired t-tests indicated the Lay-up (19.3 ± 3.3g) resulted in significantly lower TibiaPIA than the STJ (21.8 ± 3.1g; P<0.05) and higher than the DVJ (15.6 ± 4.9g; P<0.05).
Similarly, for the SacrumPIA there was a lack of agreement between the Lay-up and both the DVJ (OLOA: 13.3g, CAR: 8.3g; bias: 2.7g) and the STJ (OLOA: 11.8g, CAR: 1.1g, bias: 0.2g). The ICC was not significant between the Lay-up and the DVJ (r = 0.41, CI95%: -.69, 0.79; P>0.05). While the ICC was significant between the Lay-up and the STJ (r = 0.76, CI95%: 0.33, 0.92; P=0.04), the relationship ranged from low to very strong. Paired t-tests indicated that in comparison to the Lay-up (5.6 ± 2.8g), SacrumPIA was significantly higher than the DVJ (2.9 ± 1.4g; P<0.05), but not different to the STJ (5.8 ± 2.7g; P>0.05).
CONCLUSION: Neither of the lab-based clinical tests (DVJ, STJ) produce results that are in agreement with the training-based lay-up. Since injuries occur 'on court', this calls into question the ecological validity of the lab-based tests. The findings may explain the inconsistency in research findings that have used lab-based landing tasks to identify biomechanical-based causes of injury [3], despite a commonly accepted belief that landing-based injuries are caused by high loading [4]. The findings suggest the need to develop more ecologically valid lab-based tests, or monitor athletes' landing impact accelerations during training/matches.

BIOMECHANICAL ANALYSIS OF DISTANCE CONTROL IN VOLLEYBALL OVERHEAD PASS

OZAWA, Y.1, YAMADA, H.2, KANOSUE, K.1

1: WASEDA UNIVERSITY, 2: TOKAI UNIVERSITY

INTRODUCTION: In the volleyball game, the overhead pass skill is important. A previous study revealed that the setter's performance influences the attacker's performance. The setters frequently utilize the overhead pass during setting. The overhead pass motion is unique in that the motion is not grasping or throwing. There are few biomechanical investigations in overhead pass. The purpose of this study was getting biomechanical data of overhead pass with different distances.
METHODS: Twelve male subjects participated in this study. All of them were top level university volleyball players. Subjects were told to pass a ball with overhead pass into a ring (diameter: 1 m, height: 2.43 m) set at 3, 6 or 9 meters ahead from a subject. They repeated trials at each distance until they succeeded five times. Forty-one reflective markers were placed on the ball and the subject's body to obtain joint centers and joint angles. EMG activities were recorded from the Triceps Brachii (TB), Biceps Brachii (BB), Extensor Carpi Ulnalis, and Flexor Carpi Radialis (FCR). The time period when the hands touched the ball was denoted as the main phase. The main phase was further divided into two phases with the timing when ball position was lowest (ball catch). The periods before and after the ball catch were denoted as pull phase and push phase, respectively.
RESULTS: In the pull phase the TB and FCR activities were significantly higher for the 6m trial than the 3m trial (TB: p = 0.02, FCR: p = 0.001). There was no significantly difference in the TB (p = 1.000) and FCR (p = 0.25) between 6m and 9m. The wrist was extended. So in the pull phase the FCR was eccentrically contracted. During the 3m trial, the wrist angular velocity at the 80% normalized time was significantly lower than that of 6m (p = 0.004) or 9m (p = 0.008).
Although there were many indexes which significantly differed between 3m and 6m, there was no significantly differences between 6m and 9m in the arm movement or muscle activity. On the other hand, the legs movement was significantly different among 3m , 6m and 9m. The changes of height of waist position between the main phase in the 3m were significantly lower than that of 6m (p = 0.002) and 9m (p = 0.000). The changes of waist position were correlated with initial ball speed (r = 0.810, p = 0.000).
CONCLUSION: In our previous study, the stretch-shortening cycle in the wrist was shown to be utilized in volleyball overhead pass. In the present study, analysis was made for three distances. Especially, the utilization of stretch-shortening cycle of the wrist was shown in 6m and 9m. The movement and muscle activity in the wrist and elbow was different between only 3m and 6m. This would be because the legs movement supplemented the power given to the ball. Indeed, the hip displacement increased with the increase in the target distance. Thus in the overhead pass when the target getting long, the skill needed involves not only arm movement but also leg movement.

VALIDITY AND RELIABILITY OF THE FITLIGHT TRAINER SYSTEM IN ESTIMATING LINEAR SPRINT TIME

CONTE, D.1, SNIECKUS, A.1, SANSONE, P.2, MORALES-BELANDO, M.T.3

1 LITHUANIAN SPORTS UNIVERSITY ; 2 UNIVERSITY OF ROME FORO ITALICO ; 3 UCAM UNIVERSIDAD CATÓLICA SAN ANTONIO DE MURCIA

INTRODUCTION: The Fitlight Trainer (Sports Corp., Canada) is a wireless training and testing system consisting of light-emitting diodes. While it is currently adopted in many sports, no information is available on its reliability and validity in examining linear sprint. Therefore, the aim of this study was to assess the reliability and concurrent validity of the Fitlight Trainer system in assessing linear sprint time.
METHODS: Eleven youth basketball players (age: 12.0 ± 0.3 y; stature: 157.5 ± 4.9 cm; body mass: 39.9 ± 2.1 kg; training experience: 4.4 ± 0.5 y) performed 3 maximal 30-m linear sprint tests during a single session in which they were simultaneously timed using six lights of the Fitlight Trainer system and an iPhone app (MySprint) previously adopted in literature (Romero-Franco et al., 2016). The 5-10m, 5-15m, 5-20m, 5-25m and 5-30m split times were calculated for a total of 33 sprints (3 trials for 11 participants). Differences between devices in each split time were assessed using an independent t-test and a magnitude-based approach to assess the difference greater than the smallest worthwhile change. To assess the level of agreement between devices, the coefficient of variation (CV) and intraclass correlation coefficient (ICC) with 90%CI using the mean values of the three trials of each player were calculated for each split time. The between devices concurrent validity was assessed using Pearsons product-moment correlation coefficient with 90%CI considering together the investigated split times for a total of 165 values (i.e. 33 values for each split time). Moreover, correlation coefficients were measured singularly for each split time. The magnitudes of the Pearsons correlation coefficients were determined as: trivial = 0–0.10; small = 0.11–0.30; moderate = 0.31–0.50; large = 0.51–0.69; very large = 0.70–0.89; almost perfect = 0.90–1.00.
RESULTS: No statistically significant ($p>0.05$) or substantial (Unclear and Possibly) differences were shown between devices in each investigated split time. Results revealed a nearly perfect level of agreement between devices (CV= 0.5% - 1.4% and ICC= 0.951 - 0.993). An excellent concurrent validity was found when considering split time together [r=0.999 (90%CI= 0.999; 0.999)]. Furthermore, results revealed very large and almost perfect correlation coefficients between the two devices when considering split time singularly.
CONCLUSION: The Fitlight trainer system is a reliable and valid tool in assessing linear sprint times and can be used alternatively to the MySprint app.

AGE RELATED DIFFERENCES IN ANTHROPOMETRIC AND PERFORMANCE OF YOUNG FOOTBALL PLAYERS

MICHAELIDES, M., PARPA, K.

UCLAN CYPRUS

INTRODUCTION: The purpose of this study was to examine the effects of age on anthropometric and performance variables in a large cross-sectional sample of youth soccer players during their in-season period.
METHODS: Three hundred and twenty-four young football players grouped into 8 age categories (7-years old, n=26, 8-years old, n=43, 9-years old, n=47, 10-years old, n=48, 11-years old, n=46, 12-years old, n=47, 13-years old, n=43, 14-years old, n=24). They completed anthropometric (body weight and height measurements) and physical fitness assessments, including the countermovement jump (CMJ), standing long jump, agility T-test, 10 and 20 m, 30 m sprints, low back/ hamstring flexibility and the handgrip strength tests.
RESULTS: Results demonstrated the significant relationships ($p<0.05$) among age, anthropometric and performance parameters. There was an increased rate of performance in all variables based on age. The gains associated with age ranged from 16% - 51% with the performance in agility (T-test) to be the one that increased the most. The significant differences among age groups in anthropometrics and performances were assessed using One-way Multivariate Analysis of Variance (MANOVA) followed by an LS means post hoc analysis.
CONCLUSION: The study demonstrates the significant differences in performance and anthropometric characteristics in young footballers from very young ages up to pre-puberty. The findings may assist coaches in the process of grouping children into youth categories and for talent identification.

IS-BN04 New insights on the control of voluntary actions derived from motor unit recordings

CHALLENGES ASSOCIATED WITH HIGH-DENSITY SURFACE EMG RECORDINGS

ENOKA, R.M.

UNIVERSITY OF COLORADO, BOULDER

To decode the neural drive to muscle, it is necessary to record the discharge times of many concurrently active motor units. This can be accomplished with electrode systems that comprise multiple recording sites (high-density electrodes) and algorithms that can subsequently identify the action potentials of several different motor units (Farina et al. 2016; Negro et al. 2016).
Recordings obtained with high-density electrodes comprise superimposed action potentials from many motor units. In contrast to recordings with intramuscular electrodes, it is much more difficult to observe the action potentials of individual motor units in the signals recorded with high-density electrodes. Consequently, it is critical that decomposition algorithms used to identify the discharge times of motor units embedded in the composite signals be validated with convincing approaches (Farina et al. 2015).
One approach that can be used to validate the quality of the motor unit data derived from high-density recordings is to compare the results with those obtained with more classical techniques, namely intramuscular electrodes (Duchateau & Enoka, 2011). In this presentation, I will compare the results obtained with the two approaches on peak discharge rate, saturation of discharge rate during submaximal contractions, rate coding during fast contractions, the association between oscillations in force and discharge rate, and adjustments during fatiguing contractions. The comparison indicates that some decomposition methods are able to replicate many of the findings obtained from intramuscular recordings, but additional improvements in the methods are required. Critically, more effort needs to be focused on editing the waveforms identified by the decomposition algorithms (Glaser & Holobar, in press).

With adequate attention to detail, this technology has the potential to augment our knowledge on motor unit physiology and to provide useful approaches that are being translated into clinical practice.

INFLUENCE OF RATE CODING ON THE CONTROL OF MUSCLE FORCE DURING FAST CONTRACTIONS

DUCHATEAU, J.

UNIVERSITE LIBRE DE BRUXELLES

The objective of this talk is to emphasize the role played by rate coding during various types of voluntary contractions and to discuss its control and functional implications in movement sciences.
The force produced by a muscle during a voluntary contraction depends on both the number of motor units that are progressively activated and the rates at which these units discharge action potentials (rate coding). When force increases gradually during an isometric contraction or when muscle is shortening, both motor units recruitment and discharge rate control the force exerted by the muscle over most of its operating range. Although these two mechanisms are also involved during lengthening contractions, rate coding is less modulated and discharge rate remains relatively constant during the entire range of motion. In contrast, during fast (ballistic) contraction, rate coding plays a dominant role in force gradation and rate of force development as all motor units are recruited at force/load as low as 30-40% of maximum. In addition, discharge rate reaches much greater values during ballistic contractions (60-200 Hz) than during slow maximal contractions (20-50 Hz) and can be used as an estimate of the maximal discharge rate of motor neurons (Enoka & Duchateau, 2017).
During ballistic actions, maximal discharge rate varies, however, according to the initial condition from which the contraction is performed. For example, greater discharge rate is reached when the ballistic contraction is performed from a resting state than when it is superimposed on a submaximal sustained contraction (20-25% of maximum). Interestingly, when a brief silent period occurs between the sustained and ballistic contractions, maximal discharge rate is recovered. Furthermore, motor unit discharge rate during ballistic contraction is reduced with ageing (Klass et al., 2008) and increased by training with fast contractions (Van Cutsem et al., 1998).
Functionally, this modulation in motor unit discharge rate at the onset of ballistic actions has a substantial effect on the rate of force development (Duchateau & Baudry, 2014).

CONSEQUENCES OF CHANGES IN MOTOR UNIT DISCHARGE CHARACTERISTICS AFTER SPINAL CORD INJURY

ZIJDEWIND, I.

UMC GRONINGEN

The discharge patterns of motor units differ across muscles (hand vs limb muscle), subject groups (e.g., controls vs patients), and conditions (e.g., medication status, fatigue; Thomas et al 2014). Understanding this diversity is important for both basic science and for rehabilitation purposes.
Motor unit activity derived from intramuscular recordings made in different muscles of persons after spinal cord injury (SCI) during maximal and submaximal voluntary contractions, as well as spontaneous or involuntary contractions (e.g., spasms) will be presented. Functional consequences of changes in motor unit activity will be discussed. For instance, reductions in maximal discharge rate will directly depress maximal force, whereas a decline in the range of motor unit recruitment will result in reduced control of muscle force and coordination (Thomas et al 2014). Also, less noticeable changes in discharge rate can have a substantial impact on motor coordination and motor function.
Understanding the changes induced by SCI on motor unit rate coding and recruitment in different muscle can be useful in the design of new rehabilitation strategies.

OP-PM28 Hypoxia I

AEROBIC AND ANAEROBIC PERTURBATIONS INDUCED BY ACUTE NORMOBARIC HYPOXIA EXPOSURE IN TRAINED CYCLISTS

SOUSA, A.1,2, MILHEIRO, J.S.3,4, VIANA, J.L.1,2, REIS, V.M.1

1: RESEARCH CENTER IN SPORTS SCIENCES, HEALTH SCIENCES AND HUMAN DEVELOPMENT 2: UNIVERSITY INSTITUTE OF MAIA, MAIA, PORTUGAL 3: CMEP, PORTO, PORTUGAL 4: OLYMPIC COMMITTEE OF PORTUGAL

INTRODUCTION: Up to an altitude of 1524m, maximal oxygen consumption (VO2max) is reduced only minimally, but thereafter is about 10.5% per additional 1000m (1). These altitude-related decrements in aerobic performance likely have a profound impact on other indices, such as critical power (CP), but very little impact in anaerobic parameters (W': anaerobic working capacity) (2). Impairment in exercise

tolerance (Tlim) is also expected. However, it is still scarce the magnitude of these impacts, or how these are related to the extent in which hypoxia impacts VO2max.
METHODS: Six trained male cyclists (mean ± SD; age: 34.5 ± 6.1yrs, height: 1.73 ± 0.08m and body mass: 70.8 ± 8.8kg) performed 3 tests in an electronically braked cycle ergometer (Lode Excalibur Sport, Groningen,The Netherlands), under normoxia (N) and acute normobaric hypoxia (H: 3000m, ~14% O2): (i) incremental until exhaustion for VO2max and corresponding power (wVO2max) assessment (7*2min steps); (ii) 3min all-out for CP and W' assessment, and, (iii) time to exhaustion (80%Δ - severe intensity) for Tlim assessment. Cardiopulmonary parameters were assessed (averaged 10s) using a portable gas analyser (K5, Cosmed, Italy). Capillary blood samples were collected before and immediately after each test (Lactate Scout +, EKF, Germany) for maximal lactate production analysis (Lacmax). VO2max was considered as the highest 30s average achieved during the incremental test. In the 3min all-out test, CP was calculated as the average power output for the final 30s and W' as the power–time integral above CP. Comparison between moments (Wilcoxon test) and correlation between variables (Spearman) were done ($p \leq .05$).
RESULTS: VO2max (60.8±9.5 vs. 44.3±4.6 ml.kg-1.min-1, p=.03) and wVO2max (324±42 vs. 276±41 W, p=.03) were significantly higher in N compared with H condition, but no differences were found for Lacmax (10.4±1.1 and 13.1±2.7 mmol.L-1). %VO2max achieved and Tlim (at the same relative work rate) were similar between conditions (101±9.6 and 111±17.3 %, and, 460.8±60.9 and 463.0±144.9 s), although the Lacmax was lower in N compared with H (11.2±2.8 and 14.3±2.6 mmol.L-1, p=.03). W' was similar (11.1±2.7 and 12.7±3.9 kJ), although CP was significantly higher in N compared with H (302±45.9 vs. 243.3±39.3 W, p=.03). ΔVO2max showed a tendency to be significantly correlated with ΔCP (r=0.77, p=.10) but not with ΔW' (r=-0.54). ΔCP showed a tendency to be significantly correlated with ΔW' (r=-0.77, p=.10).
CONCLUSION: The ~27% impairment in aerobic performance likely have a profound impact on CP, but very little impact in W'. 80%Δ intensity, although performed at the same relative work rate, demanded an increase in anaerobic energy turnover for the same Tlim, suggesting a higher muscle metabolic perturbation in H.

SLEEP AT HIGH ALTITUDE AND THE INFLUENCE ON STRESS AND RECOVERY

SCHÄFER, H.1, KÖLLING, S.2,3, KRUSCHE, T.1, MATIAS SANTOS, V.1, DE MARÉES, M.1, PLATEN, P.1
FACULTY OF SPORT SCIENCE, RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: High altitude sojourn might be associated with several symptoms, e.g. headaches, dizziness, nausea, fatigue or sleep disturbance (SD) [1,2]. All these symptoms, except for SD, correlate with the onset of acute mountain sickness (AMS). Therefore, SD was excluded from the Lake Louise Score (LLS) [1,2]. SD is related to changes in environmental conditions, breathing pattern or caused by other symptoms included in the LLS [1]. According to Roach et al. [2] further research should focus on the impact of disturbed sleep and overall well-being at high altitude, independent of AMS. The purpose of this study was to analyse sleep quality at high altitude and the effect on perceived stress and recovery.
METHODS: 11 healthy moderately trained subjects (m: n=9, f: n=2, 24.4±4.6 yrs, BMI: 22.9±2.0 kg/m2) were investigated during 6-days at 156m (baseline (BL): d-6 – d-1) and a 9-day hiking intervention at moderate to high altitude with sleeping heights of 1190m (d1), 2375m (d2, d3), and 3647m (d4 – d9). Daily sleep was assessed via multi-sensor actigraphy (SenseWear™) and sleep diary. Parameters included wake frequency (WF) and wake after sleep onset (WASO). In addition, the LLS, oxygen saturation (SaO2), and the Short Recovery and Stress Scale (SRSS) [3] were measured twice a day. The Recovery-Stress Questionnaire for Athletes (RESTQ-Sport 36) [4] was evaluated every three days
RESULTS: Just one participant was diagnosed with mild AMS on d4 (LLS=3). Including the sleep item, 4 participants fulfilled the AMS criteria at d4. All participants had SaO2 values > 85% throughout the tour (range=85–99%).
Objectively determined WF and WASO remained unchanged compared to BL. In contrast, subjective WF and WASO increased on d4 compared to BL ($p<0.05$; n=9). The sleep item of the LLS showed a decreased sleep quality between BL and d4 ($p<0.05$; n=11). The SRSS (d4, morning) did not change compared to BL nor to the mornings of d3 and d5 ($p>0.05$; n=11).
The RESTQ-Sport 36 dimensions Overall Stress, Overall Recovery, Sport-related Stress, Sport-related Recovery did not change from BL to d4, d7 and d10. Only Overall Stress decreased from BL to d4 ($p<0.05$; d=0.96; n=11). The scale General Stress did not change from BL to d4, d7, d10, but General Well-being increased from BL to d4 (d=1.20), d7 (d=1.03), d10 (d=1.38) ($p<0.05$; n=11).
CONCLUSION: According to the modified LLS, AMS was no issue in this study. The reduced sleep quality at d4 was not reflected by changes of the recovery-stress state. Despite the small sample size, the findings support the application of the new LLS, as sleep was only subjectively affected. Moreover, the slight decrease of Overall Stress and the increase of General Well-being indicate that the participants were able to enjoy the tour.

EFFECTS OF "LIVING HIGH TRAINING LOW" ON MUSCLE GLYCOGEN CONTENT: A DOUBLE-BLIND PLACEBO-CONTROLLED STUDY

CASTIGLIA, M.
UNIVERSITY OF SÃO PAULO

INTRODUCTION: Precious studies demonstrated that the "living high training low" (LHTL) is effective to improve the glycolytic enzymes activity (1). Thus, if the sessions of this model were applied using high-intensity efforts, where the glycogen stores represent an important energy source, it is plausible that the LHTL induces a positive effect on the storage of this substrate. However, these effects were not confirmed in the literature. Thus, the aim of present study was investigating the effects of 18 sessions of normobaric LHTL on the glycogen content (GC).

METHODS: Fourteen healthy males (28 ± 6 yrs; 81,6 ± 15,4 kg; 179 ± 5,2 cm) participated in this study. The subjects were trained using the one-legged exercise model, allowing four experimental groups (trained leg in hypoxia, TLHIP, n=9; control leg in hypoxia, CLHIP, n=9; trained leg in normoxia, TLNOR, n=5; control leg in normoxia, CLNOR, n=5). All participants were allocated in tends being exposed or not to a normobaric hypoxia environment (14,5% iFO2; ~3000m). A double-blind, placebo-controlled strategy was applied. An experimental training program (18 sessions) consisted of stimulus near to the intensity correspondent to the maximal oxygen consumption (80-200% of VO2max, with length between 20 to 45 min) was applied. Muscle biopsies of vastus lateralis were taken before and after the training program. The GC was determinate using a calorimetric method (2). In addition, erythropoietin concentrations (EPO) were also monitored at baseline and after training program. The two-way ANOVA and Tukey's post-hoc procedures were used to investigate the possible effects ($p < 0.05$).
RESULTS: The EPO increase significantly after training program for the individuals exposed to hypoxia between (Baseline: 8.6 ± 3.3 mUI.ml-1; After training: 17.1 ± 6.6 mUI.ml-1; p = p = 0,001), which not occur for the Placebo group (Baseline: 8.9 ± 1.4 mUI.ml-1; After training: 7.9 ± 4.3 mUI.ml-1; p = 0,72). After training program, significant differences between groups were observed (p = 0,003). Baseline values of GC (TLHIP: 0.4 ± 0.1 mg.100mg-1; CLHIP: 0.3 ± 0.2 mg.100mg-1; TLNOR: 0.3 ± 0.1 mg.100mg-1; CLNOR: 0.4 ± 0.1 mg.100mg-1) was not altered after training program for all experimental groups (TLHIP: 0.5 ± 0.1 mg.100mg-1; CLHIP: 0.4 ± 0.1 mg.100mg-1; TLNOR: 0.5 ± 0.0 mg.100mg-1; CLNOR: 0.4 ± 0.1 mg.100mg-1) (p > 0.16).
CONCLUSION: Although the EPO has been increased, the LHTL program was not effective to improve the muscle glycogen stores.

CEREBRAL DEOXYGENATION DURING HYPOXIC EXERCISE AND POSSIBLE ASSOCIATION WITH ACUTE MOUNTAIN SICKNESS

MANFERDELLI, G.1,2, MARZORATI, M.1, EASTON, C.2, PORCELLI, S.1

1: NATIONAL RESEARCH COUNCIL; 2: UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: Ascending to high altitude is often associated with symptoms related to acute mountain sickness (AMS). However, factors that can accurately predict AMS occurrence remain to be discovered. While there is some suggestion that altered autoregulation of cerebral blood flow and/or impaired brain oxygenation during hypoxic exposure may determine AMS, experimental evidences do not support this hypothesis. Alternatively, it is well known that exercise alters cerebral blood flow and brain oxygenation and hypoxia can exacerbate these modifications. It is currently unclear, however, whether cerebral oxygenation status during exercise in hypoxia may be predictive for the risk of AMS. The aim of this study was to investigate the association between cerebral deoxygenation during hypoxic exercise and AMS occurrence.
METHODS: Twenty-one healthy individuals (30+-8yrs) were recruited for the study. Each subject completed the following three exercise tests on a motorized treadmill: i) an incremental exercise to exhaustion (INCR); ii) a 8-minutes constant-load exercise at moderate intensity in normoxia (CLE-NORM); iii) a 8-minutes constant-load exercise at moderate intensity while inspiring hypoxic air (FiO2=0.12) (CLE-HYPO). Breath-by-breath V'O2, V'CO2, and V'E were measured by indirect calorimetry using a metabolic cart. Heart rate (HR) was measured using a chest strap. Oxygen saturation (SpO2) was measured by pulse oximeter at the ear lobe. Brain frontal oxygenation (HbO2), deoxygenation (HHb), and total hemoglobin (Hbtot) were obtained by near-infrared spectroscopy. AMS susceptibility was evaluated by exposing subjects to normobaric hypoxia (FiO2=0.12) for 10 hours and evaluating AMS symptoms using the Lake Louise scale (LLS).
RESULTS: During INCR, V'O2peak was 3.73+-0.72L/min and it corresponded to 51.8+-8.3ml/kg/min. During CLE-HYPO, physiological response to exercise (V'O2: 1.63+-0.41L/min; V'CO2: 1.31+-0.33L/min, V'E: 44.8+-7.5L/min) was higher than in CLE-NORM (V'O2: 1.27+-0.32L/min; V'CO2: 1.00+-0.21L/min; V'E: 32.2+-3.8L/min). During CLE-HYPO, V'O2 was 1.63+-0.4L/min, V'CO2 was 1.31+-0.3L/min and V'E was 44.8+-7.5L/min. HR was significantly lower in CLE-NORM (103+-13bpm) compared to CLE-HYPO (134+-16bpm). SpO2 did not change from resting values during CLE-NORM (96+-3%), while it decreased to 77+-5% in CLE-NORM. HHb, HbO2 and Hbtot did not change from resting values during CLE-NORM. During CLE-HYPO, HHb significantly increased (46%) whereas HbO2 and Hbtot decreased (95% and 44%, respectively). Six subjects reported LLS score higher than 3 and were considered symptomatic of AMS (AMS+). In AMS+, Hbtot reduction (78+-11%) was significantly higher than in AMS- (10+-5%). Moreover, HHb increment was slightly lower in AMS+ compared to AMS-. No differences were observed for HbO2 between AMS+ and AMS-.
CONCLUSION: Cerebral deoxygenation and brain blood volume changes during hypoxic exercise were different in AMS+ and AMS- subjects, suggesting their changes may help to predict AMS occurrence.

OP-PM27 Sport injuries and orthopedics I

INJURIES IN NATIONAL TEAM DUTY: A 2-YEAR PROSPECTIVE FOLLOW-UP OF INJURIES OCCURRING IN NATIONAL TEAM FOOTBALL PLAYERS DURING THE OFFICIAL FIFA CALENDAR

BRITO, J., BECKERT, P., FERREIRA, S., FIGUEIREDO, P., NORONHA, J.C.

PORTUGUESE FOOTBALL FEDERATION

INTRODUCTION: National football teams play exclusively during the official FIFA calendar. These dates are considered as congested fixtures (1), including matches played every 3-5 days. Limited epidemiological data is available for football players during National team duty, especially during the official FIFA dates. Therefore, the present study investigated the epidemiology of injuries during National team duty, encompassing a 2-year follow up in male football players.
METHODS: The study was conducted from August 2016 until July 2018. The follow-up occurred during the Qualifiers for Russia 2018 FIFA World Cup, Russia 2018 Confederations Cup, Russia 2018 World Cup and friendly matches occurring during the official FIFA calendar. Overall, the study period encompassed 33 matches (n=440 individual matches) and 92 training sessions (n=1932 individual training sessions). All 51 players called for National duties during the study period were included in the analysis. We prospectively recorded time-loss injuries according to the consensus statement for studies in football injuries (2). The team doctors evaluated and recorded all injuries. Only injuries occurring during National team duty were logged. Any previous injuries occurring at the club level that prevented the players from training or competing in National team duty were considered for the analysis. Individual exposure to training sessions and matches was recorded by one member of the medical staff.

RESULTS: We recorded 2448 h of exposure, with 515 h of match play and 1933 h of training. In total, 18 injuries were recorded; 7 injuries occurred during match play, and 11 injuries occurred during training sessions. Total incidence was 7.3 injuries/1000 h of exposure; incidence during matches and training were 13.6 and 5.7 injuries/1000 h of exposure, respectively. Overall, we recorded 0.2 injuries per match and 0.1 per training session.
Muscle sprains had the highest injury incidence (4.9 injuries/1000 h of total exposure), followed by ligament sprains (1.2 injuries/1000 h of total exposure). The incidence of muscle sprains was 7.4 and 4.1 injuries/1000 h of exposure for matches and training sessions, respectively.
The hamstrings were the most affected body part (3.6 injuries/1000 h of total exposure), followed by the leg (2.0 injuries/1000 h of total exposure). The incidence of hamstring injuries was 5.6 and 3.1 injuries/1000 h of exposure for matches and training sessions, respectively.
CONCLUSION: During National team duty, the injury characteristics are consistent with the overall epidemiology of injuries described at the professional club level. National teams and clubs should consider sharing clinical and training load information on players competing in National teams, aiming to protect the health of the players, reducing the risk of injuries and assuring appropriate management of training loads.

SEASON TO SEASON CHANGES IN INJURY BURDEN ARE RELATED TO CHANGES IN TEAM PERFORMANCE IN ELITE AUSTRALIAN FOOTBALL

HOFFMAN, D., GASTIN, P., BOWE, S., CLIFTON, P., DWYER, D.

DEAKIN UNIVERSITY

INTRODUCTION: An association between a team's injury burden and their whole-of-season performance has been found in several sports, including basketball and football. In addition to assessing associations within seasons, it may be useful to measure the influence of the change in injury burden on the change in performance from season to season. This accounts for other factors that affect team performance, such as "team strength". Furthermore, a modelling approach that uses a combination of injury burden variables may reveal more information about this relationship than single variables alone. Therefore, the present study aimed to determine how much of a team's change in whole-of-season performance, from one season to the next, was affected by their change in injury burden. In addition, a combination of injury burden variables was modelled (within each season and as changes from season to season) to explain performance.
METHODS: This was an observational study of 15,289 injuries that caused 51,331 missed matches from 1997 to 2016 in the Australian Football League. Differences in season to season single injury burden variables (incidence, severity, prevalence, player match availability and percentage of list injured) and relationships between changes to performance variables, from one season to the next, were analysed. The combination of injury burden variables was modelled (e.g., decision tree, multiple linear regression) to explain team whole-of-season performance (finalists/non-finalists, ladder position, premiership points, the ratio of points for and against (%)). Premiership points range from 0 to 88 points and 8 out of 18 teams become finalists each season. Final model selection was based upon out-of-sample model performance then model interpretability.
RESULTS: The strongest association between a team's injury burden and their performance was found when modelling a combination of injury burden variables, especially their relative change from season to season. The best regression model, comprising of three injury burden variables (number of injuries, player match availability, percentage of list injured), typically predicted changes to premiership points within 14 points and explained 27% of the variation in the changes to premiership points of teams. Changes to ladder position were typically predicted within four positions ($r2 = 0.18$, $p < 0.001$) and the classification model achieved an accuracy of 70% for changes between finalists/non-finalists. Season to season single injury burden variable associations with performance did not provide any further insights than within season associations.
CONCLUSION: A combination of injury burden variables explains more of a team's whole-of-season performance, than any single injury burden variable. Modelling the season to season changes in injury burden variables on the season to season changes in performance variables were more accurate than within each season modelling.

CHANGES IN GLENOHUMERAL JOINT ISOKINETIC STRENGTH IN PROFESSIONAL RUGBY LEAGUE PLAYERS ACROSS A SEASON

HAINES, M.

UNIVERSITY OF HUDDERSFIELD

INTRODUCTION: Shoulder injuries are common and frequently severe in rugby league resulting in significant time loss from playing and training. The incidence of injury may also increase in the latter stages of a season as a result of accumulative micro-trauma. Strength of rotator cuff and scapula musculature could protect against contact injuries to the shoulder. The aim of this study was to assess glenohumeral joint (GHJ) rotation strength across a season in a professional European Super League club.
METHODS: A prospective cohort study was used to compare GHJ rotation pre-, mid-, and post-season. Twenty-nine players performed isokinetic dynamometry for concentric and eccentric muscle actions for shoulder internal and external rotation at 240°/s. A standing position with the GHJ placed in 30° of abduction and 30° of forward flexion into the scapular plane (scaption) was used to more closely mimic actions during rugby league game play. Peak torque, traditional strength ratios, and dynamic control ratios were compared.
RESULTS: Ipsilateral strength ratios were indicative of selective strengthening of internal rotators for concentric and eccentric muscle actions . There were no significant differences between peak torque strength parameters at any time point. Similarly, strength ratios failed to reach statistical significance at any time point across the season.
CONCLUSION: The null finding suggests that rugby league players are no more likely to sustain a shoulder injury in the latter stages of the season, at least not as a result of decreased GHJ rotator strength. Players were able to maintain rotator cuff strength across the season which is valuable to practitioners developing conditioning programmes to optimise performance and minimise the risk of injury. Increased strength of internal rotators for concentric and eccentric muscle actions may afford protection, particularly during forced external rotation during contact in rugby league. From an applied perspective a decision should be made whether to maintain an imbalance, which could optimise performance and potentially reduce risk of injury by increasing tolerance of impact forces, or to try and obtain muscular re-balance which could prevent overuse injuries but negatively affect performance.

THE EFFECT OF SHOE CUSHIONING ON INJURY RISK IN RECREATIONAL RUNNERS: DOES BODY MASS MATTER?

MALISOUX, L.

LUXEMBOURG INSTITUTE OF HEALTH

INTRODUCTION: Shoe cushioning technology of modern running shoes is expected to protect runners against repetitive loading of the musculoskeletal system, and therefore, running-related injuries (RRI). It is a common belief that heavier runners should use footwear with increased shock absorption properties to prevent RRI. Surprisingly, no study has provided evidence on the beneficial effect of increased shock absorption properties on injury risk so far. Therefore, the purpose of this study was to determine if shoe cushioning influences injury risk in recreational runners and whether the association depends on the runner's body mass.
METHODS: This double-blinded randomized control trial included 848 recreational runners who randomly received one of two shoe models that only differed in their cushioning properties. Global stiffness was 61±2 and 94±6 N/mm in the Soft and Hard versions, respectively. Participants were classified as light or heavy according to their body mass using the median as cut-off (separately for men and women). Training and injury data were collected during 6 months on an internet based platform: www.tipps.lu. An RRI was defined as any running-related musculoskeletal pain in the lower limbs that causes a restriction or stoppage of running (distance, speed, duration, or training) for at least 7 days. Cox regression analyses were used to compare RRI risk between the two groups based on hazard rate ratios (HR) and their 95% confidence intervals (95%CI), controlling for potential confounders. A stratified analysis was conducted to separately investigate the effect of shoe cushioning on RRI risk in lighter and heavier runners.
RESULTS: Median body mass was 78.2 and 62.8 kg in men and women, respectively. A total of 24954 running sessions were recorded, of which 97% were performed with the study shoes. 131 participants (15.4%) sustained at least one RRI during the intervention. The overall incidence was 5.6 RRI/1000h of running (95%CI=4.8; 6.7). Body mass was not associated with injury risk (HR=1.00; 95%CI=0.99-1.02). The adjusted Cox regression analysis revealed that the runners who had received the Soft shoes had a lower hazard rate for RRI (HR=0.67; 95%CI=0.47-0.94). Previous injury was identified as a risk factor (HR=1.78; 95%CI=1.19-2.65), while there was a trend for age (HR=0.98; 95%CI=0.86-1.00) to be a protective factor. When stratified according to body mass, results showed that lighter runners benefited from Soft shoes (HR=0.54; 95%CI=0.33-0.90) while heavier runners did not (HR=0.84; 95%CI=0.51-1.36).
CONCLUSION: The overall injury risk was lower in runners who had received the shoe version with higher cushioning properties. While body mass was not associated with RRI risk, the stratified analysis revealed that only lighter runners actually benefit from higher cushioning, in contrast with popular belief.

TIME TO CONCENTRATE? CONCENTRATION DISRUPTION AS A CONTRIBUTING FACTOR TO THE OCCURRENCE OF ACUTE INJURIES DURING ELITE FEMALE SOCCER GAMES.

VERRELST, R.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Performance anxiety can play a role in acute injury development during soccer games. The purpose of this study was to identify the possible predictive value of the Sport Anxiety Scale -2 on acute injury susceptibility in elite female soccer players.
METHODS: In this prospective cohort design 91 Belgian female football players who were selected for the national team (U13, U14, U15, U16, U17, U19, U21 and the first national team), completed the SAS-2 in the beginning of the soccer season. During the nine months follow – up, injuries were registered using an monitoring application. All registered injuries were immediately double checked during a follow-up interview. Additionally a trimonthly retrospective injury enquiry was performed and cross – checked with the data from the injury registration application.
RESULTS: During the follow – up period, 30 (32.97%) of the 91 female soccer players developed an acute injury during the game. Univariate logistic regression analyses identified a predictive value for concentration disruption (P-value= 0.034; Odds – ratio 1.240). No predictive values were found for somatic anxiety and worry.
CONCLUSION: Within a population of female elite soccer players, a predictive effect (Odds ratio: 1.240) was identified for concentration disruption on the occurrence of an acute traumatic injury during soccer games. The subscales of somatic anxiety and worry were not identified as predictive parameters.

TRAINING LOAD CHARACTERISTICS IN THE CONTEXT OF INJURY AND ILLNESS RISK IDENTIFICATION IN ELITE YOUTH SKI RACING: A PROSPECTIVE STUDY

STEIDL-MÜLLER, L.1, HILDEBRANDT, C.1, MÜLLER, E.2, RASCHNER, C.1

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Alpine ski racing is a sport with a high risk of injury. First studies in youth ski racing showed that neuromuscular control, lower limb asymmetries in unilateral leg extension strength, core strength imbalances and biological maturity status represent significant injury risk factors among athletes younger than 15 years. However, training load characteristics have not been investigated with respect to injury and illness risk, even though studies in other types of sport reported significant correlations among these aspects (Watson et al., 2017). Therefore, the aim of the present study was to assess the role of training load characteristics in injury and illness risk identification.
METHODS: Training load characteristics and training contents, as well as traumatic injuries (TI), overuse injuries (OI) and illnesses (IL) of 90 elite youth ski racers (51 males, 39 females; 10.0-14.4 years; 12.1 ± 1.3 yrs) were prospectively recorded over the period of one season. Linear regression analyses were performed (dependent variables: illnesses, injuries; independent variables: weekly training volume, weekly training intensity). Level of significance was set at $p<0.05$.
RESULTS: A total of 666 training sessions were analyzed (311 athletic, 355 skiing). Most athletic training sessions were intensive (46.6%), moderate (39.9%) or highly intensive (10.3%). Most skiing specific training sessions were intensive (69.3%) or highly intensive (16.1%). The mean weekly training volume was 680 ± 280 minutes per athlete with in mean 3.6 ± 0.8 training sessions per week. In total, 185 medical problems were reported: 41 TI (0.46 TI/athlete), 12 OI (0.13/athlete) and 132 IL (1.47/athlete). Most TI were classified as moderate (36.6%; time loss: 8-28 days) or mild (31.7%; 4-7 days) and mostly affected the knee (31.7%) followed by ankle and lower leg (12.2% each). Most traumatic injuries occurred during skiing specific training (43.9%). Most overuse injuries were mild (41.7%) and moderate (25.0%) and mostly affected the knee and the ankle (25.0% each). Most illnesses were minimal (55.2%; <4 days) or mild (40.9%). Most illnesses affected the gastrointestinal (48.5%) or respiratory tract (40.2%). Weekly training volume and weekly training intensity did not represent a significant injury risk factor. Weekly training intensity showed to be a significant risk factor for illnesses (ß=0.348; p=0.044; R^2=0.121).

CONCLUSION: Relatively high rates of TI and IL were present among youth ski racers, whereas only few OI were reported. This finding shows that a lot of preventive measures were applied and that the training load was adequate, which was emphasized by the results of the regression analyses, as well. Training load and intensity seem to not influence injury risk in youth ski racers. However, high weekly training intensities seem to affect the immune system of the athletes, which results in a higher IL rate.

DEVELOPMENT OF AN AUTOMATIC ALPINE SKIING TURN DETECTION ALGORITHM BASED ON A SIMPLE SENSOR SETUP

MARTINEZ, A., JAHNEL, R., BUCHECKER, M., SNYDER, C., BRUNAUER, R., STÖGGL, T.

UNIVERSITY OF SALZBURG, SALZBURG RESEARCH FORSCHUNGSGESELLSCHAFT M.B.H.

INTRODUCTION: In order to gain insight into alpine skiing performance, it is necessary to determine where each ski turn begins. Several methodologies have been proposed to determine turn switches. However, those methodologies are not yet feasible to use in a regular basis. The aim of this study was to develop a simple sensor set up for daily usage and an algorithm to accurately detect turns during alpine skiing.
METHODS: Ski turn imitations were performed on a ski-ergometer at different turn durations and slopes. An IMU was attached to the posterior upper cuff of each boot. Turn detection algorithms were developed to analyze multiple IMU signals. Expert raters assessed the point of the turn switch based on video recordings to establish the most accurate algorithm. The selected signal and algorithm were used for the in-field measurements. Eleven expert skiers performed a minimum of 10 turns for each of the styles e.g. carving long, carving short and drifted. To validate and fine tune the algorithm, ratio and adapted confusion matrix were used. Ratio: the relation between the number of detected and the number of actual turns. Confusion matrix: assesses the precision (how many detected turns are true turns) and recall (how many real turns are detected).
RESULTS: Acceleration signals showed less consistent behavior and lower accuracy values during the in-lab situation and were consequently discarded for further algorithm development. Within the gyroscope data, the anterior-posterior axis with a cutoff filter of 3 Hz showed the best agreement with expert evaluation. Ratios were 0.996, 1.007, and 0.833 for short carved, long carved and drifted turns respectively. Precision and recall were 0.996 and 0.991 for short carved, 0.993 and 1.000 for long carved and 0.833 for drifted turns.
CONCLUSION: The developed algorithm was based on the point of maximum angular velocity which due to the pendulum like behavior of the skiers, corresponds with the point of turn switch. The results indicate that the developed system is valid and accurate for carved turns. For drifted turns, while all the turns detected are real, some real turns are missing. Further development needs to be done to enhance the robustness for drifted turns and to include other techniques such as snowplough skiing.
This study developed a new system to accurately (95%) detect turn switches using a simple and unobtrusive set up that is feasible to use on a regular basis.

COMPARISON OF WEARABLE GPS DEVICES FOR DISTANCE AND SPEED ESTIMATION ACROSS DIFFERENT MOTION PATHS

RAIZADAY, S., SCOBIE, N.

COLLEGE OF MEDICAL, VETERINARY AND LIFE SCIENCES , UNIVERSITY OF GLASGOW

INTRODUCTION: The increasing competitiveness in elite level sports has led to the use of GPS technology to track various sport-specific physiological parameters of athletes. However, there lacks enough evidence in sports science literature comparing standard GPS devices with the latest GLONASS enabled devices. This study aimed to compare the accuracy of two 10Hz GPS devices for distance and speed estimation between a long-distance (LD) curvilinear course and a short-distance (SD) course with abrupt changes in direction at different testing speeds.
METHODS: Nine healthy adult participants (6 males, 3 females), each wearing a Playertek (GLONASS enabled) and a Catapult OptimEye X4 device, completed one lap each of an outdoor 420m oval running track at speeds of 5, 6, 9, 12, 15 and 18 km/hr and of a 40m track with three right angled changes of direction at speeds of 5, 9 and 12 km/hr. Each lap speed was maintained by beeps emitted by a speed-calibrated mobile application (Metroneme Beats v3.6.1). Another mobile application (Ultrachron Lite v1.98) manually recorded lap times. The distance covered and average speed for each lap were analyzed in the cloud-based Playertek and the Catapult Sprint v5.1 software. Estimated distances and differences in speeds were assessed as the mean with 95% confidence limits for different lap speeds. One-sample and paired-sample t-tests were used to assess the bias between the criterion and GPS measurements. Analysis Of Variance (ANOVA) was performed to establish relationship of the estimated distances and speeds with different lap speeds. All statistical tests were performed on IBM SPSS Statistics v25.
RESULTS: In the long-distance course, Playertek overestimated distance (423.61 ± 2.24 m; p = 0.01; bias = 3.61) and speed (0.09 ± 0.05 km/hr; p = 0.01; bias = 0.09) at 6 km/hr but underestimated these at 12, 15 and 18 km/hr while Catapult significantly overestimated all distances (p = 0.00). In the short-distance course, Playertek underestimated all distances and speeds (-0.47 ± 0.28 km/hr; p = 0.01 at 5 km/hr; bias = -0.47) whereas Catapult overestimated all distances (43.33 ± 2.53 m; p = 0.03 at 5 km/hr; bias = 3.33) but significantly underestimated all speeds. In the LD course, the two devices differed significantly in distance estimation at all speeds (p = 0.00) and in speed estimation at 15 km/hr (p = 0.04). Whereas, in the SD course, the devices differed significantly in distance estimation at 5 km/hr (p = 0.01) and in speed estimation at 5 and 12 km/hr (p = 0.00).
CONCLUSION: Although, for long distances, Catapult appears to improve in accuracy at high and low testing speeds for distance and speed estimation respectively, but for moderate testing speeds, Playertek proves to be relatively more accurate than Catapult for both long and short distances. Thus, even though both the 10Hz GPS devices provide fairly accurate measurements of distance and speed, the GLONASS enabled device fares comparatively better probably due to testing at a location of higher latitude.

COMPARISON OF THE WEARABLE TECHNOLOGY AND MEMS FOR MEASURING VERTICAL JUMP PERFORMANCE

GUMUS, H., GENCOGLU, C., OZDALYAN, F., KOSOVA, S., TUNAR, M., KAYATEKIN, M.

DOKUZ EYLUL UNIVERSITY

INTRODUCTION: Jumping height is one of test to evaluate the anaerobic power in sports. There are some limitations in available jumping height measurements methods such as expensive equipment demands or nonsensitive measurements. The aim of this study is to compare different jumping height assessments regarding wearable and sensor technology. Video Motion Capture Analyses (CAM), Laser Imaging Detection and Ranging System (LIDAR, LID), force sensor (FSR), ultrasonic sensors (US), Infrared (IR) and Inertial movement units (IMU) methods were compared to Photoelectronic sensors (PES) as a reference method.
METHODS: Fifty-one healthy male volunteer (23.61±4.62 year, 178.46±7.16 cm, 78.55±12.39 kg) participated in this study. They wore a vest included sensors systems and record units. FSR sensor was mounted to their shoes using a velcro band. IMU and active marker were placed to the center of mass. After the control of sensors working, they performed three CMJ (arms were stabilized to the body) with 90s recovery. All jumps were recorded as 2s periods by the high-frequency camera using buffer triggering and data was processed in Matlab. Different assessments of jumping height were compared with repeated measurements of ANOVA. The ICC was used to examine the relationships of methods. The SEM and 95% limit of agreement (LOA) method were calculated and showed as Bland Altman plots graphed. Relationships of new methods with reference jumping height assessment were evaluated by intraclass correlation (ICC).
RESULTS: The raw data of the US and IR methods could not be evaluated due to the doppler effect and artifacts caused by laser beams LIDAR sensor respectively. There is no significantly difference between FSR, CAM, IMU, LID and PES measurements ($F(3,303)= 2.338$, $p=.074$) and these variables showed significant correlation in the ICC test (respectively, r=0.9971; r=0.9573; r=0.6858; r=0.9949). There is significantly correlation ICC between PES, the reference measurement, and other measurement methods (FSR, CAM, IMU, LID) found significant ($p<0.0001$; respectively r=0.99, 0.95, 0.68, 0.99). The results of the SEM, CV, and LoA values were established between PES and other methods. In terms of standard error of measurement, the FSR measurement method has the lowest value (SEM=5.38) when compared to the PES.
CONCLUSION: The findings from the present study indicated that the FSR method was considered to have an acceptable discriminant ability. Especially shoe sole entegrated wearable products with FSR, can be used for the evaluation of complicated movements with the inclusion of jumping component, not only singular jumps. In the literature, there are many IMU-based jumping height measurement methods which the results were supported in the present study (Nielsen et al., Rantalonen et al. and Casartelli et al). As our knowledge, there is no published article in this topic of evaluating sport performance, which is using LIDAR method. This research is the first research which evaluates sport preformance with LIDAR.

NOVEL DEVICES CAN MEASURE JUMP-AND-REACH PERFORMANCE WITHOUT THE NEED FOR A REACH TARGET

BROOKS, E.R.1,2, BENSON, A.C.3, FOX, A.S.1, BRUCE, L.M.1

1: CENTRE FOR SPORT RESEARCH, DEAKIN UNIVERSITY 2: SCHOOL OF HEALTH AND BIOMEDICAL SCIENCES, RMIT UNIVERSITY, 3: DEPARTMENT OF HEALTH AND MEDICAL SCIENCES, SWINBURNE UNIVERSITY

INTRODUCTION: Jump-and-reach testing is often used to test athletes, allowing them to perform an action that replicates sporting competition movement better than constrained actions (e.g. jumping with no countermovement action or hands fixed on hips). Additionally, countermovement and arm-swing actions have both been shown to increase jump height performance (Harman et al., 1990). Jump-and-reach testing has typically required large apparatus with a physical target, such as plastic vanes to be displaced by the hand. Inertial measurement devices and smart device applications have increased both the portability and accessibility of jump-and-reach testing. The aim of this study was to determine if novel devices could be used to measure jump height without the need for a target.
METHODS: Twenty-seven (14 male and 13 female) healthy adults were recruited for this single cohort experimental research study. Participants performed a standardised warm-up, followed by the jump testing protocols. Three devices simultaneously measured jump height, those being: (i) an inertial measurement unit (VERT); (ii) a smart-device application (My Jump 2); and (iii) a force platform. A total of six maximal jumps were assessed for each participant with two minutes rest between all jumps. The first three jumps were performed with a jump-and-reach apparatus (Yardstick) to provide a physical reach target. The target was then removed, and participants performed the subsequent three jumps using the same technique (i.e. countermovement with free-arm-swing and reach). Paired t-tests were used to compare devices using the highest jump performed by participants in each condition. Mean difference and effect size (Cohen's d) were calculated to evaluate the magnitude of the effect.
RESULTS: Analysis of force platform data revealed a statistically significant difference ($p<0.05$) between the target and no-target jump conditions (mean difference 1.36 cm [95%CI: 0.33-2.39], d = 0.11; trivial). No statistically significant differences between jump conditions were found when testing with the VERT or My Jump 2 devices.
CONCLUSION: A trivial difference was found when using the force platform (Hopkins, 2004). However, the difference detected by the force platform is likely to be of an insignificant magnitude to deter use in most testing in the field, as the mean difference is less than the smallest worthwhile change in the tested population (2.42 cm). The findings of this study suggest the VERT and My Jump 2 devices can be used in field-based jump testing without the need for a reach target, as long as the participants still reach for height when performing testing.

PERFORMANCE ANALYSIS USING WEARABLE ACCELERATION SENSOR AT YOUTH ELITE SOCCER PLAYERS IN JAPAN.

MAGOME, T.1,4, GOUDA, N.2, TANAKA, T.3, YAMAGUCHI, T.3, NAKATA, K.1

**1 OSAKA UNIVERSITY GRADUATE SCHOOL OF MEDICINE, *2 GOVERNMENT & PUBLIC CORPORATION INFORMATION SYSTEMS DIVISION, HITACHI,LTD, *3 RESEARCH & DEPARTMENT GROUP, HITACHI,LTD. , *4 OTEMON GAKUIN UNIVERSITY*

INTRODUCTION: The role of sports is important to extend healthy life span. [1] Performance analysis is indispensable, especially for knowing the level of physical activity, therefore it has been carried out in various sports in recent years. However, as the algorithm for analysis is complicated, there is often a time lag in feed backing the data analysis result to the staff at the sports site. In this study, we succeeded in displaying results in real time and conducted the measurements using wearable acceleration sensor to analyse not only total players load but also team physical activity level belonging to youth elite soccer players in Japan.

METHODS: Soccer players attached the acceleration sensors of the 100Hz sampling [2] to their chest and the momentum in game and skill training was estimated. The measurements with wearable acceleration sensor were performed for two weeks and physical activity level of each players and team was examined from the collected data.
RESULTS: We extracted an interesting fact that the common points of top team player regarding exercise intensity and total distance of soccer performance. In addition, by team network analysis, we founded that excellent players movement influence on the game tactics and development ($p<0.05$).
CONCLUSION: We succeeded in performance analysis of each player's and team statement in the game and skill trainings. Furthermore, our research revealed to quantify the activation of the network in the game. However, further trial in different sports is needed for establishing accurate analysis.
Although the individual's movement had been focused on until now, the analysis of the group movement must become important because using the team tactics would be demanded recent years. We need to develop the proper analyzing system of athlete performance and team tactics. Continuous research which connects to find the various ways of analysis and performance quantification contributes not for the current situations but for the cultivation of young athletes in future. Controlling players' condition with the performance quantification by using our developed method leads to the injury prevention and contributes to the development of sports medicine.

CONTACT-FREE MEASUREMENT OF NOCTURNAL HEART RATE VARIABILITY BY BALLISTOCARDIOGRAPHY BASED EMFIT QS

VESTERINEN, V., RINKINEN, N., NUMMELA, A.

KIHU - RESEARCH INSTITUTE FOR OLYMPIC SPORTS, JYVASKYLA, FINLAND

INTRODUCTION: Nocturnal heart rate variability (HRV) provides objective method to monitor athlete´s stress and recovery balance, and further to optimize athletic training. Effective HRV monitoring should be daily basis for getting the complete view about the cardiac autonomic regulation. Traditionally, HRV has been determined by measuring RR-intervals from the electrocardiographic signal (ECG) in the morning. However, morning ECG measurements with HR straps are time-consuming and arduous to perform and consequently only a few individuals keep doing the measurements every day. Emfit QS is a ballistocardiography (BCG) based commercial device for monitoring sleep and recovery. Under a bed mattress installed EMFi sensor can detect HR, HRV, breathing and other body movements. Thus, it is a contact-free, effortless and user-friendly method and have the capacity to improve user compliance of daily monitoring. However, to the best of our knowledge, there is not previously published validation about measuring nocturnal HR and HRV from BCG under real-life conditions. The aim of this study was to evaluate the accuracy of Emfit QS in measuring HR and HRV during sleep, alongside ECG based recorder as a reference.
METHODS: Twenty, healthy participants completed nocturnal HRV recordings at home using BCG based Emfit QS and ECG based reference device Firstbeat Bodyguard 2. The recordings were started just after going to bed to sleep and stopped after waking up in the morning. HR and the natural logarithm of the square root of the mean squared differences of successive R-R intervals (Ln RMSSD) were analyzed for 3 min epochs and the mean values of the sleep period were calculated.
RESULTS: The small mean bias was observed in the mean HR (-0.8 ± 2.3 bpm) and Ln RMSSD (-0.05 ± 0.25 ms) between Emfit QS and the reference. In addition, very large correlations were found in the mean values of HR ($r = 0.90$, $p < 0.001$) and Ln RMSSD ($r = 0.89$, $p < 0.001$) between the devices. Based on the Bland-Altman method, the 95% limits of agreement (mean ± 1.96 SD) were ± 4.6 bpm in HR and ± 0.48 in Ln RMSSD. The larger error was found in smaller and greater Ln RMSSD values, which showed a proportional error in Ln RMSSD determined by Emfit QS. The greater amount of erroneous or missing data was found in the Emfit QS measurements (28.3 ± 14.4%) compared with the reference (1.1 ± 2.3%).
CONCLUSION: Based on the present results, Emfit QS provides the mean nocturnal HR and HRV with the acceptable small mean bias, for non-clinical purposes. In addition, the results showed the relatively large limits of agreements and some under- and overestimation in high and low HRV levels. Emfit QS seems to be a potential and practical tool to monitor athlete´s stress and recovery status on a daily basis. However, further development is needed in the ability of heart beat detecting for avoiding large bias in some individuals. Furthermore, more studies are needed to clarify reliability in HR and HRV detecting.

OP-SH16 Psychology: Physical activity promotion

PROMOTING PHYSICAL ACTIVITY AMONG OLDER ADULTS LIVING IN RURAL AREAS: ASSESSING EXPERIENCES OF AND BARRIERS FACED USING ACTIVITY TRACKERS

CHANG, C.H.1, CHOW, H.W.1, LIN, L.C.1, CHOU, J.W.1, LIU, B.C.2, CHEN, Y.W.2

1:NATIONAL CHENG KUNG UNIVERSITY, 2:DEPARTMENT OF NURSING, NATIONAL CHENG KUNG UNIVERSITY HOSPITAL

INTRODUCTION: Fitness trackers have become a popular means to motivate people to monitor their physical activity levels and maintain regular active lifestyles. However, little attention has been paid to the effects of fitness tracker use among older adults. Therefore, this study explored older adults' experiences with and barriers faced when using activity trackers.
METHODS: A total of 30 older adults living in a rural county in Taiwan wore activity trackers daily for six consecutive weeks. In the first week, the research team instructed the participants on how to use the activity tracker and tested whether they were able to 1) wear and take off the activity tracker, 2) understand the information on the screen, and 3) charge the activity tracker. Each test was further divided into several tasks. The test was readministrated after 6 weeks. Semistructured interviews were conducted to solicit the participants' experiences and any barriers they faced when using the activity trackers.
RESULTS: The mean age of the participants was 76.8 years (range: 61–89 years). A total of 70% were women. Most of the participants had little education; 30% were illiterate, and 60% had only graduated from elementary school. Among the participants, 55% did not use

mobile phones. In the initial test, 20% of the older adults found it difficult to wear the activity trackers. Moreover, 8% of the older adults found it difficult to check the time, 24% had trouble checking the total number of steps walked, and 24% were unsure how to check distance travelled on the activity tracker screen. Other challenging functions included separating the device, assembling the device, and plugging in the charger, with failure rates of 12%, 32%, and 12%, respectively. After 6 weeks, all participants passed the test for wearing the activity trackers; however, all other tests maintained similar failure rates. Although many participants stated in the interviews that wearing the fitness tracker helped them check the time and motivated them to increase walking behavior, many participants had difficulty using or understanding the information related to their physical activity.
CONCLUSION: As population aging continues, numerous health promotion campaigns and research interventions have adopted fitness trackers to monitor older adults' physical activity levels or related health information to develop future applications (e.g., in telemedicine). However, in this study, we found that many older adults in rural areas of Taiwan are unfamiliar with products of such technology. Consequently, they face several obstacles when using activity trackers, such as inability to assemble and charge the device, inability to understand the on-screen information, and inconvenience due to their lifestyles (e.g., participating in agricultural work). In the future, to ensure success, interventions that involve older adults with low education levels should start with detailed instructions on how to use fitness trackers.

WILL THE USE OF FITNESS TRACKER IMPROVE OLDER ADULTS' SUBJECTIVE ASSESSMENT OF PHYSICAL ACTIVITY?

CHOW, H.W., CHANG, C.H., LIN, L.C., KAO, C.C.
NATIONAL CHENG KUNG UNIVERSITY,

INTRODUCTION: Although self-report of physical activity has been a popular method to assess physical activity due to its low-cost and convenience to gather large sample data, it has long been criticized for its subjectivity. In contrast, the traditional objective measurements of physical activity are costly, and most of them are limited to a control laboratory environment. As the fitness tracker is becoming popular in the market, this study aims to assess the correlation of self-report of physical activity and objective measurement of steps from the fitness tracker and examine whether the subject will improve the accuracy of his/her self-report of physical activity over time.
METHODS: This study recruited 30 older adults who live in a rural area as seniors are a target for physical activity promotion. The research team carefully instructed the seniors on how to use the fitness tracker first and asked the participants to wear it for six weeks. The International Physical Activity Questionnaire-Short Form (IPAQ-SF) was used to assess self-report of physical activity every week. Wilcoxon signed-rank test was used to examine trajectories of physical activity (steps, METs-min/wk and sedentary behavior time) over the six weeks. Spearman rank order correlation coefficient was utilized to examine the relationship between the objective and subjective measurement in rural elders' physical activity levels.
RESULTS: Twenty-four older adults (mean: 76.8 yrs, range: 61-89) completed the study. The majority of participants had little education. The participants showed significant increase in physical activity in terms of objective measurement from the fitness tracker with the average steps of 3752 steps/day (range 794– 15026) in week 1 to 6297 steps/day (range 1084– 18068) in week 6 ($p<0.001$) as well as subjective measurement by IPAQ (2808 METs-min/wk in week 1 to 6156 METs-min/wk) ($p<0.001$). However, there was no significant correlation between the subjective assessment of physical activity (in terms of walking time and METs-min) and the objective number of steps from the fitness tracker over the six weeks.
CONCLUSION: This study proved that fitness trackers could improve the physical activity level of rural older adults from both the objective and subjective measurement. However, the study did not support the assumption that the subject will improve the accuracy of his/her self-report of physical activity over time. The reason might be attributed to the participants' low education level, recall difficulty in older adults, reliability, and validity of IPAQ-SF, or issues related to repeated measurements of questionnaires. This study has confirmed the limitations and inaccuracy of subjective self-report of physical activity, especially from older adults with low education level. It is suggested that adopting fitness trackers could be considered in future health promotion interventions to objectively and precisely monitor older adults' daily physical activity.

THE EFFECTS OF THE CAMPUS WALKING TRAIL APP ON PSYCHOLOGICAL WELLBEING AND PHYSICAL ACTIVITY LEVEL OF THE UNIVERSITY STUDENTS

LEUNG, E.F.L.1, YUEN, B.P.K.1, NG, R.S.K.1, CHUI, H.T.Y.2, LI, P.C.L.1, TANG, T.M.1, HON, S.S.1
THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Regular physical activity (PA) is beneficial to human health. However, the PA levels of young people in Hong Kong have been reported to be below the levels sufficient to gain the health benefits that exercise can offer (LCSD, 2013). Most university campuses are pedestrian-oriented with aesthetic and shaded footpaths, thus walking as a means of transportation to classes and social destinations can be facilitated and encouraged. The purpose of the research was to evaluate the effect of the campus walking trail application (app) on psychological wellbeing and PA level of the university students.
METHODS: A fitness walking mobile app was developed for encouraging university students to attend to walking for fitness. Three trail routes were designed which passed through different unique landmarks and halls of the university. A total of 1606 students from a university were volunteers who enrolled in the current study. Eligibility criteria included 1) access to Internet; 2) current full-time undergraduate student; 3) absence of any physical conditions that would severely restrict the ability to be physically active. The PA level and psychological wellbeing of the participants were collected online using the IPAQ-SF and PANAS Questionnaire before the commencement of the intervention and every week after a walking trial within the program in 12 weeks.
RESULTS: For all participants, a decrease in walking distance ($t = 11.211$, $df = 886$, $p = 0.001$) and walking time ($t = 2.572$, $df = 886$, $p = 0.01$) between their first registered walking entry and the post intervention entry were found. However, when participants were categorized into the positive change group (PC) with increased walking distance and the negative change group (NC) with no change or decreased walking distance, an increase in positive mood ($t = 2.983$, $df = 156$, $p = 0.003$) and also an increase in negative mood ($t = 2.806$, $df = 156$, $p = 0.006$) were found in participants in the PC before and after the intervention.
CONCLUSION: The results showed that the walking mobile app was not effective in promoting gradual increases in walking on campus. However, there was a positive effect observed; participants who had been walking more and longer did improve their mood afterward. In order to have more understanding on the effectiveness of the walking mobile app on psychological wellbeing and PA level of the participants, future studies should be on strategies to increase the compliance rate.

IN SEARCH OF KEY ATTRIBUTES OF PEER LEADERS FOR THE PROMOTION OF PHYSICAL ACTIVITY IN OLDER ADULTS

KRITZ, M., THØGERSEN-NTOUMANI, C., NTOUMANIS, N., MULLAN, B.
CURTIN UNIVERSITY

Introduction
Regular physical activity can help older people maintain/and or increase independence, mobility, physical health, mental wellbeing and quality of life. However, the majority of older adults are physically inactive. Peer-led interventions have become a common method of promoting physical activity behaviour and these approaches may be cost-effective. However, the attributes ,making an older peer leader effective at encouraging physical activity among their peers, are currently unknown. The aim of the present study is to determine what older adults, differing in their physical activity engagement, perceive to be ideal peer leader characteristics.
Methods
A mixed-methods concurrent triangulation design was used to identify key attributes of effective older peer leaders, as perceived by participants differing in their physical activity engagement and leadership experience. Participants (N=101; M age (SD) = 75.44 (7.67); age range: 60-93) were recruited from retirement villages and existing walking groups in Perth, Australia. Participants consisted of inactive individuals interested in joining a walking group (N=43), physically active residents interested in the peer leader role (N=25), and individuals who had already served as walk peer leaders (N=15) or had taken part in other peer-led walking programs (N=18). Semi-structured interviews (N=68) were conducted and complemented with questionnaire data (N=101) to identify important leadership characteristics. Interviews were analysed using content analysis. Questionnaire data was analysed using descriptive analysis.
Results
Questionnaire data showed that walkers rated the attributes "friendly", "outgoing and dependable" as the most important traits of an older peer leader. Content analysis revealed that being encouraging (48%), compassionate (46%) and competent (40%) were the most frequently mentioned leadership attributes across the whole sample. Most experienced leaders described effective leaders as inclusive (73%) and communicative (80%). In contrast, inexperienced leaders placed the highest importance on the leader being encouraging (64%) and demonstrating leadership competence (48%). Most experienced walkers described effective leaders as friendly (67%) and inclusive (56%) while inexperienced walkers primarily sought a leader who is entertaining (47%), compassionate (40%) and competent at leading a group (44%).
Conclusion
Results suggest that perceptions towards an effective older peer may differ depending on individual leadership experience and physical activity engagement. These differing perceptions may need to be taken into account in the planning of future peer leader training in order to effectively promote walking in older adults.

DISTINCTION BETWEEN RESPONDERS AND NON-RESPONDERS IN ACTIVITIES OF DAILY LIVING DEPENDENT ON INTERVENTION-RELATED MOTOR AND COGNITIVE SKILLS

BEZOLD, J., BARISCH-FRITZ, B., TRAUTWEIN, S., SCHARPF, A., WOLL, A.
KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION
The performance of activities of daily living (ADL) is influenced by motor and cognitive skills that are impaired in individuals with dementia (IWD) [1]. Improving these skills might have positive effects on performing ADL independently (Bossers et al., 2016). In IWD, there is still no clear evidence for the efficacy of physical activity (PA) on ADL, although some studies found positive effects [2]. For further improvement of PA interventions, it is important to characterize ADL-responders (ADL-R) and ADL-non-responders (ADL-NR). Therefore, our aim is to investigate if changes in motor and cognitive skills due to a multimodal exercise program (MEP) can predict the probability to be an ADL-R.
METHODS
The "Physical Activity Against Dementia" project [3] was designed as a RCT including baseline and post-assessment. Participants (>65 years) with mild to moderate primary dementia, living in nursing homes completed a 16-week MEP (2x/week, 60min). Four our purpose, this analysis only includes participants of the intervention group (n=106, age 85±6, MMSE=18±4). ADL performance (7-item Physical Performance Test, PPT-7), was defined as primary outcome. Cognitive skills were measured with Mini Mental State Examination (MMSE, global cognition). Frailty and Injuries: Cooperative Studies of Intervention Techniques (FICSIT, balance), 6m-Walk Test (WT, gait speed) and Sit-to-Stand Test (STS, lower limb function) were included for measuring motor skills. A binomial logistic regression analysis was calculated to identify the effects of MMSE, FICSIT, WT and STS on the probability to be an ADL-R.
RESULTS
The results show a significant model correctly classifying 72.0% of cases in the presented sample (Nagelkerke R^2=0.37; p=0.02). Changes in MMSE (p=0.001, OR=1.341[1.130-1.592]), WT (p=0.034, OR=1.288[1.020-1.627]) and STS (p=0.017, OR=1.349 [1.055-1.725]) are significant parameters predicting ADL-R. Changes in FICSIT were excluded from the model (p=0.15).
CONCLUSION
Concerning the relevance of reducing health care burden, this study provides first ideas which motor and cognitive skills should be addressed in individualized PA interventions aiming at the improvement of ADL performance. However, further studies should investigate if intervention programs based on motor and cognitive individualization are more effective than general PA interventions.

THE PHYS-CAN STUDY: MEANINGFUL AND CHALLENGING - SUPERVISING PHYSICAL EXERCISE IN A NON-CLINICAL SETTING FOR PERSONS UNDERGOING CURATIVE ONCOLOGICAL TREATMENT

HENRIKSSON, A.1, IGELSTRÖM, H.2, ARVING, C.1, NORDIN, N.1,3, JOHANSSON, B.1,4, DEMMELMAIER, I.1,3

UPPSALA UNIVERSITY , SWEDEN UNIVERSITY OF AGDER, NORWAY

INTRODUCTION: Supervised exercise is one of the most effective ways to improve physical function and quality of life during oncological treatment. Yet, it is not possible to provide exercise support for all patients at hospitals. Instead, supervised community based exercise programmes may be a realistic alternative. Knowledge about the professional's experience of supervising exercise may be helpful for implementation.
Phys-Can is a randomised controlled trial evaluating effects of exercise on cancer-related fatigue during curative oncological treatment. Physiotherapists and gym instructors supervised the exercise at public gyms, and thus Phys-Can provides a unique opportunity to explore professionals' views on exercise supervision in a non-clinical setting. This study aimed to explore professionals' experiences of supervising exercise in a non-clinical setting for persons receiving curative oncological treatment.
METHODS: Eleven of 13 eligible physiotherapists/gym instructors (the coaches) were interviewed individually after signing a consent form. The semi-structured interviews lasted between 33-67 minutes and were analysed using thematic analysis.
RESULTS: The analysis resulted in two main themes: "A meaningful task" and "A challenging task". The coaches experienced supervising exercise as meaningful, as they became a link between oncological care and health promotion, allowing them to bring their clinical knowledge into the healthy environment of the public gym and making a difference in people's lives. They grew more confident in their role and became aware that exercising during treatment was feasible. Challenges included managing barriers such as side effects from treatment and contradictory information from oncology care advising patients not to exercise.
CONCLUSION: Linking oncological care and health promotion by providing exercise in a non-clinical setting may be rewarding for professionals and thus promising for implementation of an exercise programme as part of cancer rehabilitation. Practical experience may be important because this increases confidence in the safety and feasibility of supervising exercise for persons receiving oncological treatment. Collaboration and consensus between oncology care and the providers of exercise about the benefits of exercise is important for facilitating exercise being performed in a public setting. Further studies are needed to identify effective collaboration and implementation strategies and to investigate how to reach consensus that exercise is beneficial for persons undergoing oncological treatment.

IS-SH05 The role of sport history in the scientific community - Aims, opportunities, challenges

SPORT HISTORY IN THE UNITED STATES: STATUS, FUTURE DIRECTION, AND INFLUENCE

GEMS, G.

NORTH CENTRAL COLLEGE

This presentation provides a short history of the development of the discipline of sport history in the United States, its current status within the fields of social and cultural history, and future directions for study. More importantly it addresses the necessity of sport history and its relevance for the sciences and how it can and should contribute to the traditional fields of sport science. Knowledge within the fields of sport science is dependent upon the knowledge achieved in the historical past, or else condemned to commit the same mistakes of previous practitioners. The humanities provide insight for scientists to develop a more complete understanding of human physiology, nutrition, performance, etc., and such interdisciplinary cooperation can only enhance their research.

SPORT HISTORY IN EUROPE: DISPENSABLE OR ESSENTIAL FOR THE PE TEACHER EDUCATION?

HECK, S.

INSTITUTE OF SPORT SCIENCE

Sport History has been traditionally part of the Physical Education (PE) teacher training at sports science departments in Europe. Despite these strong links and the continues engagement of sport historians in some European countries, sport history positions are increasingly reduced or fully replaced by other disciplines of sports science. This leads to a loss of importance of sport history as it is in many European countries no longer a compulsory part of the university studies of future PE teachers.
This presentation aims at a first glance to describe the status quo of sport history in the PE teacher education at different European universities. It furthermore tries to find reasons for the reduction of those positions by evaluating the content of PE curricula and possible changes in their aims and directions which come along with this trend.
Finally, an outlook shall be given by highlighting consequences of this development which for instance lead to a less broad education of future PE teachers. Humanities, and sport history in particular, allow the sport sciences to achieve a fuller understanding of the mind and body which deems important for everyone, but more particularly also for those teaching our children how to practise and understand sports.

THE ROLE OF SPORT HISTORY IN GENDER STUDIES

PFISTER, G.

UNIVERSITY OF COPENHAGEN

Gertrud Pfister will explore the changing opportunities and challenges of males and females in different sport related contexts which varied dependent on the time period as well as on the country and the region. Whereas the (lack of) participation of girls and women in recreational physical activities and in competitive sports has been found considerable interest among historians, sport as a marker of masculinities is severely under researched as mens participation in sporting endeavours seems to be "normal" and "natural". This paper provides an overview about the "gendering" of various sports and discusses the causes and consequences of "degendering" processes. Another focus will be the definition of femininity and the current discussions about the eligibility for womens competitions. A historical

perspective on gender verification regulating the access to various sport events provides insights into current sport discourses which may indicate a decreasing interest in gender.

IS-MI04 Individualization and optimization of exercise training prescription [Clinical track]

MONITORING AND OPTIMIZING TRAINING PRESCRIPTION IN CYCLING AND THE DEVELOPMENT OF A FATIGUE INDEX.

LAMBERTS, R.P.
STELLENBOSCH UNIVERSITY

Introduction
Monitoring training load and recovery with the aim to prescribe the best possible training prescription is a challenge for coaches and trainers and of increasing interest to researchers (1-3). Various parameters both non-invasive and invasive have been proposed to optimize this process (2,3), however a multivariate approach to monitor and prescribe training has not been studied in a limited context.
Methods
The data from several studies (reliability, overreaching in elite female cyclists (4), overreaching study in male trained mountain bikers the Cape Epic ('Hors Classe' UCI event)) will be used to study the effectiveness of monitoring cyclists with a single parameters approach or a multi-variate parameters approach. A newly developed 'Lamberts Fatigue Index' (LFI), incorporating 7 different variables, was compared to single outcome parameters to monitor and fine-tune training in trained to elite cyclists.
Results
A multivariate approach to monitoring the accumulation of fatigue and fine-tune training prescription, is superior to using a one outcome parameter approach. Some parameters such as heart rate recovery and power output are more sensitive to reflect a state of fatigue, while others seem to respond slightly slower. In addition, a single parameter approach can be misleading and inform the cyclists and coach incorrectly. For example, a faster heart rate recovery in combination with increased RPE levels, reflect something different than a faster hear rate recovery with similar or lower RPE levels. As some parameters such as heart rate recovery seem to be more sensitive to reflect a state of fatigue compared to for example a rating of perceived exertion, a weighted multi-variate monitoring approach should be used.

Discussion
A multivariate approach is superior to monitor and fine-tune training prescription than a single parameter approach. By using a weighed multi-variate approach for monitoring and fine-tuning training prescription in cyclists, such as the LFI, the sensitivity to detect maladaptation and/or the accumulation of fatigue can be substantially improved, while incorrect interpretation of monitoring data can be prevented.

ACUTE AND CHRONIC RESPONSES TO INDIVIDUALIZED TRAINING PRESCRIPTIONS

HOPKER, J.
UNIVERSITY OF KENT

There appears to be increasing agreement that the response to a standardised training programme can be remarkably diverse. It has long been established that an individual's time to exhaustion at the same relative intensity can vary hugely (e.g. 88% VO2max cyclists' time to exhaustion varied from 12 min to 75 min; Coyle et al. 1988). However, the method for prescribing training in most studies remains standardised as a percentage of maximum. Consequently, it seems unsurprising that the training response may differ between two individuals training at a standardised intensity that yields such a diverse response to even a single bout of exercise. Even where the ability to sustain a standardised training intensity is more carefully controlled, the underlying assumption that this is linked to a training response remains open. Moreover, the fact that submaximal and/or maximal laboratory measures (such as lactate threshold, or VO2max) are correlated with exercise performance does not make these indices appropriate benchmarks for setting training intensities (Vollard et al., 2009). Rather the benchmarks for appropriate training intensities should be those that elicit a consistent training response (Coakley & Passfield, 2018). The aim of this presentation is to discuss some approaches to standardise a training stimulus by varying training intensity across different individuals, and consider their ability to provide a beneficial training adaptation.

OPTIMISING HIGH-INTENSITY AEROBIC TRAINING SESSIONS AND MONTHLY TRAINING ORGANISATION IN ENDURANCE ATHLETES

RONNESTAD, B.R.
INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

Optimising high-intensity aerobic training sessions and monthly training organisation in endurance athletes
Rønnestad, BR.1

1: Inland Norway University of Applied Sciences (Lillehammer, Norway)
Introduction
There are almost an endless number of ways to design the training for endurance athletes. Researches, coaches and athletes are continuously hunting the best training program. Amongst the biggest challenges are the myriad of alternative ways of designing the program and that there are no unique combination that fits all athletes. This presentation will focus on some potential fruitful methods to optimize the acute exercise stimulus to high-intensity aerobic interval sessions (HIIT) in endurance athletes. Amongst the promising variables for evaluating HIIT is time above 90% of maximal oxygen uptake. Furthermore, the organization of the different training sessions in the weekly or monthly training cycle seems also to affect the training adaptations. Effects of different strategies in organising the training on a weekly and monthly basis will be discussed in order to optimise the adaptations in endurance athletes.

OP-PM30 Cardiovascular physiology

CARDIOVASCULAR DRIFT AND LEFT VENTRICULAR PERFORMANCE DURING PROLONGED EXERCISE AT MODERATE INTENSITY

LAGINESTRA, F.G., WANG, E., BERG, O.K., NYBERG, S.K., VENTURELLI, M., HELGERUD, J.
UNIVERSITÀ DEGLI STUDI DI VERONA AND NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Prolonged exercise leads to a progressive upward drift in heart rate (HR) that may compromise stroke volume (SV) response (1). Some studies reported a transient diminished left ventricle (LV) systolic function in the post-exercise recovery phase (2). However, it is unclear whether a decrease in LV systolic performance exists also during exercise. The aim of this study was to examine the dynamics of LV regulation during prolonged exercise. We hypothesized that LV systolic function would be maintained while ventricular filling would be diminished.
METHODS: Eight healthy non-endurance trained young males (25±2yrs) completed a 60 min cycling bout on a semi-recumbent cycle ergometer at 57% VO2max. Measurements of HR, end-diastolic volume (EDV) and end-systolic volume (ESV) were obtained by Doppler ultrasound at nine time points throughout the trial and were used to calculate SV, cardiac output (Q) and ejection fraction (EF). Ear temperature (Te), skin temperature (Tsk) and oxygen consumption (VO2) were also collected. Fluid intake was tightly matched to the individual sweat rate. Percentage changes in blood volume (%BV) and body mass (pre to post bout) were recorded to assess eventual changes in hydration and loading conditions.
RESULTS: From min 10 to min 60, both EF and EDV were maintained ($p=0.85$ and $p=0.17$). In the same time span, HR increased by 12% ($p=0.01$) while SV was kept stable ($p=0.82$). VO2 and Tsk increased respectively by 8% ($p=0.01$) and 6% ($p<0.01$) from min 10 to min 60. All the other variables did not change throughout the trial.
CONCLUSION: Overall, our findings suggest that LV systolic performance is not blunted during prolonged exercise. In addition, we did not find a diminished ventricular filling but a maintained EDV in spite of the increased HR. This finding may indicate an improvement in the relaxation of the ventricle with the augmented sympathetic drive.

DIFFERENCES BETWEEN RIGHT AND LEFT VENTRICULAR STROKE VOLUMES AFTER CHANGES IN BODY POSITION - INFLUENCES FROM BREATHING MANEUVERS

HOFFMANN, U., KOSCHATE, J., DRESCHER, U., DUMITRESCU, D., WERNER, A.
GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Changes of body position influences cardiovascular factors as stroke volume (SV), heart rate (HR), blood pressure (BP), peripheral resistance and perfusion as well pulmonary components as lung perfusion, alveolar aeration and arterio-venous oxygen difference in the tissue. The aim of this study was to show the effect of changing position on right and left ventricular SV (SV-RV, SV-LV) and the influence from exerted exhalation (ex-ex).
METHODS: 14 healthy male subjects (age: 30 ± 4 y) were tested on a tilt seat (65° (pre-baseline) to 90° for 25 s (tilt up), to -6° for 22 s (tilt down), to 90° for 25 s (tilt back) and back to 65° (recovery)). During the -6° phase the subjects remained either in the resting condition or the subjects performed ex-ex (in random order). Pulmonary gas exchange (V'O2) was measured breath by breath using Zan 680 (Zan Meßgeräte GmbH, Oberthulba, Germany), applying the corrections of Beaver et al. (1981) for alveolar gas exchange. Heart rate (HR) was recorded beat to beat via ECG and blood pressure was measured continuously using Portapres M2 (Finapres, Amsterdam, The Netherlands). SV-LV was calculated from blood pressure using the Modelflow algorithm (Beatfast-Analysis Software; Finapres, Amsterdam, The Netherlands). The data was synchronized and interpolated to 1 s intervals. SV-RV was calculated for each second from tilt up to tilt back from arterio-venous difference in O2 concentration (avDO2) during pre-baseline and the continuously measured HR and V'O2 according to the Fick Principle during tilt up, tilt down and tilt back.
Three-way ANOVA (ventricle, maneuver, time) was used for statistical analysis of SV differences to the first 5 s in each mode (ventricle, maneuver). Paired t-test was applied to investigate the differences between SV-RV and SV-LV.
RESULTS: Significances were found for all factors and its interactions. Remarkable significant SV-RV/SV-LV differences were found immediately after tilting at rest (up to 150 mL) and were significantly lower for ex-ex (35 mL). SV-LV at rest increased less pronounced after tilt down and was found stable during this phase, for ex-ex time courses of SV-RV and SV-LV were found similar. After the tilt back in the ex-ex condition SV-RV showed an increase in contrast to SV-LV.
CONCLUSION: The volume shift by tilting to -6° provokes an increase in SV-RV. This effect is damped by ex-ex. This implies a transient thoracic filling during -6° at rest which was attanuated by ex-ex. After ex-ex - combined with the tilt back - the immediate increase of SV-RV indicates either a remarkable venous return and/or change in avDO2. However, the increase in SV-LV is greater after the combination of relaxation of ex-ex and tilt back compared to resting tilt. This might be beneficial for e.g. orthostatic tolerance.
These results may have an impact on all sports with rapid position changes (e.g. start in swimming) or high gravity changes (e.g. bobsleigh, sledging).

AGE EFFECTS ON THE DEFLECTION OF THE HEART RATE PERFORMANCE CURVE IN MAXIMAL INCREMENTAL CYCLE ERGOMETER EXERCISE IN A LARGE COHORT OF HEALTHY SUBJECTS

BIRNBAUMER, P., TRANINGER, H., FALGENHAUER, M., MODRE-OSPRIAN, R., HOFMANN, P.

UNIVERSITY OF GRAZ

INTRODUCTION: Heart rate performance curve (HRPC) in incremental exercise was shown to be neither linear nor uniform. Regularly, HRPC´s show a downward HR deflection at higher exercise intensities but a considerable amount of subjects show a linear HRPC or even an upward deflection, having major consequences for exercise prescription (1). We analyzed a large dataset regarding age effects on HRPC time course.
METHODS: HR data from 9 635 incremental cycle ergometer tests with uniform 20 W steps were classified into age groups. A second-degree polynomial optimal fit (least error square) was applied to mean HR for each single load-step between 40% (HR40%) and 100% (HR100%) of maximum power output (Pmax) to quantify the direction and the degree of the HRPC deflection. From these quadratic functions the slopes of the tangents at the points HR40% and HR100%, k1 and k2 were calculated, as well as the difference of the slopes via K=(k1 - k2) / (1 + k1 x k2). K-values were classified as downward deflection K+ (K > 0.01), linear K0 (0.01 < K > -0.01) and upward deflection K- (K < -0.01). The analyzed data represent data from males and females, tested several times at different age in some cases.
RESULTS: 6 193 tests were from male (55 ±15 yrs.; Pmax 217 ±5 W) and 3 442 from female (55 ±14 yrs.; Pmax 144 ±31 W) subjects. Eight age groups (decades) from ≤ 20 yrs. up to > 80 yrs. were analyzed. Variance analysis showed significant different K values in age groups > 31 yrs. (m) and > 41 yrs. (f). The heart rate curves with upward deflection increased linear in male (yK=0.50 x age + 1.77, r2=0.86, p=0.001, CI=0.30-0.71) and female (yk=0.29 x age + 1.99, r2=0.82, p=0.002, CI=0.15-0.42) between ≤ 20 yrs. and > 80 yrs. from 10 to 38% (m) and 6 to 20% (f). Conversely, the percentage of regular downward deflection decreased (m: 74 to 43%; f: 86 to 70%). The number of linear curves was unaltered by age.
CONCLUSION: Findings provide reference data for HRPC deflection for a large local cohort. We confirm earlier results that the HRPC in incremental exercise is neither linear nor uniform. We show for the first time a linear increase of non-regular HRPC´s with an upward deflection with age. As a consequence, the use of fixed percentages of HRmax to prescribe exercise intensity is not recommended as the probability of incorrect determination increases with age.
The study was supported by Zukunftsfonds Steiermark.

INCREASED LEVELS OF PLASMA ENDOTHELIN-1 (ET-1) IN RESPONSE TO ACUTE EXTREME PHYSICAL BUT NOT TO MENTAL STRESS WITH PRESERVED LEFT VENTRICULAR FUNCTION IN MALE HUNGARIAN ATHLETES

LIGETVÁRI, R., ÁCS, P., FAR, G., FARKAS, I., VÉGH, J., SZILÁGYI, G., CSÖNDÖR, É., KOMKA, Z., SZOKODI, I., TÓTH, M.V., TÓTH, M., STROMÁJER-RÁCZ, T., BETLEHEM, J., OLÁH, A.

FACULTY OF HEALTH SCIENCES, UNIVERSITY OF PÉCS, INTERNATIONAL TRAINING CENTRE, EÖTVÖS LÓRÁND UNIVERSITY, SEMMELWEIS UNIVERSITY, UNIVERSITY OF PHYSICAL EDUCATION, HUNGARY

INTRODUCTION: ET-1 has not only a vasoconstrictor and positive inotropic effect but direct arrhythmogenic potency, too inducing prolongation of the QT-interval, early afterdepolarization and fatal ventricular fibrillation. ET-1 therefore is a strong candidate for playing a role in sudden cardiac death. NT-proBNP is a good measure of ventricular function since unchanged plasma levels exclude cardiac dysfunction.
METHODS: We investigated the response of male athletes (n=62; mean age=23) to extreme physical (vita maxima treadmill test) and mental stress (simulated military combat model). Circulating peptide levels were analysed with ELISA systems (ET-1: Elabscience, NT-proBNP: Biomedica). Heart rate (HR) and blood pressure (BP) values were monitored in both stress models whereas metabolic (lactate) and gas-exchange (VO2 max) parameters only in the physical stress situation. All values were measured at baseline, at maximum stress situation and 30 minutes in the restitution phase. The investigations were approved by the ethical committee and the subjects provided informed consent.
RESULTS: BP and HR were elevated in a both models. NT-proBNP levels remained unchanged in all experimental settings corresponding to an intact cardiac function under both basal and stimulated states in both models. ET-1 levels were unchanged in mental stress but showed significantly elevated values at the peak of physical stimulation returning to basal levels 30 minutes later (baseline: 5.5±3.7; peak: 6.82±4.6; recovery: 6.04±5.5 pg/ml). Interestingly, our subjects showed differential ET-1 answers in the physical stress model: 85% of the individuals showed elevated whereas 15% on the contrary, lower levels after the treadmill test (peak minus baseline values ranged from -7.9 pg/ml to +16.6 pg/ml). ECG recordings revealed no arrhythmias during physical exercise.
CONCLUSION: Despite the positive inotropic effect, ET-1 has a pathophysiological potency having the capacity to induce direct, fatal arrhythmias. Our observation of elevated ET-1 levels in the whole experimental group indicates that plasma ET-1 levels are worthy to monitor upon extreme physical load. The experimental population was inhomogeneous in terms of stimulated ET-1 levels. Therefore some people in the general population might have higher risk of ET-1 induced pathological states in response to physical load.

CHANGES IN QT INTERVAL AND T-WAVE OF THE ELECTROCARDIOGRAM IN MALE MIDDLE-LONG RUNNERS OVER A THREE-YEAR TRAINING PERIOD*

SHI, Q., LOU, M.I., LAM, K.L., NIE, J.

MACAO POLYTECHNIC INSTITUTE

INTRODUCTION: The occurrence of adaptive remodelling in cardiac structure and electrical conductivity could be caused by long-term intense athletic training, and this leads to variations in their electrocardiogram (ECG). However, although the variations in ECG have been thoroughly studied in athletes, data are generally limited to cross-sectional studies. The study aimed to investigate changes in QT interval and T-wave of ECG in athletes throughout three years.
METHODS: Resting 12-lead ECGs were recorded in 19 male middle-long runners (years of training 9.8±5.5), aged 15-36 years (average 26.0) before and after three-year endurance training. The heart rate-corrected QT interval (QTc) and voltage and duration of T-wave were analyzed.
RESULTS: The athletes had significantly reduced QTc interval in II (386±95 vs. 376±93 ms), V4 (402±14 vs. 394±17 ms) and V5 (401±17 vs. 392±18 ms), compared with the pre-training (all P < 0.05). After training, the voltage and duration of T-wave were similar to pretraining values (P>0.05).

CONCLUSION: The findings from the present study show that, for the middle-long runner with training experiences, routine endurance training might lead to shortened QT interval on ECG measurements, suggests an increase in the stability of cardiac electrical conduction. The present study also provides new information that might help clinicians with decision-making in explaining the resting ECG of middle-long runners during their routine training period.

PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR LEVELS BETWEEN HIGH-INTENSITY INTERVAL TRAINING AND MODERATE-INTENSITY CONTINUOUS TRAINING EXERCISE INTERVENTIONS IN PREVIOUSLY INACTIVE, OVERWEIGHT ADULTS

TAYLOR, K., VELLA, C.A.
EASTERN WASHINGTON UNIVERSITY

INTRODUCTION: On average, US adults spend 7.7 hours/day in sedentary behaviors and only 20% of adults currently engage in sufficient physical activity for health benefits (≥150 min/week of moderate-to-vigorous physical activity). Recently, research has focused on high-intensity interval training (HIIT) as a time-efficient and more enjoyable form of exercise than traditional, moderate-intensity continuous training (MICT). However, little research has shown if HIIT is able to improve levels of physical activity and sedentary behavior beyond MICT. Therefore, the aim of the study was to determine the changes in physical activity and sedentary behavior levels during and immediately after an 8-week exercise intervention of HIIT or MICT in previously inactive adults.
METHODS: Physically inactive, overweight and obese adults (n=17; age 26.2±7.8 yrs; BMI 31.6±5.0 kg/m2) were randomized to an 8-week, supervised during the first 3 weeks, HIIT (n=8) or MICT (n=9) exercise intervention. Physical activity and sedentary behavior levels were recorded at week 0 (pre), 4 (mid), and 9 (post) using a hip-mounted triaxial accelerometer worn for 7 consecutive days. Physical activity was analyzed as light (150-2689 counts/min), moderate (2690-6166 counts/min), or vigorous (≥6166 counts/min) intensity. Time spent in sedentary behavior (<150 counts/min) and number of steps were also recorded. A 2 (protocol) x 3 (time) repeated measures ANOVA was used to compare sedentary behavior and physical activity levels across all time points.
RESULTS: Sedentary behavior, light and moderate physical activity were not different between protocols (p=0.57-0.94) or over time (p=0.11-0.83). Although vigorous physical activity was not different between HIIT and MICT (p=0.45), mean levels for both groups increased from pre (8.62±18.42 min/day) to mid (12.57±17.14 min/day; p=0.003) and decreased from mid to post intervention (6.34±10.17 min/day; p=0.007). There were no differences in vigorous physical activity pre to post intervention (p=0.92). Number of steps increased from pre (7561±3529 steps/day) to mid (9239±3369 steps/day; p=0.005) and decreased mid to post intervention (7736±2494 steps/day; p=0.005). There were no differences in steps pre to post intervention (p=0.83) nor between HIIT and MICT (p=0.73).
CONCLUSION: An 8-week exercise intervention increased levels of vigorous physical activity and number of steps in previously inactive adults during the intervention but not immediately following. These changes in physical activity occurred independently of the exercise protocol. There were no differences in sedentary behavior or lower intensities of physical activity in this cohort. These findings suggest that short-term exercise interventions may not be successful in promoting post-intervention exercise adherence, particularly without supervision. Future research should examine the long-term effects of an exercise intervention on free-living sedentary behavior and physical activity levels in adults.

THE LONG-TERM EFFICACY OF NORDIC WALKING VERSUS WALKING EXERCISE FOR OVERWEIGHT TREATMENT

MUOLLO, V.1,2, MILANESE, C.1, ROSSI, A.3, MASCIOCCHI, E.3, TAYLOR, M.3, SCHENA, F.1,2, PELLEGRINI, B.1,2
1,2,3 UNIVERSITY OF VERONA

INTRODUCTION: Overweight and sedentary lifestyle are two health-related problems, that can be alleviated with regular physical exercise. Recently, the interest in Nordic Walking (NW) is rapidly growing as easily accessible and safe, especially for people with low fitness levels. In the literature there is a need of studies comparing the efficacy of NW versus walking (W) in long period of time (>12 weeks), where the capacity to continue the exercise also without the supervision has to be considered [1]. The aims of the study were: 1) to compare the effects of 6 months of supervised NW and W exercise on anthropometric indices, aerobic capacity and strength, in overweight adults; 2) to verify the maintenance of any positive changes after 6 months of unsupervised training.
METHODS: Participants were randomized in NW (n=19, 66±7 yrs, BMI 33±5) and W (n=19, 66±8 yrs, BMI 32±5) group that performed supervised training (3 times · week) for 6 months and were encouraged to continue the training without the supervision for other 6 months. During each unsupervised training session, the subject collected the steps count through a pedometer. At baseline, after 6 and 12 months we evaluated: a) body mass index (BMI); b) aerobic capacity (Oxygen Consumption (VO2peak), Peak Power Output (PPO) and six-minute walking test (6MWT)); c) strength of the upper and lower limbs (arm curl (AC) and chair stand (CS)).
RESULTS: After 6 months of supervised training BMI decreased in NW and W group (6% and 4% respectively, $p<0.05$), PPO increased similarly in both NW and W group (12% and 10% respectively, $p<0.001$), VO2peak increased only in NW (8%, $p<0.05$), while 6MWT increased in both NW and W group (13% and 9% respectively, $p<0.001$). After the supervised training, only NW group showed an increase in AC (35%, $p<0.01$) with no significant changes in CS in both groups. During the 6 months of unsupervised training, there was a decrease in number of steps over time ($p<0.05$) with a time x group interaction ($p<0.05$); the number of steps · sessions was 31% higher in NW compared to W group ($p<0.01$). At the end of supervised training, both groups maintained the improvements in 6MWT, but only NW group maintained the gain in AC with a significant increase in CS (31%, $p<0.05$). All the other variables returned at baseline.
CONCLUSION: Although both forms of exercise may be effective in inducing positive changes in overweight adults, NW can give greater and more benefits than W that can persist also in long period of time. However, the improvements in many parameters were lost; this indicates that the supervision of training is crucial in this population and that 6 months of structured program is not enough for inducing changes in exercise behaviour.

EFFECT OF AN 8-WEEK FREE PRE-PREPARED LOW-CARBOHYDRATE DIET AND PRESCRIBED EXERCISE ON FITNESS, BODY COMPOSITION, AND BLOOD LIPID PROFILE IN OVERWEIGHT AND OBESE INDIVIDUALS.

POLMAN, R., BORKOLES, E., PERISSIOU, M.

QUEENSLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Low-carbohydrate diets have become widely known as one of the most effective methods of obesity treatment and weight management (Ebbeling et al., 2018). Whilst evidence support that a successful treatment for overweight and obese adults requires a combination of lifestyle alterations, including daily dietary intake and physical activity (Miller et al., 1997), data are limited regarding the combined effect of exercise and low-carbohydrate diet on metabolic parameters in this population. Therefore, the objective of the current study was to compare the short-term effects of the 'THR1VE' protocol (combined effect of commercially pre-prepared meals and structured exercise program) compared to standard dietary guidelines with a structured exercise program on body composition, cardiorespiratory fitness and blood lipid biomarker changes.
METHODS: This was a randomised controlled trial consisting of two conditions. Over an eight week period, participants in the experimental condition (n = 33; 35.3 years of age; BMI 29.8 kg.m-2) were provided with low-carbohydrate pre-prepared meals and participated on a prescribed supervised exercise program. Participants in the control condition (n = 31; 34.2 years of age; BMI 31.2 kg.m-2) were provided with dietary guidelines as developed by the Australian Government (www.eatforhealth.gov.au) and followed the same supervised exercise program. Measurements of cardiorespiratory fitness (VO2peak), body composition (DEXA), and blood lipid biomarkers were performed before and after the 8 week intervention.
RESULTS: Baseline characteristics for VO2peak, body composition and blood biomarkers were similar between groups (P>.05). Both groups demonstrated improvements in body composition and blood lipids profile compared to baseline (P>.05).The experimental condition demonstrated significantly greater increase in VO2peak and decrease in Fat Mass Index and blood glucose levels compared to the control group (P < .05).
CONCLUSION: Overall, participation in the trial was beneficial for all the participants in terms of cardiorespiratory fitness, body composition, and blood lipids profile. However, those in the experimental condition following a low-carbohydrate diet achieved additional benefits in terms of improved fitness, reduced Fat Mass Index, and lower blood glucose levels. Our results are the first which provide some support that a low-carbohydrate diet in combination with a prescribed exercise regime can result in improved health outcomes for overweight and obese individuals.

CHANGES IN BODY COMPOSITION DUE TO TWO DIFFERENT TYPE OF PHYSICAL ACTIVITY IN OBESE AND/OR HYPERTENSIVE ADOLESCENTS: PRELIMINARY RESULTS OF A PROSPECTIVE COHORT STUDY

ABATE DAGA, F.

UNIVERSITY OF TURIN

INTRODUCTION: It has been demonstrated that obesity can be consider as the initial condition for developing osteosarcopenic obesity (OSO). OSO was identified as the impairment of bone, muscle, and adipose tissues. It is perpetuated by low-grade chronic inflammation, usually caused by an inadequate diet and lifestyle (1). Physical activity has been identified as the best and most economic method to fight against obesity and to prevent OSO (2). However, different kinds of physical activity produce different physiological effects and changes in body composition. It is still not clear what kind of physical activity can be considered as the most suitable to face obesity and OSO. Thus, the aim of this study was to assess the effects of 6 months of resistance training versus a combined schedule (both resistance and aerobic training) on body composition in obese adolescents.
METHODS: 20 adolescents (15.5±1.55 years, BMI 33.3±5.1 kg/m2, prevalence of male 43.8%, prevalence of clinic hypertension 18.8%) with moderate to severe obesity were enrolled for this study. We performed a body composition analysis with BIA-ACC medical device (Biotekna, Italy) before starting the training period (T0). The subjects were randomly assigned to either resistance or combined training. All assessments were re-evaluated after 6 months (T1) of low to moderate-intensity training and after 3 months of detraining (FU).
RESULTS: Total Body Water (TBW), Fat Mass (FM), Abdominal Adipose Tissue (AAT), Intra Muscolar Adipose Tissue (IMAT) were significantly reduced after 6 months (T1) in both training programs (p< .05), while Free Fat Mass (FFM) and Body Density showed a significant increase (p< .05). Furthermore, increments in Resting Metabolic Rate (RMR) Bone Mass, T-score, Muscle Mass and S-Score were detected just in resistance group (p< .05) while BMI were reduced only in combined group (p< .05) No more differences were identified at FU both comparing FU vs T1 and FU vs T0.
CONCLUSION: Both resistance and combined training can provide modifications in body composition and loss of FM even in a brief period of 6 months. However, only resistance training produce grater effects on RMR, muscle and bone mass. This fact, together with a decrease in FM contribute to level the impairment of muscle bone and fat and, consequently, to prevent OSO. In addition, increased RMR can facilitate the weight loss process. Considering this, it might be affirmed that resistance training at low to moderate-intensity should be considered to fight against obesity and to prevent OSO. Further participants are warranted to confirm our preliminary findings.

EFFECTS OF 12-WEEK SUPERVISED AND FOLLOW-UP WITH 12-WEEK SELF-REGULATED MIIT ON BODY COMPOSITION AND ADHERENCE IN OBESE SEDENTARY FEMALE ADULTS

WEN, H.J.1, ANG, B.S.2

TZU-CHI UNIVERSITY1, UNIVERSITI SAINS MALAYSIA IN KALANTAN2

INTRODUCTION: Obesity is a concerned public health problem and contributes to huge medical expenses. Sedentary lifestyle and lack of physical activity are parts of the key problems resulted in obesity. A success weight management needs a lifelong habit. Adherence to an exercise is one of the key factors. Study indicated that in a short period, moderate-intensity interval training (MIIT) able to reduce body

weight and percentage of body fat (1). Currently, MIIT with a combination of aerobic exercise and resistance training is ranked at top place in the world fitness trend (2). Supervised exercise programs and peers always enhance adherence rate to exercise programs (3). However, the adherence rate of self-regulated MIIT after cessation of supervised MIIT program and its effects on weight control still not known. Therefore, the purpose of this study was to explore the effect of 12-week supervised and follow-up with 12-week self-regulated MIIT on body composition and adherence in obese sedentary female adults.
METHODS: Sixteen obese sedentary female adults (age 34.2±5.4 year-old, BMI = 30.92 ± 3.41 kg/m2) were recruited for the study. All participants were required to attend a 12-week supervised MIIT, 30 min/session, 5 sessions a week, then followed by a 12-week self-regulated MIIT. Body composition was measured using dual-energy X-ray absorptiometry at baseline, end of the 12th weeks and the 24th week intervention. The MIIT sessions were recorded in training log during the intervention period. The exercise program included 5 minutes warm-up, 30 minutes interval training at 55% of heart rate (HR) reserve (4) and 5 minutes cool down. The MIIT program consists of 4 cycles, six sets/cycle, 1 minute/set, 15 seconds break between each set. Exercise intensity was monitored to ensure participants reaching their target HR zone.
RESULTS: The results showed that both 12-week supervised- and 12-week self-regulated MIIT were significantly improved body composition (wk0 vs. wk12th vs. wk24th; % body fat: 39.8±4.7% vs. 36.9±3.7%, 36.3±3.8%; total lean mass: 45.37±5.51, 45.67±6.48, 45.57±5.75 kg) and total body weight (78.5±9.9, 76.1±10.2, 75.3±10.1 kg). The attendance rates in supervised session were significantly higher than that in self-regulated session (91.8±16.3%, vs 64.3±30.4%, p<.001).
CONCLUSION: Both supervised MIIT and self-regulated MIIT significantly improved body composition, but the adherence rate was significantly dropped in self-regulated MIIT.
The study was supported by Ministry of Science and Technology (MOST107-2410-H-320-005) and Buddhist Tzu Chi Medical Foundation (TCMMP105-03-01).

EXERCISE-INDUCED MUSCLE DAMAGE THROUGHOUT THE MENSTRUAL CYCLE

ROMERO-PARRA, N., PEINADO, A.B, ALFARO-MAGALLANES, V.M., RAEL, B., BARBA-MORENO, L., ROJO-TIRADO, M.A., MAESTRE-CASCALES, C., CUPEIRO, R.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Muscle soreness and the decrease in the range of movement (ROM) and in counter movement jump performance (CMJ) seem to be related to muscle damage and fatigue after an intense strength training (1,2). These effects have been previously investigated in women providing quite controversial findings commonly associated to differences in methodologic aspects. Therefore, the purpose of this study was to evaluate the influence of female sex hormones on exercise-induced muscle damage (EIMD) throughout the menstrual cycle.
METHODS: Nineteen well-trained eumenorrheic women (31±6 years, 1.63±0.06 m, 58.8±6.7 kg), performed an eccentric-based resistance protocol consisting of 10 x 10 back squats at 60% of their maximum RM in the early follicular phase (EFP), late follicular phase (LFP) and luteal phase (LP) of the menstrual cycle (3). Phases were counterbalanced and randomly assigned. In order to evaluate muscle soreness, a visual scale from 0 (no pain at all) to 10 (extremely painful) was administered, whilst ROM for hip flexion and knee flexion was assessed by goniometry. Also, CMJ was evaluated with MyJump App. Pre-trial, 0h, 24h and 48h post-trial measurements were assessed. A two-way repeated measures ANOVA was conducted to analyze the data.
RESULTS: Muscle soreness (points) was affected by moment, being 24h and 48h post-trial values (2.9±3.6 and 2.5±1.7, respectively) significantly higher in comparison to baseline (0.2±0.6). Regarding hip ROM (degrees), a significant effect of phase was observed with lower ROM in EFP and LP than in LFP (78.1±17.8; 78.1±19.4 and 81.5±18.6, respectively). On the other hand, knee ROM (degrees) was significantly affected by time, indicating an increase 24h post-exercise (59±10.7) from pre-trial (57.4±12.3) and recovered at 48h post-exercise (55.7±10.5). Finally, CMJ performance (cm) was significantly affected by time being the higher decreases 0h post-exercise (25.9±5.6; 22.1±4.7, 24.8±5.8 and 25.2±5.8 respectively for pre-trial, 0h, 24h and 48 post-trial). In addition, a significant trend (p=0.059) was observed for phase in CMJ.
CONCLUSION: An eccentric-based resistance protocol of back squats seems to cause muscle damage in well-trained women as post-trial measurements showed higher muscle soreness and lower CMJ values than pre-trial. In addition, an increase in the knee ROM was also observed 24h post-exercise suggesting an impairment in mobility. Regarding hormones influence, we observed a lower hip ROM during EFP and LP, indicating a better mobility. This finding disagrees with the existing literature that suggests higher joint laxity during the pre-ovulatory and ovulatory phases (4). However, estrogen or progesterone by themselves may not be responsible for changes in joint laxity or performance.

SKELETAL MUSCLE TROPONIN RELEASE AFTER WHOLE-BODY ECCENTRIC EXERCISES RESULTING IN LARGE INCREASES IN PLASMA CK ACTIVITY

CHEN, T.C.1, LIU, H.W.1, CHOU, T.Y.2, NOSAKA, K.3

1,2: NATIONAL TAIWAN NORMAL UNIVERSITY, 3: EDITH COWAN UNIVERSITY

INTRODUCTION: A previous study (1) showed that fast skeletal muscle troponin I (fsTnI) but not slow skeletal muscle troponin I (ssTnI) increased from baseline (0.8-14.6 ng/mL) after 210 maximal eccentric contractions of the unilateral elbow flexors performed by young men, and peaked at 4 days post-exercise (3.3-158 ng/mL). The time course of changes in fsTnI was similar to that of plasma creatine kinase (CK) activity, and the changes of the two were significantly correlated (r = 0.80). In our recent study in which a whole-body eccentric resistance exercise was performed, large increases in plasma CK activity (peak: 101,668 ± 58,955 IU/L) and myoglobin (Mb) concentration (3,111 ± 993 μg/L) were observed (2). The magnitude of the increases in CK activity was much greater than that (4,229 ± 4,271 IU/L) of the previous study (1). We analysed plasma fsTnI and ssTnI concentrations for the blood samples obtained from the previous study (2) using a newly established method.
METHODS: Eleven sedentary men (20-25 y) performed 5 sets of 10 eccentric contractions with 80% of pre-exercise maximal voluntary isometric contraction load for the elbow flexors and extensors, pectoralis, knee extensors and flexors, plantar flexors, latissimus, abdominis, and erector spinae in a randomised order. Changes in plasma fsTnI, ssTnI and Mb concentrations, and plasma CK activity were measured before and 1-5 days following the exercise. Plasma fsTnI and ssTnI concentrations (LSBio kits) were measured by ELISA. The relationships between plasma CK activity or Mb concentration and fsTnI concentration were alanysed by a Pearson's product moment correlation.
RESULTS: Large increases in plasma CK activity (peak: 27,547 – 207,304 IU/L) and Mb concentration (1,047 – 3,936 μg/L) were observed after the exercise, and the peak values were observed at 4 days and 3 days post-exercise, respectively. Plasma fsTnI concentration increased after the exercise from the baseline (0.0 – 5.2 ng/mL), peaking at 4 days post-exercise (2,017 - 45,182 ng/mL). No significant changes in plasma ssTnI concentration were observed from the baseline (< 0.1 ng/mL). When comparing the peak values, fsTnI was positively correlated with CK (r=0.73, P=0.005) and Mb (r=0.71, P=0.007).
CONCLUSION: These results confirmed the previous study (1) showing that plasma fsTnI but not ssTnI concentration increased after eccentric exercise resulting in muscle damage, and the change in plasma fsTnI concentration was correlated with that of plasma CK activity. Compared with the magnitude of the increases in plasma fsTnI concentration of the previous study (1), the present study found much greater increases in the fsTnI after the whole-body eccentric exercises that resulted in very large increases in CK and Mb in the blood. It appears that damage of fast twitch muscle fibres of the muscles involved in the exercises was responsible for the increase.

CONTRALATERAL EFFECTS OF ECCENTRIC TRAINING ON NEUROMUSCULAR FUNCTION OF THE ELBOW FLEXORS DURING FOUR WEEKS OF IMMOBILISATION

VALDES, O., RAMIREZ, C., PEREZ, F., ZBINDEN-FONCEA, H., NOSAKA, K., PENAILILLO, L.

UNIVERSIDAD FINIS TERRAE

INTRODUCTION: Immobilisation decreases neuromuscular function and muscle mass, which takes a long time to recover. It has been shown that unilateral strength training improves function of the contralateral untrained homologous muscle. A previous study (1) showed that eccentric training produced greater cross-transfer of strength to the non-trained immobilised arm, when compared with concentric training. The present study compared the effects of eccentric only and mixed eccentric and concentric resistance training of the non-immobilised arm on muscle function and size of the contralateral immobilised elbow flexors (EF).
METHODS: Young (18-30 y) men (n=18) and women (n=12) were randomly allocated to three groups (n=10/group): immobilisation only (IM), immobilisation and contralateral eccentric training (IM+CECT), and immobilisation and contralateral mixed eccentric and concentric training (IM+CMIXT). The elbow and shoulder joints of the non-dominant arm were immobilised by wearing a sling for 8 hours a day for 4 weeks. The IM+CECT and IM+CMIXT groups performed EF training of the non-immobilised (dominant) arm 3 times a week during the four weeks of immobilisation. Each training session consisted of 3-4 sets of eccentric only contractions (4 s) at 80-120% of one repetition maximal (1RM) for CECT, or 4-6 sets of eccentric (2 s) and concentric (2 s) contractions at 60-90% 1RM for CMIXT, in which the total volume was matched. Maximal voluntary isometric contraction (MVC) and 1RM strength of EF, mean amplitude electromyogram (EMG) of the biceps brachii during MVC, elbow joint position sense (JPS) and upper arm circumference (CIR) of both arms were measured before and after the 4-week immobilisation.
RESULTS: MVC and 1RM strength decreased after IM (25.9% and 10.1%, respectively). However, no significant decreases in MVC and 1RM were observed after immobilisation for the IM+MIXT group, and the IM+CECT group showed 15.7% increase in MVC strength in the immobilised arm. MVC and 1RM of the trained arm increased (P<0.05) for the IM+MIXT and IM+CECT groups (10-15%). A decrease in EMG amplitude was found after immobilisation for the IM (42.8%) and IM+CMIXT group (10.3%), but the IM+CECT group showed an increase (15.7%) in the immobilised arm. CIR decreased 5.5% in the IM, did not change in the IM+CMIXT, but increased 3.7% in the IM+CECT group. A decrease in JPS (36.4%) was observed only for the IM group.
CONCLUSION: These results showed that the contralateral training was effective for preventing decreases in muscle function and atrophy of the immobilised arm, and eccentric only training was more effective than mixed eccentric and concentric training. It seems that eccentric contractions contributed greater to the contralateral effect than concentric contractions as shown in the previous study [1]. It is concluded that contralateral eccentric training is effective for reducing the deleterious effects of immobilisation.

EFFECT OF MUSCLE LENGTHS DURING ECCENTRIC CONTRACTIONS ON DAMAGE AND THE REPEATED BOUT EFFECT OF THE RECTUS FEMORIS

EMA, R.1, KAWASHIMA, R.2, KANDA, A.2, IKEDA, K.2, NOSAKA, K.3, AKAGI, R.2

1: SHIZUOKA SANGYO UNIVERSITY 2: SHIBAURA INSTITUTE OF TECHNOLOGY 3: EDITH COWAN UNIVERSITY

INTRODUCTION: Eccentric exercise induces muscle damage represented by a prolonged strength loss and delayed onset muscle soreness (DOMS) (1). A bout of eccentric exercise confers protection against subsequent bouts of the same or a similar exercise, which is

known as the repeated bout effect (RBE). For the elbow flexors, it has been reported that muscle lengths during eccentric contractions affect the magnitude of damage and RBE; greater damage and RBE are produced at long than short muscle lengths (1). The rectus femoris (RF) acts as both hip flexor and knee extensor, but other quadriceps femoris muscles work only for knee extension, and RF length has been reported to be approximately 10% longer in supine than in sitting position (2). Thus, effects of muscle lengths on muscle damage and RBE of RF can be investigated by comparing the two positions. We tested the hypothesis that RF damage and RBE after knee extensor eccentric exercise would be greater for the supine than sitting position.
METHODS: Twenty-eight young (21–24 yr) men were placed into two groups (n = 14/group), and performed two bouts of exercise consisting of 100 eccentric knee extension contractions separated by 4 weeks. One group performed the exercise in sitting position (short RF lengths) for the first bout and in supine position (long RF lengths) for the second bout (S-L group). The other group performed the exercise in supine position for both bouts (L-L group). Before and every 24 h for 3 days after each exercise, peak torque during maximal voluntary isometric contraction (MVC) was measured for knee extension and hip flexion in a sitting position (knee joint: 90°, hip joint: 80° flexion), and DOMS of RF was assessed by a 100-mm visual analogue scale (VAS) with palpation by the same investigator.
RESULTS: No significant group differences were found for the decreases in knee extensor MVC torque (S-L group: 38–43%, L-L group: 32–41%) and increases in DOMS (32–47 mm, 31–55 mm) after the first bout. However, hip flexor MVC torque, which mainly reflects force produced by RF, decreased at 1-2 days (12–17%) after the first bout for the L-L group only. After the second bout, the changes in these variables were smaller than those after the first bout for both groups, without significant group differences.
CONCLUSION: These results show that RF muscle damage was greater for the supine than sitting position, confirming that greater muscle damage is induced when muscle lengths during eccentric exercise are greater, but this did not affect the magnitude of RBE.

RUNNERS WITH REDUCED PACE EXHIBIT A SHORT STRIDE LENGTH AND HIGH MUSCLE DAMAGE VALUES OF AT THE END OF A MARATHON

ISHIKURA, K.1, TOKINOYA, K.2,3, YOSHIDA, Y.2, SEKINE, N.2, KOSAKI, K.2, KUMAMOTO, S.2, MAEDA, S.2, NABEKURA, Y.2, TAKEKOSHI, K.2

1: SOJO UNIVERSITY, 2: UNIVERSITY OF TSUKUBA, 3: RESEARCH FELLOWSHIPS OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE

INTRODUCTION: The phenomenon of hitting the wall (HTW) is well-known among recreational marathon runners. HTW is characterized by a generalized sense of fatigue and an unintentional slowing of pace, in addition to other indicators. Our previous study showed that a decreasing rate of pace during the marathon was significantly correlated with the activity of muscle damage markers, such as serum CK and AST immediately after the marathon. However, the cause of muscle damage makers during a marathon remains unknown. In general, eccentric contraction exercise elicits muscle damage. Also, a running form including bending at waist induces eccentric contraction in the anterior thigh. The purpose of this study was to investigate the relationships between the rate of decrease in pace at the end of a marathon and muscle damage, muscle soreness, stride length, and stride rate.
METHODS: Twenty-three healthy male non-professional runners who participated in the 38th Tsukuba Full-Marathon race (Tsukuba-city Japan) were recruited as volunteers. They ran with a GPS watch and a heart rate band which has a built-in accelerometer. Stride rate and stride length were obtained from the watch. Serum creatine kinase (CK), Myoglobin, C-reactive protein (CRP) concentration as well as systemic fatigue and muscle soreness, were measured before, immediately after, and 1 day after the event.
RESULTS: The pace of participants peaked in the second segment (5-10 km) and gradually decreased thereafter. Hence, we defined the Opening stage as the segment from 5 to 10 km and the Final stage as the segment from 35 to 40 km, and calculated the ratio of change in pace. Seventeen runners reduced the ratio of change in pace (reduced pace of more than 20 %: Reduced group), while the remaining 6 runners maintained the ratio of change in pace (reduced pace of less than 20 %: Maintained group). Serum CK, CRP, and Myoglobin activities at one day after and muscle soreness after the marathon in the Reduced group tended to present higher values than those measured in the Maintained group. Stride rate decreased significantly in the Final stage compared to that in the Opening stage in the Reduced group, but not in the Maintained group. Also, in the both groups, stride length decreased significantly in the Last stage compared in the Opening stage, however, the reduction of the stride length in the Reduced group was greater than that in the Maintained group
CONCLUSION: These results suggest that stride length was shorter in the Last stage and muscle damage makers were higher values one day after the marathon in the reduced group than that Maintained group. In the Reduced group runners, their running form with a bending at waist might induced eccentric contraction at their anterior thigh resulted in highly value of muscle damage markers.

DOES MATURATION INFLUENCE NEUROMUSCULAR PERFORMANCE AND MUSCLE DAMAGE AFTER COMPETITIVE MATCH-PLAY IN YOUTH MALE SOCCER PLAYERS?

DE STE CROIX, M., LEHNERT, M., MAIXNEROVA, E., ZAATAR, A., SVOBODA, Z., BOTEK, M., VAREKOVA, R., STASTNY, P.

UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Poor neuromuscular control and fatigue have been proposed as a risk factor for non-contact injuries especially around peak height velocity (PHV). This study explored the effects of competitive soccer match-play on neuromuscular performance and muscle damage in male youth soccer players.
METHODS: 24 youth players aged 13-16y were split into a PHV group (-0.5 to 0.5y) and post PHV group (1.0-2.5y) based on maturity offset. Leg stiffness, reactive strength index (RSI), muscle activation via electromyography, creatine kinase (CK), and muscle soreness were determined pre and post a competitive soccer match. Paired t-tests were used to explore differences pre and post competitive match play and independent sample t-tests for between group differences for all outcome measures.
RESULTS: There were no significant fatigue related change in absolute and relative leg stiffness or muscle activation in both groups, except for the gastrocnemius in the post PHV group. RSI, CK and perceived muscle soreness were significantly different after soccer match-play in both groups with small to large effects observed (ES:0.41-2.82). There were no significant differences between the groups pre match-play except for absolute and relative leg stiffness ($P < 0.001$; ES = 1.16 and 0.63 respectively). No significant differences were observed in the fatigue related responses to competitive match play between groups except for perceived muscle soreness.
CONCLUSION: The influence of competitive match-play on neuromuscular function and muscle damage is similar in male youth around the time of PHV and those post-PHV indicating that other factors must contribute to the heightened injury risk around PHV.

OP-BN19 Motor learning and motor control: Coordination

ANALYSIS OF INTERFERENCE BETWEEN PLAYERS DURING FACE-TO-FACE COOPERATIVE BALL-INTERCEPTION TASK

FAURE, C., LIMBALLE, A., BIDEAU, B., PERRIN, T., SOREL, A., KULPA, R.

UNIV RENNES

INTRODUCTION: When two or more players coordinate their actions, they generally expect to be more effective than they would if acting alone. Although their ability to coordinate actions as a team is often paramount for succeeding in competitive team sports (Silva et al. 2013), in some cases, interference between them occurs and results in conflicting situations with an unsuccessful interception or even a collision. For example, if two volleyball players collide while performing a serve reception, they can both miss the ball. The main goal of this study is to explore the way two persons regulate their actions when performing a cooperative task of ball interception, and how interference between them may occur.
METHODS: Starting face to face, twenty-four participants (twelve teams of two) had to physically intercept balls moving down from the roof to the floor. They were immersed in a stereoscopic virtual reality setup that allows the control of the situation and the visual stimuli they perceived, such as ball trajectories and the quantity of information available on the partners motion. They controlled a virtual paddle attached to their hand moving along the anterior-posterior axis. No communication was allowed between participants so they had to focus on visual cues to decide if they should perform the interception or leave the partner do it.
RESULTS: Results globally showed participants were often able to intercept balls without collision by dividing the interception space in two equivalent parts: they tacitly divided task so they each covered approximately 50% of space. However, when looking deeper at the results, an area of uncertainty (where many trials were not intercepted) appeared at the center of the scene highlighting the presence of interference between participants. The width of this area increased when situation became more complex (facing a real moving partner and not a stationary one) and when less information was available (only the paddle and not the partners avatar). Moreover, participants initiated their interception later when real partner was present and often interpreted balls starting above them as balls they should intercept, even when these balls were in fine intercepted by their partner.
CONCLUSION: Overall, results showed that team coordination emerges from between-participants interactions in this ball interception task and that interference between them depends on task complexity (uncertainty on partners action) and the quantity of visual information available on the partner. Using the same experimental platform, further studies would help to study this interference in various team sports.

MOTOR COMPETENCES PREDICT CHANGES IN NEUROPHYSIOLOGICAL INDICES OF WORKING MEMORY MAINTENANCE

LUDYGA, S., MÜCKE, M., KAMIJO, K., GERBER, M., PÜHSE, U., HERRMANN, C.

UNIVERSITY OF BASEL

INTRODUCTION: Body of cross-sectional evidence suggests an interrelation between motor competences and working memory in children. The association between both concepts has mainly been examined by behavioral measures, whereas less is known on the neurophysiological basis underlying this link. The purpose of the present study was the examination of the longitudinal association between motor competences and changes in preparatory cognitive processes recruited during a task requiring working memory maintenance using a neurophysiological measure of task preparation.
METHODS: For a longitudinal study, fifty-two healthy children aged 10 to 12 years were recruited from local schools. All participants completed the MOBAK-5 test battery and a modified version of the Sternberg task at baseline. During the Sternberg task, event-related potentials (ERPs) associated with task preparation processes, including the cue-P300 and the initial contingent negative variation (iCNV), were recorded using electroencephalography. After a period of 9 months, the Sternberg task was administered again to assess changes in these neurophysiological indices of task preparation and behavioral performance.
RESULTS: Path-analyses revealed that baseline motor competences predicted the change in cue-P300 and iCNV amplitude from baseline to follow-up. In this respect, an decrease of amplitudes was found for both ERP components in children with low motor competences. Additionally, baseline motor competences were associated with reaction time in the working memory task at follow-up. When controlling for autoregressive effects, this relation did not reach a statistically significant level.
CONCLUSION: The present findings indicate that the cognitive control strategy changes as a function of childrens' motor competences. Specifically, children with low performance on motor competence tests show a change towards less effective cue-utilization and response orienting in a working memory task.

ACUTE EFFECTS OF PHYSICAL AND MENTAL FATIGUE ON POSTURAL SWAY AND CORTICAL ACTIVITY IN HEALTHY YOUNG ADULTS

GEBEL, A., BUSCH, A., GRANACHER, U.

UNIVERSITY OF POTSDAM

INTRODUCTION: Postural control requires the complex interaction of different structures within the sensorimotor systems to maintain and recover balance during sports performance and/or activities of daily living. It is well-documented that physical or mental fatigue result in impaired postural control leading to an increased risk of injury or falls in young (1) and particularly old adults (2). However, there is scarce information available in the literature on the effects of fatigue on postural control and cortical activity. Therefore, the objectives of this study were to examine the acute effects of physical and mental fatigue on postural sway and cortical activity in young adults.
METHODS: Fifteen healthy young adults aged 28±3 years were enrolled in this study. All participants performed five trials of a balance task on a balance board (Wobblesmart, Artzt GmbH) before and after two ran-domly assigned fatigue protocols in two separate sessions. Physical fatigue was induced until failure using a sit-to-stand task with an additional load of 30% of the individual body mass. A

30-minute computer-based attention network test (ANT) was performed to provoke mental fatigue. Postural sway (center of pressure displacements) was assessed using two measuring sensor mats (novel GmbH) that were placed on the balance board. Cortical activity was recorded using a 64-channel electroencephalography (EEG) system. Absolute spectral power was calculated for two frequency bands (4-7 Hz [theta], 10-12 Hz [alpha-2]) in frontal and central, and central and parietal regions of interest (ROI). All power values were normalized to baseline values recorded during quiet standing with eyes opened prior to the pre-test of each fatigue condition.
RESULTS: A two-way repeated measures ANOVA revealed a significant large-sized interaction effect (fatigue condition*time: p=0.009, d=1.62) for postural sway. Post-hoc tests showed a significant increase of postural sway following physical but not mental fatigue (p=0.009, d=0.71). The statistical analyses for cortical activity revealed a significant large-sized interaction effect for alpha-2 power in central (fatigue condition*time: p=0.004, d=1.95) and parietal (fatigue condition*time: p<0.001, d=3.09) areas. Post-hoc tests showed a significant increase in central (p<0.001, d=0.2) and parietal alpha-2 power (p<0.001, d=0.35) after physical but not mental fatigue. No changes were found for frequencies of 4-7 Hz, irrespective of the fatigue protocol and ROI.
CONCLUSION: Physical fatigue increased postural sway and was accompanied by enhanced alpha-2 power in central and parietal ROI whereas mental fatigue showed no acute effects on postural sway and cortical activity in the respective ROI. An increase in alpha-2 power after physical fatigue may be interpreted as impaired somatosensory information processing which impairs postural control.

DOES A RELATIONSHIP EXIST BETWEEN CORE ENDURANCE AND STATIC BALANCE SCORES IN ADULT FEMALE COLLEGE WOMEN?

SEGER, D., MILLETT, C., MURGIA, M., SHIM, A., SEKENDIZ, B.

1: DEPT. OF KINESIOLOGY, COLLEGE OF SAINT MARY, ; 2: SCHOOL OF HEALTH, MEDICAL AND APPLIED SCIENCES, CENTRAL QUEENSLAND UNIVERSITY,

INTRODUCTION: Several attempts have been made through several studies have attempted to derive identify variables that can help to improve overall balance scores in various populations over the past several yearsdecade (1,2). Core endurance has been identified as a possible variable that could assist with coordination of the trunk musculature which could contribute to developing balance. Core stabilization and endurance has been shown to assist or improve athletic performance with regards to swinging or moving coordination (3). However, there has not been literature demonstrating any relationship between core endurance and static balance. The question lies if core endurance has a relationship with static balance scores?
METHODS: Twenty-seven (27) female college students from a Midwestern University volunteered for the study (age 22.66±.87, height 174.77±4.12 cm, mass 76.56±9.17 kg, body mass index 25.06±2.75). Center of pressure (CoP) measurements were taken with the eyes open stable surface (EOSS), eyes closed stable surface (ECSS), eyes open perturbed surface (EOPS), and eyes closed perturbed surface (ECPS) using a Bertec Computerized Posturography Plate. A timed assessment measured with a stopwatch in .001 seconds, using a push up plank with the subjects resting their forearms on the ground while maintaining linear posture was given after the static balance test to measure core endurance. Time was taken until fatigue was observed in each participant (4).
RESULTS: Pearson correlations (SPSS version 24) were not significant (p = .06) between any of the static balance scores and the timed plank scores (EOSS r= -.30; ECSS r= -.36; EOPS r = -.34; ECPS r = -.38).
CONCLUSION: This study did not find any significant relationship between Core Endurance and Static Balance Scores on a stable or perturbed surface with the eyes opened or closed. Further studies using other methods to measure core variables such as strength or targeted muscle activation are warranted to determine if other direct relationships exist with stability outcomes.

POSTURAL CONTROL, INTER-MUSCLE COORDINATION AND MUSCLE ACTIVITY DURING HANDSTAND IN YOUNG AND ADULT GYMNASTS

MIESZKOWSKI, J., NIESPODZINSKI, B., GRAD, R., KOCHANOWICZ, A.

KAZIMIERZ WIELKI UNIVERSITY IN BYDGOSZCZ, POLAND

INTRODUCTION: The topic of postural control, inter-muscle coordination and muscle activity in gymnastic sports is very important due to its involvement in muscle activity. However, there is limited insight into the activity of individual muscles during handstand and the development of neuromuscular coordination of gymnasts in different ages. The aim of the study was to evaluate relative muscle activity and inter-muscle coordination pattern (amplitude ratios) of muscles involved during handstand in relation to the postural control performance.
METHODS: Additionally analyzed outcome was compared in group of fifteen young male gymnasts (13.9 ± 0.7 years) and eleven elite adult (23 ± 3 years) gymnasts – experts. Participants performed 10-sec. handstand on the force platform with simultaneous EMG signal recording
RESULTS: Adult gymnasts had significantly better postural control in each studied variable. Wrist flexors were the muscle group with the highest relative mean (60%) and peak (200%) EMG activity during a handstand. There were also highly correlated with postural variables in both groups. However, the relations in groups were opposite. In the relative mean activity young compare to adults showed a significantly higher activation in the triceps brachii, biceps brachii and rectus femoris, 88% (p = 0.023), 150% (p = 0.003) and 75% (p = 0.0388) respectively. The most involvement in handstand muscle activity (amplitude ratios) had upper trapezius (20-26%) and wrist flexor muscles (25.5-28%), followed by anterior deltoid (15-18%) and triceps brachii (13-16%) in both groups.
CONCLUSION: Long-term gymnastic training causes specific muscle adaptations demonstrated by a different relations of muscle activity and postural control variables

SOLEUS MUSCLE MOTOR CONTROL MAY BE MODULATED AT SPINAL BUT NOT IN CORTICAL LEVEL DURING ANTERIOR AND POSTERIOR BALANCE PERTURBATIONS.

POIKOLAINEN, J., KAMULA, M., PIIRAINEN, J.M., AVELA, J.

UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: It has been shown that motor control of soleus muscle can be modulated during posterior balance perturbations (Taube 2006). Motor evoked potentials (MEP) and conditioned H-reflex responses were enhanced at the onset of long latency reflex responses, indicating involvement of direct transcortical pathways. It is unknown, how speed and direction of the perturbation may affect this control and how its possible modulation is related to balance control. The aim of this study was to find out whether corticospinal excitability

responses are velocity and direction dependent during perturbations and whether these responses have consequences on the balance control.
METHODS: Nine participants (6 women and 3 men, aged 19-39) completed the study. Dynamic balance control was measured with 2 sets (SLOW: v=10 cm/s, FAST: v=22 cm/s) of 8 anterior and 8 posterior perturbations in random order, each with 30 cm amplitude using a special perturbation device modified from Piirainen et al. (2013). Average maximal center of pressure (COP), peak displacement and COP displacement speed were measured and analyzed. H-reflexes (5% Mmax-wave) and MEPs (120% of passive motor threshold) were measured during these perturbations at three time points from the onset of perturbation: 0ms (baseline), SLR (latency of individual soleus short-latency reflex) and SLR+120ms.
RESULTS: SLR H-reflex responses were enhanced during FAST posterior perturbation (122%, $p<0.01$) compared to the baseline, while in SLOW no changes were observed. In anterior perturbation, soleus H-reflexes were reduced in both SLOW (-47%, $p<0.05$) and FAST SLR+120 (-67%, $p<0.05$) conditions. No significant changes were seen in MEP responses in anterior or posterior perturbation in either condition. Similarly to H-reflex responses, H/MEP-ratio was increased in FAST posterior SLR condition (71%, $p<0.05$), which was not observed in SLOW. Contrarily H/MEP-ratio was reduced in both SLOW (-67%, $p<0.05$) and FAST (-74%, $p<0.01$) anterior SLR+120 conditions. In SLOW, baseline MEP correlated positively ($r=0.944$, $p<0.05$) and in FAST, baseline H-reflex correlated negatively ($r=-0.914$, $p<0.05$) with posterior displacement.
CONCLUSION: MEP size was not altered by the direction of the perturbation, yet H-reflexes were larger in posterior perturbation at SLR+120 and lower in anterior perturbation at SLR+120. Possible reason for increasing H-reflex at posterior SLR might be higher Ia-afferent activity caused by the stretch reflex. However, changes in pre-synaptic inhibition can also have a strong effect on H-reflex responses and cannot be ruled out. These results may indicate stable cortical excitability regardless of the direction and speed of the perturbation and that the modulation of the muscle control occurs mainly at the spinal level.

OP-BN20 Training and testing in swimming II

DOES ALTITUDE TRAINING ENHANCE SPRINT-SWIMMING PERFORMANCE?

WINTHER, A.K.1, TØNNESSEN, E.2, WELDE, B.3, OLSEN, O.E.3
<1,3> UIT THE ARCTIC UNIVERSITY OF NORWAY, TROMSØ, NORWAY, (2) KRISTIANIA UNIVERSITY COLLEGE, OSLO, NORWAY

INTRODUCTION: Altitude training is a common training strategy among sprint swimmers although the efficacy of such a strategy has been questioned (Truijens & Rodríquez, 2010). The "live high-train high" (LHTH) strategy is typically used, an approach that has shown to increase hemoglobin mass and possibly decrease time-trial performance compared to sea-level training (Rodríguez et al., 2015). However, more research is needed regarding the effect of LHTH altitude camps on performance across varying swimming distances in elite athletes. Thus, the aim of this study was to compare the effects of national team-led LHTH altitude training versus sea-level training on competitive performance in varying sprint-swimming distances.
METHODS: Race records across three distances (50, 100 and 200 m) for 41 elite swimmers were sourced from several online databases. Swimmers were allocated to either an altitude training group or a sea-level training group based on whether they sojourned to altitude or not. Competitive performance before and after two three-week training camps at 2320 meters above sea-level (one in 2015, one in 2016) were investigated, and percent changes in performance were calculated before and after each period. Race results from the last swim competition 2-3 weeks prior to the camps were compared to results obtained 1-2 weeks post-altitude for the 2015 and 2016 seasons, respectively. Bayesian estimation (Kruschke, 2013) initialized with a vague prior, and a region of practical equivalence (ROPE) set between 0.2% and -0.2%, was used to compare differences between groups. Results are displayed as posterior estimates of the mean percentage change ± 95% credible intervals (CI).
RESULTS: For the 2015 season, the altitude group performed similarly across all distances compared to the sea-level group (50m: 0.2% ± 1.8% vs. -1.0% ± 1.8; 100m: -0.2% ± 1.2% vs. -0.8% ± 1.3%; and 200m: 0.3% ± 1.6% vs. -0.5% ± 1.3%). However, for the 2016 season, the altitude group decreased their 50-m performance substantially compared to the sea-level group (-1.4% ± 1.4% vs. -0.1% ± 0.6%), with 99% of the posterior credible values falling entirely below the lower ROPE threshold. However, no differences in 100 and 200-m performance between the groups were observed (100m: 0.1% ± 1.0% vs. 0.0% ± 0.8%; 200m: -0.6% ± 1.3% vs. -0.1% ± 0.9%.
CONCLUSION: Altitude training does not enhance sprint-swimming performance in elite athletes compared to sea-level training and may adversely affect 50-m performance up to two weeks post-altitude.

CRITICAL VELOCITY RELATIONSHIP WITH PHYSIOLOGICAL PARAMETERS ASSESSED THROUGH TETHERED SWIMMING

ESPADA, M.C.1,2,3, SIQUEIRA, L.O.3, SIMIONATO, A.R.3, ALMEIDA, T.F.1,3, REIS, J.F.1,4, ALVES, F.B.1, PESSÔA-FILHO, D.M.4
1CIPER, FACULTY OF HUMAN KINETICS, LISBON, PORTUGAL; 2SCHOOL OF EDUCATION OF POLYTECHNIC INSTITUTE OF SETÚBAL, PORTUGAL; 3LABOREH, SÃO PAULO, BRASIL; 4UNIVERSIDADE EUROPEIA, LISBON, PORTUGAL.

INTRODUCTION: Swimming research has sought procedures to evaluate and enhance the performance of athletes. Among these are the determination of critical velocity (CV) and tethered swimming, less expensive and time-consuming procedures compared to other physiological parameters such as the lactate threshold or maximal lactate steady state. The aim of this study was to examine the relationship between CV and parameters assessed through tethered swimming.

METHODS: Eleven male (18.0±4.0 yrs, 180.2±6.8 cm and 71.8±9.5 kg) and five female swimmers (16.8±3.6 yrs, 166.2±5.5 cm and 61.1±9.8 kg) underwent the following evaluations: 1) Maximal tethered swimming force, which consisted of two 30 seconds maximal efforts in tethered apparatus (Cefise®) with 10 minutes in between to determine maximum and mean force (Fmax and Fmean)2 and 2) a incremental test with a conventional load system tied to the swimmer with in increments of 5% per minute (range 30-100% of Fmean). Oxygen uptake (VO2) was assessed breath-by-breath with a portable system (K4b2 Cosmed, Italy) attached to the swimmer by a snorkel with a tri-dimensional valve (Aquatrainer®). Maximal oxygen uptake (VO2max), respiratory compensation point (RCP) and gas exchange threshold (GET) were determined. CV was determined from the modeling of the d–tLim relationship from maximal swimming trials in 200, 400, 800 and 1500 m (respectively, V200, V400, V800 and V1500). Paired samples t-test was used to assess differences and correlations were analysed using Pearsons coefficient. In all cases $p \leq 0.05$ was adopted.
RESULTS: CV200-400 (1.24±0.16 m.s-1), CV200-400-800-1500 (1.22±0.10 m.s-1) and CV200-400-800 (1.19±0.13 m.s-1) were not statistically different. CV200-400-800 was the only CV determination correlated with RCP (3046.2±588.7 ml.min-1; r=0.50, p<0.05), and along with CV200-400-800-1500 was correlated with VO2max (3423.0±601.9 ml.min-1; r=0.52 and r=0.50, p<0.05, respectively). None of determined CV were correlated with GET (2214.8±455.0 ml.min-1), Fmax (19.0±4.7 kg) or Fmean (17.7±4.3 kg). The later two were only correlated to V200 (1.48±0.13 m.s-1; r=0.55 and r=0.51, p<0.05, respectively). Fmax and Fmean were correlated to VO2max (r=0.64 and r=0.66, p<0.01, respectively) RCP (r=0.72 and r=0.75, p<0.01, respectively) and GET (r=0.71 and r=0.75, p<0.01, respectively).
CONCLUSION: This study highlighted that tethered swimming associated with VO2 data collection provides important information that can be useful for enhance swimming performance. This procedure combined with CV may also represent a valuable tool to assess training adaptations and provide to swimmers and coaches important information regarding daily training practice.

EFFECTS OF DIFFERENT IN-WATER AND DRY-LAND RECOVERY STRATEGIES ON REPEATED 100M FREESTYLE PERFORMANCE, PHYSIOLOGICAL RESPONSES AND PERCEPTUAL STATUS OF COMPETITIVE ADOLESCENT SWIMMERS.

TAYLOR, D.

UNIVERSITY OF LINCOLN

INTRODUCTION: There has been limited comparison between different formats of active recovery that could be adopted by adolescent swimmers, or between the more specific approaches to each type of recovery they might follow (e.g. intermittent versus continuous). Furthermore, a number of previous studies have focussed only on physiological markers of recovery (i.e. blood lactate), before inferring how swim performance might be altered as a result of these biological responses (i.e. Lomax et al., 2012). Given these points, this study examined the effects of different in-water and dry-land recovery protocols on repeated swimming performance, and associated physiological and perceptual responses, of competitive adolescent swimmers.
METHODS: Sixteen regional to national level youth swimmers (m=8, f=8) were recruited from the same performance development squad (13.9±2.5yrs, 100m freestyle PB 63.8±4.5s). Following protocol and equipment familiarisation, each swimmer completed four trials in a counterbalanced crossover design. All trials involved a standardised warm-up followed by two 100m freestyle time-trials, separated by one of four different time-matched recovery strategies (~18min). Passive recovery [REST] was performed seated on poolside. Active dry-land recovery [BAND] was performed on an exercise bench using thera-band arm-pulls and body-weight leg kicks. Intermittent in-water recovery [INT] involved 18x50m repeats, alternating between 80% and 70% of 100m PB pace. Continuous in-water recovery [CONT] consisted of 5x200m repeats at <65% of 100m PB pace. Trials were completed at the same time of day and were separated by 3-4 days. In addition to 100m performance times, physiological (i.e. blood lactate) and perceptual (i.e. RPE) responses were captured during each recovery period.
RESULTS: Performance was significantly slower during the second 100m time-trial following both CONT (68.58±4.59, 70.29±4.78s) and REST (68.59±5.03, 69.50±5.17s, p<.01). Conversely, there were no significant differences between time-trial performances following BAND (69.12±4.98, 69.69±5.04s) or INT (68.86±4.68, 69.51±4.59s, p>.05). The greatest rate of blood lactate clearance between time-trials was evident during INT (2.93±0.54%·min), which did not significantly differ to CONT (2.63±0.78%·min) but was significantly higher than both REST and BAND (1.89±0.69 and 2.19±0.53%·min, respectively, p<.05). There were no significant differences in perceived recovery or post time-trial RPE across conditions (p<.05).
CONCLUSION: These findings suggest an intermittent in-water recovery strategy may be the best option to maximise physiological recovery and maintain swimming performance across repeated trials, compared to continuous in-water or alternative dry-land strategies. Furthermore, in the absence of a cool-down pool, swimmers may consider stroke-specific thera-band exercises as a more effective recovery strategy than passive rest.

A METHOD OF DETERMINING DRAG COEFFICIENTS OF SWIMMERS DURING FRONT CRAWL SWIMMING TO ASSESS ITS RELATIONSHIP WITH TORSO SHAPE

PAPIC, C., MCCABE, C., SANDERS, R.

THE UNIVERSITY OF SYDNEY AND ULSTER UNIVERSITY

INTRODUCTION: Active drag force is the resistance encountered by a swimmer while swimming with the usual stroking and kicking actions. Active drag has been found to have a relationship with body shape characteristics such as the projected frontal area of a swimmer (1). However, commonly used methods of estimating active drag force impose changes to the regular swimming technique of a swimmer. In this study we determined the drag coefficients of swimmers during the lag phase between propulsion of each arm of the front crawl stroke cycle, representing the time point of maximum deceleration.
METHODS: Intra-cyclic velocity data of 15 male Scottish front crawl specialists were used from data previously collected by McCabe (2). Swimmers had performed a maximal 400m front crawl swim through a 6.75m^3 calibrated space recorded by six above and below water gen-locked cameras. One complete stroke cycle relative to hand entry was obtained for each 50m segment of the swim. Velocity of the swimmer's centre of mass (COM) during the stroke cycle was represented for 200 equal time increments. Drag coefficient (Cd) was calculated by rearranging the equation embodying Newton's second law of motion to obtain the total drag force as a function of body mass (m), frontal area (A), velocity (v^2), acceleration (α) and fluid density (ρ) (1000kg/m^3) (Equation 1). Frontal area was calculated by modelling the swimmer's torso as a series of 1mm thick vertically stacked ellipses (3) using differences in X and Y coordinates as diameters of each ellipse. Maximum deceleration (m/s^2) prior to minimum COM velocity was used to calculate Cd.

Equation 1: Cd = (m · α · 2) / (ρ · A· v^2)
RESULTS: Mean body mass and frontal areas of the cohort were 73.9±8.7kg and 0.070±0.009m^2 respectively. The total number of analysed stroke cycles was 60, with an average maximal Cd of 2.509±0.843 per swimmer. No significant relationship was found with maximal Cd and body mass (r=0.077, p=0.393) or frontal area (r=0.243, p=0.191).
CONCLUSION: This study has demonstrated a novel method of assessing the hydrodynamic resistance of a swimmer during front crawl swimming, without alteration of regular swimming technique. The method has implications for the analysis of hydrodynamic resistance in middle and long distance swimming where a lag phase between arm propulsion occurs. The results reveal no significant influence of singular anthropometric variables of body mass and frontal area on Cd during maximal deceleration of the stroke cycle. Future direction of the study involves investigating the influence of body pitch and curvatures and indentations of the torso on Cd.

AGE-RELATED PERFORMANCE DETERMINANTS OF YOUNG SWIMMERS.

SEFFRIN, A., LIRA, C.A.B., ANDRADE, M.S.
UNIVERSIDADE FEDERAL DE SÃO PAULO

INTRODUCTION: Swimming performance is influenced by several factors, such as anthropometric and physiological aspects. However, the level of relative contributions of these variables to swimming performance in different age groups is not clear. Therefore, we evaluated the characteristics of aerobic endurance, anthropometry and neuromuscular fitness to fit a multiple regression model to verify which factors better explain performance in 400-meter freestyle swimming events in different age groups from 11 to 23 years old.
METHODS: Sixty swimmers from both sexes participated in the study (13.80 ± 2.61 years old, 1.62 ± 0.10 m, 52.36 ± 12.01 kg). They were divided into three groups: 11 to 12 years old (G1), 13 to 14 years old (G2) and 15 to 23 years old (G3). Aerobic endurance (critical velocity), anthropometry (height, seated height, body mass, lean mass, percentage of body fat, length of upper limbs, lower limbs, armspan, hands, feet, and trunk width and circumference), neuromuscular fitness (manual grip strength, swim speed, upper and lower limb peak torque and power, height and vertical jump power) and performance in 400-meter assessments were conducted. Stepwise multiple regression models were fitted to determine the relationships between performance and the parameters evaluated.
RESULTS: In the G1 group, critical velocity (ß = -0.937, t = -36.182, p <0.001) and age (ß = -0.106, t = -4.083; p = 0.001), clarified 99% of the variation (r2 = 0.992, F = 1013.530, Df [Degrees of freedom] = 2, 17, p < 0.001, SE [Standard error of estimate] = 3.240) of time in the 400-meter event. However, for the G2 group, anthropometric and neuromuscular fitness variables contributed significantly to the model. Almost all the variation (r2 = 0.993, F = 743.331, Df = 3, 15, p < 0.001, SE = 1.672) was explained by the combination of variables, critical velocity (ß = -0.921, t = -35.727, p <0.001), lean mass = (ß = -0.112, t = -4.797, p <0.001) and power of the countermovement jump (ß = -0.060, t = -2.205, p = 0.043). In addition, in the G3 group different variables compose the multiple linear regression models. The G3 group had 99% of the time variation (r2 = 0.993, F = 462.937, Df = 3, 10, p < 0.001, SE = 2.108) explained by critical velocity (ß = -0.968, t = -34.864 p <0.001), lean mass = -0.174, t = -4.407, p = 0.001) and length of the upper limbs (ß = 0.104, t = 2.652, p = 0.024).
CONCLUSION: The results of this study indicated that aerobic endurance, anthropometric and neuromuscular fitness parameters independently contribute to the stepwise prediction model of the performance of young swimmers and that the models are different between different age groups. The comprehension of what determines performance in each age group can contribute to the development of appropriate training programs, to determine parameters of sports selection and to help choose the events to which the athletes have the greatest aptitude.

OXYGEN UPTAKE KINETICS DURING MODERATE-INTENSITY FRONT CRAWL AND BREASTSTROKE SWIMMING

LOMAX, M.
UNIVERSITY OF PORTSMOUTH

INTRODUCTION: Differences in swimming economy and breathing patterns exist between swimming strokes. It is unknown if these differences impact pulmonary oxygen uptake (VO2) kinetics. This study aimed to characterise the kinetics of VO2 during moderate-intensity front crawl (FC) versus breaststroke (BR) swimming.
METHODS: Eight club level swimmers (4 females; 20 ± 1 y, 1.74 ± 0.06 m, 66.8 ± 6.3 kg) undertook 6-7 experimental swimming sessions in a swimming flume (SwimEx, 600-T, USA, water temperature 29.9 ± 0.3 C), during which breath-by-breath changes in pulmonary gas exchange and ventilation were measured continuously (MetaSwim, Cortex, Germany). The first two swims were progressive intensity FC and BR tests to exhaustion (GXT) with supramaximal verification testing, to determine maximal VO2 (VO2max). The gas exchange threshold (GET) from FC and BR GXT was also determined by two investigators. During the subsequent 3-4 visits, swimmers undertook two moderate-intensity (80% GET) constant velocity six-minute swims (CVS) from a prone floating position. One test was completed swimming FC and the other BR (counterbalanced order), separated by 30-minutes seated recovery. CVS transitions for FC and BR were linearly interpolated to 1-second time bins, time aligned to exercise onset and ensemble averaged. The cardiodynamic phase was visually determined and excluded from analysis and the time constant (t), time delay (TD) and amplitude (A) of phase II were determined using standardised methods, along with the mean response time (MRT) (GraphPad Prism, USA). Minute ventilation (VE), breathing frequency (fr) and tidal volume (VT) were calculated per CVS and averaged per stroke. Paired samples t-tests and Wilcoxon Signed rank tests were used to assess differences between FC and BR. Data are displayed as means ± standard deviations.
RESULTS: VO2max (FC: 3.78 ± 0.89 l/min, 54.1 ± 13.4 ml/kg/min; BR: 3.36 ± 0.78 l/min, 50.6 ± 12.2 ml/kg/min) and VO2 at GET (absolute or %VO2max) were similar (p>0.05) between FC (absolute: 1.97 ± 0.83 l/min; %VO2max: 53 ± 12%) and BR (absolute: 1.90 ± 0.59 l/min; %VO2max: 57 ± 8%), but velocity at the GET was faster in FC (1.18 ± 0.20 m/s) than BR (0.91 ± 0.04 m/s; p=0.02). VE (FC: 31.6 ± 10.0 l/min; BR: 33.2 ± 7.2 l/min), fr (FC: 18 ± 5 b/min; BR: 20 ± 5 b/min) and VT (FC: 1.87 ± 0.40 l; BR: 1.53 ± 0.57 l) were similar (p>0.05) between strokes. No differences were observed between strokes for t (FC: 24.44 ± 7.30 s; BR: 27.37 ± 9.12 s), TD (FC: 18.33 ± 4.98 s; BR: 16.27 ± 7.01 s), A (FC: 1.04 ± 0.43 l/min; BR: 0.96 ± 0.22 l/min) or MRT (FC: 41.63 ± 8.58 s; BR: 39.94 ± 7.73 s).
CONCLUSION: The use of a snorkel permits ad libitum breathing during FC and BR swimming thereby removing the stroke-induced breathing constraint. In this situation, VO2max is similar between FC and BR swimming and so too are the absolute and percentage VO2 at GET and VO2 kinetics during moderate-intensity FC and BR swimming.

Invited symposia

IS-BN05 Hamstring strain injuries: Prevention, rehabilitation and prediction - [Clinical track]

HAMSTRING STRAIN INJURY PREVENTION/INTERVENTION: HOW TO MAKE SENSE OF ALL THE CONFLICTING VIEWS AND WHY CANT WE ALL GET ALONG?

TIMMINS, R.

AUSTRALIAN CATHOLIC UNIVERSITY

This presentation will discuss the conflicting views on exercise prescription for hamstring injury prevention and rehabilitation. This will include presenting evidence (or arguments for an approach where the evidence is lacking) for the various exercise prescriptions being advocated in hamstring injury prevention. There is a basic misconception that exercises should be prescribed independent of one another and that you must sit in one camp or the other, be it eccentric, functional or isometric. This talk will aim to address the various views on exercise prescription from all these camps. The presentation will then progress into outlining how each view has arrived at their conclusions and why they think they're the one way to go.This will be done by using basic animal models, musculoskeletal modelling and level 1 RCT's to support all cases, should the evidence exist. If the evidence doesn't exist to support an approach, this presentation will hypothesize the theoretical underpinning, using evidence, as to why this approach may or may not work. This talk will then conclude by suggesting an approach which may allow all views to be implemented, whilst not increasing the athletes risk of injury and increasing time to return to play. This conclusion will be based on evidence, risk vs reward and the practical application of these programs.

ACUTE HAMSTRING INJURIES: AN EVIDENCE-BASED ON DIAGNOSIS, PROGNOSIS, REHABILITATION AND RETURN TO SPORTS

WANGENSTEEN, A.

NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Acute hamstring injury is one of the most common non-contact muscle injuries in sports. The incidence remains high, causing a significant loss of time from training and competition and a substantial risk of sustaining a reinjury. When an injury has occurred, medical staff face pressure to return the athlete to training and competition as soon as possible, and the need for a quick and accurate diagnosis and prognosis, as well as an efficient rehabilitation program is therefore essential.
METHODS AND CONTENT OF THE TALK: This talk (invited presentation) is based on the following main questions: How do we optimise the diagnostic and prognostic approach following acute hamstring? What is the most effective rehabilitation approach after acute hamstring injuries? And how do we determine return to sport (RTS) and reduce the risk of reinjuries?
In her talk, Arnlaug Wangensteen will give an evidence-based update and reflections from a clinical point of view around these questions. She will discuss the usage and value of clinical examinations and Magnetic Resonance Imaging (MRI) as diagnostic and prognostic tools. Futhermore, she will present the current rehabilitation programs investigated in the literature, their strengths and weaknesses, and how to apply the evidence in a clinical setting. Finally, she will present and discuss the different steps of the RTS process following an acute hamstring injury, including the final steps related to returning to optimal performance and reinjury prevention.
CONCLUSIONS: In the conclusions, a summary of the talk will be provided. The specific questions addressed in the talk will be presented in the take home messages.

PREDICTING HAMSTRING STRAIN INJURIES: IS IT POSSIBLE AND IS IT PRACTICAL?

RUDDY, J.

AUSTRALIAN CATHOLIC UNIVERSITY

Hamstring strain injuries (HSIs) are a common occurrence in team sports and can have significant physical and financial consequences for an athlete and their sporting organisation. As such, an abundance of research has attempted to identify risk factors for HSI, which is an important step when developing prevention and risk mitigation strategies. There are a number of methods that have been used to identify HSI risk factors. However, there is a level of confusion that can result from a misunderstanding and a misinterpretation of the different methodologies that are commonly employed. Research has traditionally taken reductionist approaches to identifying HSI risk factors. These approaches can be informative at a group level. However, they fail to account for the complex nature of HSI and are unable to shed light on how the aetiology of HSI contributes to injury risk at an individual level. Studies employing reductionist approaches, however, can be used to inform and implement complex approaches in future research. Complex approaches can be difficult to apply to a concept such as HSI. However, there are a number of emerging methodologies (such as machine learning) which may assist in better understanding HSI aetiology. In turn, this may improve our ability to identify risk and ultimately prevent HSIs from occurring

OP-BN21 Gait II

IMMEDIATE GAIT ADAPTATION FROM WALKING ON A TREADMILL TO WALKING ON A TREADMILL IN A FULLY IMMERSIVE VIRTUAL ENVIRONMENT

BOVIM, L.P., GJESDAL, B., MAELAND, S., AASLUND, M., BOGEN, B.

WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Fully immersive virtual environment (VE) using head mounted displays (HMD) seems to be a feasible addition to traditional treadmill training, with little or no simulator sickness, and with little impact on the coordinative dynamics of walking. However, previous studies have allowed time for adaptation before measuring the impact of the virtual environment. The aim of this study was to investigate the immediate response of walking in a VE, and further, the effect of familiarisation.

METHODS: A cross-sectional design was used, with 32 healthy participants (age: 29±5 yrs, height: 172±7 cm, weight: 72±14 kg, gender (M/F): 7/25) being tested during treadmill walking with and without VE. Participants were excluded if they had disease, injury or used medication expected to affect gait pattern. The participants were equipped with a six degrees-of-freedom inertial sensor (MTx, Xsens, Enschede, NL) that captured accelerations in the anteroposterior (AP), mediolateral (ML) and vertical (V) directions, attached over the lower back. Gait regularity, as an indication of balance control during walking, was estimated using an autocorrelation procedure (values tending towards 0.0=low regularity, values tending towards 1.0=high regularity). An increase in gait regularity after extended time of a new exposure indicates gait adaptation. Self-defined walking speed for a "stroll" was used. The participants first walked two minutes for treadmill familiarisation, and then 15 seconds for data collection without VE. After adding the HMD and reaching self-defined strolling speed, 15 seconds of immediate walking in VE was captured. The VE displayed had speed-synchronized visual flow and displayed a pathway in a tropical landscape. Finally, another 15-second period of strolling was captured after approx. 150 m of familiarisation walk in the VE.
RESULTS: After 0.01, ML: 0.64±0.16, p=>0.01 & V: 0.86±0.10, p=>0.01). Already after 150 m familiarisation in VE, the gait variability is almost normalised, however still slightly different from treadmill walking (AP: 0.90±0.05, p=0.02, ML: 0.73±0.10, p=>0.01 & V: 0.89±0.06, p=0.02).
CONCLUSION: We found that there was an immediate decrease in gait regularity after putting on the head-mounted display and entering the virtual environment, but after a short period of familiarisation, patterns tended to return towards pre-VE values. However, they were still significantly lower than on the treadmill without VE. This suggests that walking in VE might perturb walking and holds potential for balancing exercises. However, there is a tendency towards adaptation after a short period, and so VEs should perhaps vary, being stimulating and challenging, to obtain exercise effects.

LATERALITY OF FEMALE BREAST MOTION IN TREADMILL RUNNING

HASSMANN, M., STÖGER, S., KORNFEIND, P.

UNIVERSITY OF VIENNA

INTRODUCTION: Treadmill running is an established method of testing sports bras for support and comfort (1). Manufacturers define different levels of low, medium or high support. Support is indicated by the reduction of breast motion in all three directions or mainly of the vertical amplitude, either compared to everyday bras or to the unsupported condition without bra. The nipple can reliably represent breast motion (2) even though the breast is non-rigid. The nipple trajectory shows a typical horizontal eight or butterfly shape with two maxima and minima within one stride (2). Literature review reveals no consensus on the existence of laterality (2,3), i.e. the difference between left and right breast motion in treadmill running, nor on the explanation (differences in breast volume or dominant side). Therefore, both right and left breast should be analyzed (3) in contrast to the majority of studies analyzing only the right breast.
METHODS: 58 women (33.7±11.4 years, bra size 75B to 95G) not currently pregnant nor breastfeeding and without history of breast surgery were fitted the appropriate size of three different high support sport bras from two different manufacturers according to bra fitting criteria (4). They ran with each fitting sports bra at 8 km/h on a single belt treadmill (cardiostrong TX50) (N=110 trials). Eight Vicon MX cameras were placed around the treadmill (five front, three rear) and ten strides were recorded at the end of 5 min runs at 200 fps using Vicon Nexus 2.5. Retroreflective markers (6 mm) were placed according to the Plug-in-Gait marker set on the thorax (CLAV, STRN, C7, T10, RBAK) and shoulders (LSHO, RSHO). Five additional markers were placed on each bra cup, among which the nipple marker trajectories (LBRN, RBRN) were evaluated. Strides were identified using treadmill marker (5). Data of 10 strides was averaged in MATLAB R2014a. Vertical amplitudes of LBRN and RBRN were compared using T-test for independent samples in IBM SPSS 24.
RESULTS: T-test of vertical amplitudes revealed no significant difference between left and right breast (p=0.702) even though the mean absolute difference for each woman was 4.74±3.80 cm. While the CLAV marker trajectory as the origin of the thorax segment shows a rather symmetrical butterfly pattern, the LBRN and RBRN marker trajectories are not symmetrical. In addition, amplitudes of the same breast after ipsi- and contralateral step differ significantly for RBRN (p=0.007) and strongly for LBRN (p=0.079).
CONCLUSION: Sports bra testing should be performed analyzing both breasts for reliable judgement of support irrespective of dominant side. From the difference of vertical amplitude of nipple motion due to ipsi- and contralateral step can be concluded that running style (hardness of initial contact, upper body rotation) has to be taken into account.

INTRA-LIMB COORDINATION AND COORDINATION VARIABLITY OF SEMI-PROFESSIONAL SOCCER PLAYERS DURING AN ACCELERATION SPRINT RUN

WDOWSKI, M.1, GITTOES, M.2

1 COVENTRY UNIVERSITY, 2 CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: Mechanical insights into the determinants of sprint running performance have typically been examined using lower-order, discrete single joint and segment analyses. However, increased investigation into the coordination of joint couplings, the associated variability of these couplings throughout the gait cycle, and the relationship the coordination and coordination variability have on acceleration sprint performance are warranted. The aim of this study was to examine the association between intra-limb coordination (CRP) and coordination variability (VCRP) of lower-limb joints and acceleration sprint running performance for semi-professional soccer players. The CRP and CRPV of intra-limb joint couplings were hypothesised to not be correlated with acceleration sprint running performance.
METHODS: Twenty male semi-professional footballers were recruited in the study (mean±standard deviation: age 21±1.9 years, body mass 78.7±7.7 kg and stature 1.78±0.06 m). Participants completed ten maximal sprint runs over 20m from a right foot forward standing start during. Unilaterally located active marker data (CODAmotion, Charnwood Dynamics Ltd, Leicester, UK) were collected (sample rate: 200 Hz) for the right side for the full 20 m maximal sprint. Acceleration sprint performance was determined for each trial by dividing the 20 m distance by the absolute time data (0 - 20 m) captured two Smartspeed™ (Fusion Sport, Grabba Ltd, London) light gates (resolution: 1 millisecond test/retest reliability). The mean intra-individual CRP and VCRP of sagittal plane hip-knee, knee-ankle and hip-ankle joint couplings were determined for each stride for the entire 20 m acceleration sprint performance and examined in relation to the average sprint velocity.

RESULTS: Mean joint coupling CRP (p>0.05; r = -.236 to 0.014) and VCRP (p>0.05; r = -.088 to -0.286) were not found to be correlated with average sprint velocity. Hip-ankle (26.98±10.91 °), knee-ankle (88.07±6.32 °) and hip-knee (74.22±4.69 °) joint coupling CRP were significantly different [F(2, 38)=286.94, p=0.000, ηp2=0.94] to one another. The CRPV of each joint coupling was found to be similar [F(2, 38)=1.92, p=0.16, ηp2=0.09], with the KA, HA and HK joint couplings being 10.92±2.53 °, 10.86±2.19 ° and 9.94±2.16 ° respectfully.
CONCLUSION: Intra-limb coordination and coordination variability across the stride cycle was not explicitly correlated with acceleration sprint running performance. The findings potentially suggest that, in order to understand the underlying movement patterns of acceleration sprint running performance, coordination measures should be used in a process-oriented approach rather than in a product-oriented approach of deterministic models. Furthermore, the increased coordination state in the HA joint coupling may provide a compensatory mechanisms to facilitate for the reduced coordinative state of other joint couplings such as the KA and HK during transitions at touchdown and toe-off.

THE ANKLE POSITION AFFECTS THE HAMSTRING ACTIVATION DURING THE NORDIC EXERCISE PERFORMANCE

RADAELLI, R., NESKE, R., TEODORO, J., BRUSCO, C.M., PINTO, R.S.

UNIVERSIDADE FEDERAL DO RIO GRANDE DO SUL

INTRODUCTION: The Nordic Hamstring exercise (NHE) has been widely recommended in rehabilitation purposes and for improving sports performance. However, some methodological aspects regarding the exercise performance have not yet been sufficiently explored. Regarding the ankle position, it is possible to perform the NHE in plantar-flexion (PF) or dorsiflexion (DF) position, and as the plantar flexors contribute to the knee flexion movement, changes in muscle length may affect exercise performance. Thus, the aim of the present study was to compare the electromyographic activity (EMG) of the knee and the plantar flexors and also the total work produced during NHE performed in plantar-flexion (NHE-PF) and dorsiflexion (NHE-DF) position.
METHODS: Twelve physically active young adults (7 women and 5 men; 28.5 ± 5.4 years) participated in the present study. The body composition of participants (total mass and fat free body mass) was measured using dual energy X-ray absorptiometry. Six repetitions of the NHE were performed in each ankle position (NHE-PF and NHE-DF), with the ankles stabilized in an isokinetic dynamometer where total work during exercise execution was measured. In addition, EMG signal of biceps femoris (BF) and medial gastrocnemius (GM) were measured with superficial electrodes of both legs. Maximal EMG activity was obtained in a maximal isometric voluntary contraction (MIVC) in order to normalize the EMG activity during NHE performance.
RESULTS: No significant (p > 0.05) differences between NHE-PF and NHE-DF conditions were found for absolute total work (2952.7 ± 1529.5 J vs 2771.6 ± 1675.5 J), for total work relative to total mass (47.5 ± 30.7 J.kg-1 vs 44.6 ± 30.5 J.kg-1), for total work relative to fat free body mass (79.6 ± 48.7 J. kg-1 vs 75.1 ± 51.4 J.kg-1), and also for GM activation of the dominant (75.5 ± 45.5% of MIVC vs 79.1 ± 31.1% of MIVC) and non-dominant leg (90.4 ± 73.9 %MIVC vs 87.3 ± 55.6 %MIVC). Significantly higher (p < 0.05) BF muscle activation was observed in the NHE-PF compared to NHE-DF, in the dominant (77.0 ± 38.0 %MIVC vs 86.6 ± 40.2 %MIVC) and non-dominant leg (72.3 ± 41.1 %MIVC vs 80.6 ± 48.2 %MIVC).
CONCLUSION: Greater eletrocmyographic activity of the BF was observed when the NHE was performed in plantar-flexion position (NHE-PF), although no significant differences between positions (NHE-PF and NHE-DF) were found for GM activity and total work (absolute and relative).

DO CUSTOM FOOT ORTHOSES MODIFY THE BIOMECHANICAL MANIFESTATION OF FATIGUE DURING REPEATED TREADMILL SPRINTS?

GIRARD, O., RYU, J.H., MORIN, J.B., VAN ALSENOY, K.

MURDOCH UNIVERSITY

INTRODUCTION: Fatigue substantially alters force production/application characteristics and impact parameters during run-based repeated-sprint exercise. To date, whether custom foot orthoses (CFO) protect from the biomechanical manifestation of fatigue is unknown. We determined the effect of CFO manufactured from ethyl-vinyl acetate (EVA) and expanded thermoplastic polyurethane (TPU) materials, both compared to a control condition (CON; shoes only) during repeated sprints on alterations in running kinetics and kinematics, with special reference to horizontal force production.
METHODS: Eighteen well-trained male athletes performed eight, 5-s sprints with 25-s recovery on an instrumented sprint treadmill (ADAL3D-WR) in three footwear conditions (EVA, TPU and CON). Mechanical data consisted of continuous (step-by-step) measurement of running kinetics and kinematics, which were averaged for each sprint for further analysis.
RESULTS: Distance ran in 5 s decreased from the first to the last sprint (-3.9±3.1%; P<0.001), yet with higher sprints 1–8 values for both EVA (23.3±1.4 m; P=0.004) and TPU (23.1±1.5 m; P=0.018) versus CON (22.7±1.6 m). The eight sprints for both EVA and TPU produced lower heart rates (~4 bpm; P<0.001) compared to CON, while oxygen uptake (P=0.280) and ratings of perceived exertion (P=0.680) values did not differ between conditions. Disregarding the footwear condition, mean horizontal forces (-11.1±5.8%), step frequency (-5.7±4.8%), vertical (-11.7±9.8%) and leg stiffness (-9.5±8.8%) decreased from sprint 1 to sprint 8 (all P<0.001), while peak and mean vertical forces remained constant (both p>0.261). Contact time lengthened from the first to the last sprint (+9.6±8.7%; P<0.001), with averaged values for the eight sprints also being significantly shorter for EVA (-2.3±2.8%; P=0.010), but not TPU (-1.1±3.3%; P=0.432), compared to CON. Specifically, duration of the push-off phase was globally shorter for both EVA (-4.7±4.6%; P=0.002) and TPU (-4.0±5.7%; P=0.021) versus CON, while braking phase duration was similar (P=0.919). In the horizontal direction, peak push-off (-8.0±6.7%; P<0.001), but not braking (+2.0±6.7%; P=0.172), forces also decreased from sprint 1 to sprint 8, independently of conditions.
CONCLUSION: We confirm that kinetics and kinematics, especially forward-oriented force production, deteriorate substantially during repeated treadmill sprinting. Compared to shoe only, wearing CFO improves repeated sprint ability (external load) and concomitantly reduces heart rates (internal load), yet with essentially similar positive effects for EVA and TPU materials. Running mechanical adjustments occurring during the push-off as opposed to the braking phase are mainly responsible for these changes.

CHANGES IN CONTACT AND FLIGHT TIMES WITH INCREASED SPEED DURING OVERGROUND AND TREADMILL RACE WALKING

HANLEY, B., TUCKER, C.B.
LEEDS BECKETT UNIVERSITY

INTRODUCTION: Race walking is an Olympic event dictated by a rule that states that no visible loss of contact with the ground should occur and that the leg must be straightened from first contact with the ground until the 'vertical upright position' (IAAF Rule 230.2). The measurement of contact and flight times during race walking is therefore of great interest to coaches and athletes. The aim of the study was to compare the effects of changes in speed on temporal variables in elite race walking during treadmill and overground race walking.
METHODS: Eleven male race walkers (stature: 1.77 m (± 0.06), mass: 64.4 kg (± 4.7)) and eight female race walkers (stature: 1.67 m (± 0.09), mass: 56.1 kg (± 10.3)) participated. Fifteen of the athletes had competed at the 2016 Olympic Games or 2017 World Championships. For the overground condition, the men race walked multiple times down a 45-m indoor track at 11, 12, 13, 14 and 15 km/h in a randomised order, whereas the women's trials were at 10, 11, 12, 13 and 14 km/h. Contact and flight times were measured for each trial using five connected 1 m strips of an OptoJump Next system (1000 Hz). For the treadmill condition (conducted on a separate day), each athlete race walked on a treadmill at five speeds for 3 min each. The speeds chosen were the same as during the overground condition and were conducted in a randomised order after a 10-min warm-up and familiarisation period. Results from the OptoJump Next system were extracted using specific settings based on the number of LEDs found optimal during a reliability study; for the overground tests, this setting was 2_2, whereas for the treadmill tests it was 0_0.
RESULTS: For the overground condition, the values changed as follows (contact time / flight time): men – 11 km/h: 0.327 s / 0.015 s; 12 km/h: 0.304 s / 0.025 s; 13 km/h: 0.281 s / 0.035 s; 14 km/h: 0.267 s / 0.040 s; 15 km/h: 0.251 s / 0.044 s. For women, the values changed as follows – 10 km/h: 0.331 s / 0.012 s; 11 km/h: 0.307 s / 0.022 s; 12 km/h: 0.286 s / 0.033 s; 13 km/h: 0.269 s / 0.040 s; 14 km/h: 0.248 s / 0.049 s. For the treadmill condition, the values changed as follows: men – 11 km/h: 0.313 s / 0.021 s; 12 km/h: 0.296 s / 0.029 s; 13 km/h: 0.279 s / 0.038 s; 14 km/h: 0.261 s / 0.047 s; 15 km/h: 0.247 s / 0.053 s. For women, the values changed as follows – 10 km/h: 0.319 s / 0.023 s; 11 km/h: 0.293 s / 0.036 s; 12 km/h: 0.276 s / 0.045 s; 13 km/h: 0.258 s / 0.054 s; 14 km/h: 0.245 s / 0.059 s.
CONCLUSION: Although it was unsurprising that contact time decreased with increased walking speed, and that there was a concurrent increase in flight time, what was interesting was that women had higher flight times when their speeds were matched with the men's. Women therefore need to be more careful about displaying visible loss of contact. In addition, flight times tended to be higher during treadmill race walking at the same speed as overground (and contact times lower), suggesting that treadmill training could induce non-legal technique.

LONGEVITY AND CAUSES OF DEATH IN FORMER US OLYMPIANS

ANTERO, J., TANAKA, H., DELAROCHELAMBERT, Q., POHAR-PERME, M., TOUSSAINT, J.F.
INSEP

INTRODUCTION: United States (US) send a greatest number of athletes to Olympic Games but their longevity and specific causes of deaths have not been examined. We aimed to quantify US Olympic athletes' longevity and to determine the impact of specific causes of deaths (CoD) on Olympians life duration in relation to the general population.
METHODS: Female (n = 2,301) and male (n = 5,823) US athletes who have participated at least once in the summer or winter Olympic Games between 1912 and 2012 were followed up to 2016. Their life status and CoD were certified by the National Death Index. The years-saved method was applied to quantify longevity gains/losses in former US Olympians in comparison to the general population.
RESULTS: Former US Olympians lived on average ~5 years longer (95% CI 4.3 to 6) than their referents in the general population, based on the 2,309 deaths observed out of 8,124 former athletes. The burden of each CoD was distributed according to its impact on the total number of years of life saved: cardiovascular diseases (CVD), 2.2 years (1.9 to 2.5); cancer, 1.5 years (1.3 to 1.8); respiratory diseases, 0.8 years (0.7 to 0.9); and external causes, 0.5 (0.4 to 0.6). Nervous system diseases and mental disorders mortality rates were not significantly different from their peers in the general population.
CONCLUSION: US Olympians live ~5 years longer than their referents in the general population, advantage mainly driven by lower risks of CVD and cancer. Nervous system diseases and mental disorders do not appear to contribute to the extended longevity that Olympians display.

IMMUNOMODULATORY EFFECTS OF REGULAR EXERCISE TRAINING IN YOUNG AND OLDER ADULTS

PAPP, G., SZABÓ, K., JÁMBOR, I., BERKI, A.R., MILE, M., CSIKI, Z., BALOGH, L.
UNIVERSITY OF DEBRECEN

INTRODUCTION: Studies of the last decade revealed the important effects of physical activity on immune functions. These effects may largely depend on the type of activity, its intensity and duration. However, little information is available regarding the immunological effects of sporting activities in older ages. The aim of our study was to examine the changes in a wide spectrum of lymphocyte subtypes after a period of regular workout among healthy women of different ages.
METHODS: In our study, we enrolled 26 young adult women (between ages of 19-23 years), who were not engaged in regular physical activity. Additionally, we enrolled 16 elderly women (between ages of 60-75 years) not engaged in regular physical activity. Seventeen persons from the group of young adults completed a 12-week Pilates workout program, while the whole group of elderly women took part in a 6-week lightweight conditioning gymnastic exercise program once a week. The percentages of peripheral natural killer (NK), NKT cells, T and B lymphocyte subtypes (early-/late-activated T, naive and memory T, cytotoxic T (Tc), T-helper (Th)1, Th2, Th17, T regulatory type 1 (Tr1), CD4+CD127-CD25bright Treg, as well as naive and memory B cells) were determined by flow cytometry based on the staining of extracellular markers and intracellular cytokines.

RESULTS: In the elderly women, levels of CD3+6B11+ NKT cells were lower, while ratios of CD4+ Th/CD8+ Tc cells were higher compared to the values of younger individuals at baseline. At the end of exercise programs, changes observed among 60-75 year-olds were more pronounced compared to alterations developed in younger subjects. In elderly women, percentages of IgD+ naive B cells decreased, while levels of CD27+ switched-memory B cells increased. Furthermore, proportions of CD4+IL-4+ Th2 cells increased, while levels of CD8+IFN-gamma+ Tc cells and immunosuppressive CD4+CD127-CD25bright Treg cells decreased as the result of regular exercise.
CONCLUSION: Differences observed after lightweight exercise programs reflect a presumably enhanced immunoreactivity and increased ability for immune responses, especially in older ages. The research was supported by the GINOP-2.3.2-15-2016-00062 project. The project is co-financed by the European Union from the European Regional Development Fund.

EFFECT OF AEROBIC EXERCISE AND PM2.5 ON LUNG PULMONARY FUNCTION AND INFLAMMATION IN AGED RATS

ZHAO, J., QIN, F., XU, M., DONG, Y., WANG, Z.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Exposure of particulate matter of less than 2.5 μm (PM2.5) has been associated with adverse respiratory and the risk of inflammation. While regular physical activity (PA) reduces the risk of many adverse health effects. This study aimed to examine the protection of pre-exercise on adverse health effects of Pulmonary Function and inflammatory induced by PM2.5 exposures in aged rats.
METHODS: 24 male wistar rats, aged 16 months, were randomly divided into 4 groups: Sedentary (S), Exercise (E), Sedentary+ PM2.5 exposures (S+PM), and Exercise+ PM2.5 exposures (E+PM). The rats in all E-related groups went through an 8-week aerobic treadmill exercise protocol (65-75%VO2max, 30 min) at every other day. The PM-related groups of aged rats were exposed to concentrated PM2.5 in Beijing (7 days/week, 4 hours/day). After 2-week PM Exposure, the pulmonary function examined by whole body plethysmography, structure of lung tissues were observed by HE staining, and the counts of leukocyte, sIgA, CRP and TNF-α concentration were examined.
RESULTS: 1) Compared with S group, following changes occurred in S+PM group after 2-week PM2.5 exposure: lung tissues were seriously damaged, local bleeding, pus exudation, and inflammatory cell infiltration, as well as the decline of sIgA level (↓45%, ES=0.87, $p<0.05$) and percentage of neutrophil (↓62%, ES=0.45, $p<0.05$), while the incline of the Index of constriction (↑76%, ES=3.97, $p<0.05$), the rejection index, CRP (↑24%, ES=0.83, $p<0.05$), and TNF-α (↑38%, ES=0.84, $p<0.05$) were observed. 2) Compared with S+PM group, the structure of lung tissues and pulmonary function were obviously improved in E+PM group. In addition, the sIgA concentration (↑85%, ES=0.70, $p<0.05$) were enhanced markedly, while CRP (↑21%, ES=0.76, $p<0.05$), and TNF-α level (↑25%, ES=0.74, $p<0.05$) were decreased in E+PM group compared with S+PM group.
CONCLUSION: 2-week PM2.5 exposures led to an increased susceptibility of infections, index of constriction and susceptibility of pulmonary function in aged rats. Moderate pre-exercise has beneficial effects on pulmonary function and reducing the susceptibility to inflammation.

CAPACITY OF CARE HOME RESIDENTS TO PERFORM FUNCTIONAL ABILITY TESTS

BAMPOURAS, T., SWAINSON, M., YASAR, Z., HAYES, L.D.

LANCASTER UNIVERSITY

INTRODUCTION: Currently, 4% of older adults over the age of 65 in the UK are care home residents, requiring some assistance to complete daily living activities. Recommendations for physical activity to improve functional ability exist for this population (de Souto Barreto et al, 2016). Their capacity, however, to perform various functional ability tests, has not been examined.
METHODS: Twenty three care home residents (age: 86.8±5.4 years, height: 1.62±0.09m, body mass: 70.9±17.6 kg, males: n=14) from 5 different care homes in the North West of England, were assessed on back scratch (BS; with one hand reaching down over the shoulder and the other one up the middle of his/her back, the distance between the extended fingers of the two hands was measured), chair sit-and-reach test (CSR; reaching down toward his/her toes, the distance between the extended fingers and the tip of the toes was measured), handgrip strength (HS; whole arm strength when squeezing maximally against a dynamometer), sit-to-stand (STS; number of sit-to-stands from a seated position to fully erect and back in 30 secods), and 3m timed up-and-go test (TUG; time taken to rise from a seated position, walk 3 m, turn, and return to the seated position) during November and December of 2017. Descriptive statistics of numbers able to complete the tests were calculated, while Spearman's correlation was used to examine the relationship between HS and TUG.
RESULTS: Residents (69.6%) used a walking aid but only 52.2% was tested with the aid. 59.1% were able to perform the BS test (32.9±21.3 cm, with only 36.4% able to perform three trials), 68.2% were able to perform the CSR (15.7±18.6 cm, with only 27.3% able to perform three trials), 100% were able to perform the HS (16.1±8.5 kg, with 72.7% completing three trials), 68.2% were able to perform the STS test (8.8±5.7 sit to stands, one trial only) and 77.3% were able to perform the TUG (28.2±19.3 s, 4.5% completing three trials). No significant correlation ($p=0.229$) existed between HS and TUG.
CONCLUSION: Only HS had 100% completion rate (one trial) from all tests. The HS and TUG had the highest completion rate, but with no correlation between them, suggesting these two should be used for functional ability assessment in care home residents, as they appear well tolerated and offer an assessment of upper and lower body ability. These results raise concerns regarding a) the reliability of any such measurements in this population, b) the ability to comprehensively asses this population, and c) their functional ability status. In line with previous reports in care home populations (Bampouras et al, 2018), these findings support the promotion of physical activity at early stages to prevent this functional decline.

INFLUENCE OF SPEED DIFFERENCE IN CHAIR SIT-TO-STAND EXERCISE ON HEART RATE AND BLOOD PRESSURE RESPONSES IN THE ELDERLY

SHIMA, N.1, KANNO, M.2, NAGASAKI, M.2, SHIOZAWA, K.3, SAITO, M.4

1: TOKAI GAKUEN UNIVERSITY, 2: AICHI GAKUIN UNIVERSITY, 3: NAGOYA UNIVERSITY, 4: TOYOTA TECHNOLOGICAL INSTITUTE

INTRODUCTION: Physical training involving high-speed chair sit-to-stand movement could improve the ability of daily living [1]. However, it is unclear whether heart rate (HR) and blood pressure (BP) responses are safe during high-speed chair sit-to-stand exercise. The speed

of chair sit-to-stand exercise was found to be associated with a change in the BP response among male college students [2]; however, the change in response among the elderly has not been investigated. Thus, the present study examined the changes in HR and BP responses among the elderly during chair sit-to-stand exercise at different speeds.
METHODS: In this study, 8 men (73±4 yrs) and 10 women (71±4 yrs) performed repeated chair sit-to-stand exercises 10 times at 3 different speeds: slow (3 s standing and 3 s sitting), medium (free; their comfortable speed) and fast (as quickly as possible according to subjective maximal effort). The exercises were performed in random order with a rest period of >4 min between exercises . Before, after and during the exercise, we measured the HR using an electrocardiogram and BP from the middle finger using a Finometer (Finapres Medical Systems BV, Amsterdam, The Netherland), which is used to calculate the systolic BP (SBP), diastolic BP (DBP) and mean BP (MBP). Two-way repeated measure analysis of variance was used to assess changes in the HR, SBP, DBP and MBP over time; subsequently, Dunnett's post-hoc tests were used to assess differences from the baseline value (25–30 s before exercise).
RESULTS: On changing the speed of the exercise, we found that HR and BP responses had significant interactions with time. The fast condition more increased the HR during the 7th to 10th chair exercises than slow condition. Moreover, the slow condition increased the HR slowly, but the recovery time was delayed. The fast condition caused no significant changes in the SBP after the start of exercise, and the value remained about the same. However, the slow and free conditions were associated with significant increases in SBP after the start of exercise, and it returned to the value at rest 10 s after the exercise. The fast condition caused an increase in the DBP immediately after the exercise, but it quickly recovered to the baseline value. The slow and free conditions caused no changes in the DBP during exercise. The DBP and MBP decreased after the exercise under all three conditions.
CONCLUSION: Under the fast condition, the HR tended to increase while SBP barely increased; whereas under slow condition, the HR slowly increased and SBP significantly increased . These results suggest that different speeds of chair sit-to-stand exercise have different influences on the heart and vascular systems in the elderly. In conclusion, fast and slow chair sit-to-stand exercises are considered as safe training approaches in patients with hypertension and heart diseases, respectively.

ASSOCIATION OF DAILY DIETARY INTAKE AND INFLAMMATION INDUCED BY MARATHON RACE

CURY-BOAVENTURA, M., PASSOS, B., LIMA, M., SIERRA, A., OLIVEIRA, R., MACIEL, J., ROGANTE, J., MANOEL, R., PESQUERO, J.
1 CRUZEIRO DO SUL UNIVERSITY, 2 UNIVERSITY OF SÃO PAULO, 3 FEDERAL UNIVERSITY OF SÃO PAULO

INTRODUCTION: Prolonged exercise is a physiological stress which promotes hyperinflammation follow anti-inflammatory compensatory response characterized by the increase on inflammatory mediators. Daily food intake is crucial to maintain immune health and determine endogenous fuel to practice endurance exercise. Recently studies have been reporting an inadequate daily intake characterized by low intake of carbohydrate, dietary fiber sources, fruits, dairy beverages and vegetables in long-distance runners. We investigated the association between quantity of macronutrients and micronutrients daily intake and inflammation induced by long-distance exercise.
METHODS: Forty-four Brazilian male amateurs' marathon finishers from 30 to 55 years old participated in this study. Blood samples were collected 1 day before, immediately after, 1 day and 3 days after São Paulo International Marathon. The serum levels of IL-6, IL-1β, IL-10, IL-8, IL-12p70 and TNF-α were measured to evaluate inflammation. Dietary intake was determined using a retrospective method of three food records in the week before marathon race.
RESULTS: Marathon race promoted an elevation on IL-6, IL-8, IL-1-β and IL-10 immediately after race. The energy intake (EI), carbohydrate, fiber, folic acid, vitamin E, vitamin D, calcium, magnesium and potassium intake were below recommended. Immediately after the marathon race, we observed a negative correlation between IL-8 and daily EI, carbohydrate, fiber, fat, iron, calcium, potassium and sodium intake and higher levels of IL-8 on runners with <3g/kg/day of carbohydrate intake compared to runners with >5g/kg/day. We demonstrated a positive correlation between daily carbohydrate intake and IL-10 and a negative correlation between TNF-α and % of energy intake recommended, carbohydrate and fiber intake. Finally, runners with adequate EI had lower levels of IL-1β and TNF-α compared with low EI immediately after race.
CONCLUSION: The inflammatory process induced by exercise may be influenced by many factors including food adequate intake. The daily intake of energy, carbohydrate, fiber, vitamins B3, B6 and D, calcium, magnesium and potassium were below daily reference value in amateur's marathon runners in the pre-competition period. We suggest that pro-inflammatory cytokines IL-8 or TNF-alpha release induced by exercise are associated with low energy, carbohydrate, fiber and/or minerals daily intake. Moreover, higher daily consumption of carbohydrate may improve IL-10 levels in the recovery period of long-distance exercise. Nutrition strategies to promote balanced diet in amateurs runners seems to be as important as immunonutrition sports market. Daily food intake, mainly EI, eletectrolytes and carbohydrate intake may modulate exacerbated inflammation after endurance exercise.

CHARACTERISTICS OF RIBOSOMAL ACCUMULATION DURING SHORT-TERM RESISTANCE TRAINING WITH VARIABLE TRAINING VOLUME AND THE EFFECT OF SHORT-TERM DE-TRAINING

HAMMARSTRÖM, D., ØFSTENG, S.J., JACOBSEN, N.B., FLOBERGSETER, K.B., RØNNESTAD, B.R., ELLEFSEN, S.
INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Ribosome abundance increases in response to resistance training and this is thought to be a critical mechanism enabling muscle hypertrophy. The purpose of this study is to explore fluctuations in ribosome accumulation in response to resistance training of constant and variable volume and short-term de-training.
METHODS: Fourteen untrained men (n=7, mean(sd) age: 25(4) yrs) and women (n=7, 23(3) yrs) where recruited to either an experimental group (n=7) or as non-training controls (CTRL, n=7). The experimental group performed twelve sessions of unilateral knee-extension with one leg performing 6 sets during the whole period (CONST) and the other leg varied volume (VAR) with 6 sets in sessions (S) 1-4, 3 sets in S5-8 and 9 sets in S9-12. Target intensity was 10RM in both groups. Vastus lateralis (VL) muscle-thickness was assessed by ultrasound prior to and 2 and 8 days after the last session in the experimental group and before and after a control period in CTRL. Bilateral muscle

biopsies were obtained from VL prior to the intervention and 48-h after S1, S4, S5, S8, S9 and S12 as well as after 8 days of de-training. Biopsies were analyzed for total-RNA and expression of ribosomal protein S6 (rpS6) and Upstream Binding Transcription Factor (UBTF) total protein.
RESULTS: Muscle thickness increased (mean [95% CI]) 6.97 [1.45-12.49] and 8.95 [3.43-14.47]%-points from pre to two and eight days after the last session respectively in CONST compared to CTRL. The effect was less clear in VAR 3.07 [-2.48-8.63] and 4.53 [-1.02-10.09]%-points compared to CTRL.
Total-RNA increased 1.07 [1.01-1.12]-fold per session in CONST with no differences over the course of the intervention and no different to VAR. Eight days of de-training reduced total-RNA content to 0.77 [0.6-0.99]-fold of values measured at 48-h post S12 session with no clear difference between conditions (1.19 [0.83-0.83]-fold in VAR compared to CONST).
Total levels of rpS6 and UBTF protein increased 1.04 [1.02-1.06] and 1.07 [1.04-1.09]-fold per session respectively with no differences between groups. The de-training period left rpS6 unaffected in both conditions but UBTF was expressed 0.55 [0.36-0.83]-fold compared to 48-h post S12 in CONST. The de-training effect tended to be rescued in VAR (1.69 [0.94-3.03]-fold compared to CONST).
CONCLUSION: Variations in training volume and short-term de-training shows small but possibly meaningful effects on markers of ribosomal biogenesis. Twelve sessions of resistance training is not enough to reach a plateau in the accumulation of total-RNA.

THE EFFECT OF AN ANTI-INFLAMMATORY TREATMENT ON SKELETAL MUSCLE REGENERATION IN A CARDIOTOXIN-INDUCED INJURY MODEL

DALLE, S.
KU LEUVEN

INTRODUCTION: Skeletal muscle regeneration is a complex interplay between myocytes and immune cells, generating pro- and anti-inflammatory phases in muscle regeneration. Some evidence suggests that non-steroidal anti-inflammatory drug (NSAID) treatment following muscle damage lowers muscle strength, probably due to an impaired regeneration process [1]. Therefore, we want to investigate whether suppressing inflammation via NSAID treatment affects parameters of muscle anabolism during muscle regeneration.
[1] Mishra et al., Anti-inflammatory medication after muscle injury. A treatment resulting in short-term improvement but subsequent loss of muscle function, J. Bone Jt. Surg., vol. 77(10), 1510–1519, 1995.
METHODS: 72 C57/BL6 mice were injected in the m. Tibialis Anterior with either cardiotoxin (CTX, to induce muscle injury, n = 48) or PBS (control, n = 24). CTX-injected mice were subdivided in an untreated (PLAC) group and an ibuprofen-treated (IBU) group. Mice were sacrificed 2 days (d2), 5 days (d5) and 12 days (d12) following the injection to study the different phases in the regeneration process. Skeletal muscle tissue was biochemically analysed to assess parameters of muscle inflammatory signaling (COX-2, IL-6/1β) and muscle anabolic signaling (mTOR signaling).
RESULTS: At d2, COX-2 mRNA expression was significantly higher in PLAC vs. PBS, while this was not the case for IBU. IL-6 and IL-1β were significantly higher in CTX compared to PBS, irrespective of treatment. At d2, mTORC1 signaling was improved in IBU and not in PLAC, while no differences between treatments were observed at d5 and d12.
CONCLUSION: Ibuprofen induces a decrease in COX-2 expression and an associated upregulation of the anabolic signaling early in the regeneration process following muscle injury in mice. However, this effect was not persistent during the following phases of regeneration.

DISRUPTION OF MUSCLE STEM CELLS NICHE AFTER ACUTE RADIATION EXPOSURE DURING MUSCLE DEVELOPMENT

COLLAO, N.
UNIVERISTY OF OTTAWA

INTRODUCTION: With an increase in long-term cancer survival, the late effects of radiation therapy is an area of clinical concern, particularly with respect to muscle health. Radiation induced fibrosis (RIF) a debilitating late-effect of radiation therapy that affects up to 80% of childhood survivors. The developmental potential of skeletal muscle is maintained by a pool of resident adult stem cells, called satellite cells. This process is a highly orchestrated, involving the activation of various cell types such as mesenchymal stem/stromal cells (MSCs) and cells form the immune system, such as macrophages. The effects of juvenile radiation exposure on muscle development and stem/progenitor cell populations has not been investigated. As such, the purpose of this study was to examine the effects of juvenile radiation exposure on mouse muscle morphology and stem/progenitor cell populations throughout a time course of development.
METHODS: Using a within design, one lower limb of 5-6 week old male CBA mice was exposed to a single dose of 16 Gy radiation (IR) while the other limb served as the non-irradiated control (CON). Mice were sacrificed at 3, 7, 14, and 56 days post-radiation (n=8/group). Gastrocnemius/soles complex were isolated for histochemical and immunofluorescent analyses for the different cell population.
RESULTS: Average gastrocnemius/soleus myofibre cross-sectional area (CSA) was reduced after IR (main effect of radiation, $p<0.05$ vs. CON). The number of Pax7+satellite cells was not different between IR and CON; however, there was a significant reduction in the number of differentiated myoblasts (Pax7-MyoD+) in IR compared to CON group at 7 and 14 days post-radiation ($p\leq0.05$). In the IR muscle MSC content was significantly decreased at 14 and 56 days post-radiation ($p\leq0.05$ vs. CON). Muscle adiposity as evaluated by perilipin content was increased in the irradiated limb at 56 days post ($p<0.05$). Similarly, muscle fibrosis was elevated at 7, 14, and 56 days in the irradiated limb ($p<0.05$). Macrophage content was increase after IR (main effect of treatment and a main effect of time).
CONCLUSION: Our findings indicate that juvenile radiation decreases muscle size, reduces differentiation capacity of myoblasts, and reduces MSCs content. These findings were associated with increased adiposity, fibrosis, and macrophages. These findings could have implications for late effects of radiation therapy on muscle health in juvenile cancer survivors.

EFFECT OF EXTREME EXERCISE ON SKELETAL MUSCLE MITOCHONDRIAL FUNCTION IN YOUNGER AND OLDER MEN

SAHL, R.E., FRANDSEN, J., NIELSEN, A.B., LARSEN, S., DELA, F., HELGE, J.W.
UNIVERSITY OF COPENHAGEN

INTRODUCTION: Health benefits are achieved when changing a sedentary lifestyle to a moderate active lifestyle but the benefits in the extreme end of the scale is debated. In this study we investigated the effect on skeletal muscle mitochondrial function, when repeated excessive exercise was performed in younger and older male cyclist.
METHODS: Younger (age 30 y, n=7) and older (age 65 y, n=7) male cyclist covered 3008 km (22350 meters of altitude) from Copenhagen (Denmark) to Palermo (Italy) in 15 days. 7-14 days before departure and 2 days after arrival a muscle biopsy (v. lateralis) was obtained

followed by measurement of mitochondrial respiration and H2O2 emission (Oroboros, Austria). ADP sensitivity was measured as the ADP concentration to elicit ½ Vmax. From embedded frozen muscle tissue fiber type I, IIa and IIx were identified using the myofibrilar histochemical ATPase technique. Fibers and capillaries were defined by antibody staining with UEA-I and anti-collagen IV. Citrate Synthase (CS) activity was measured in freeze-dried and dissected muscle tissue and used to normalize mitochondrial measurements.
RESULTS: No changes in mitochondrial complex I respiration (0.19±0.02 to 0.23±0.01 and 0.31±0.01 to 0.26±0.03 pmol O2/s/mg/CS activity in the young and old group respectively, mean±SEM), complex I+II respiration (0.45±0.02 to 0.52±0.03 and 0.59±0.04 to 0.59±0.02 pmol O2/s/mg/CS activity in the young and old group respectively) or uncoupled respiration (0.47±0.03 to 0.53±0.03 and 0.64±0.04 to 0.62±0.02 pmol O2/s/mg/CS activity in the young and old group respectively) were observed after the intervention. H2O2 emission decreased after the intervention (4.56±1.01 to 4.02±1.97 and 6.22±1.21 to 4.01±1.48 pmol H2O2/s/mg/CS activity*1000 in the young and old group respectively, P = 0.04). ADP sensitivity showed opposing changes. In the young group ADP sensitivity decreased (0.33±0.13 to 0.64±0.12 mM) and in the old group ADP sensitivity increased (0.67±0.13 to 0.34±0.10 mM, interaction P <0.001). No changes were observed in fiber type expression, fiber size or capillarization.
CONCLUSION: We show here how skeletal muscle tissue in younger and older men adapt to prolonged exercise. Mitochondrial respiratory capacity do not increase, despite the large exercise load. This is probably due to an already high training status in both groups. H2O2 emission decreased after the intervention, which is expected with training. ADP sensitivity showed divergent effects between the two groups, where the young group show an expected decrease in ADP sensitivity and the old group increased the ADP sensitivity. Beside from this, we have no findings suggesting a negative effect on skeletal muscle when trained athletes engage in extreme exercise.

AEROBIC EXERCISE AND CALORIES RESTRICTION PROMOTE SKELETAL MUSCLAR MITOPHAGY WITH MTORC1 INHIBITION IN AGING RATS

WEN, L., ZHAO, Y.Q., YU, M.C.H., ZHANG, Y., LIU, J., JIN, Z.Q.

TIANJIN UNIVERSITY OF SPORT

INTRODUCTION: It is well known that mitophagy is important in the maintaining cell homeostasis through the selective clearance of damaged mitochondria; and there is a decreased mitophagy during the process of aging. It has been reported that the rapamycin complex 1 (mTORC1) signalling pathway plays a key role in the promoting mitophagy. However, whether mTORC2 also involved in the regulation of mitophagy remains unclear. Recently, it has been reported that mTORC2/PHLPP1 kinase-phosphatase pair can modulate the chaperone-mediated autophagy (CMA) activity by the control of the lysosomal Akt. The aim of this study was to determine the role of mTORC1 and/or mTORC2 signaling pathway in the effect of aerobic exercise, with or without caloric restriction, on mitophagy in the aging skeletal muscle.
METHODS: 24-month old male Sprague-Dawley rats were randomly allocated into four groups (n=8 in each): control (C, ad lib feeding), caloric restriction (CR, 60% caloric of C group), exercise (E) and exercise combined calorie restriction (CRE). The treadmill exercise was performed by the E and CRE groups. The treadmill was set with the speed at 15m/min and the slop at 5 degree, that was equivalent to intensity of 64% VO2max. The exercises were applied 60 min per day, five days per week for 12 weeks. Under anaesthesia, soleus muscles were collected 24 hours after the last session. Mitochondria were isolated immediately from the part of soleus muscles by differential centrifugation, and then mitochondrial DNA was extracted. Finally, the specific primers PCR amplification was performed to determine the intact and deleted fragments, and then the nucleic acid electrophoresis was used to test the deletion mutation rate. The left soleus muscles were stored at -80°C. The targeted proteins including AMPKα, p-AMPKα (T172), mTOR, p-Raptor, ULK1, p-ULK1 (S757), p-ULK1 (S555), LC3, p62, Parkin and BNIP3 were analysed by Western blot.
RESULTS: The AMPK was significantly higher in the groups of CR, E, and CRE than the C group respectively (p <0.01). The TSC2 was significantly increased in the groups of E and CRE as compared to the C group (p <0.05). Both groups of E and CRE have significantly lower of the Rheb than that in the C group (p <0.01). The R-Raptor was significantly higher in the groups of R (p <0.05), E (p <0.01) and CRE (p <0.05) as compared to the C group respectively. On the contrary, neither of Rictor and AKT had significant difference between any groups. The BNIP3 was significantly increased in the groups of R, E, and CRE as compared to the C group respectively (p <0.01). The P62 in the R group was significantly lower than that in the C group (P < 0.01). The mtDNA deletion mutation rate was significantly lower in the E group (p <0.05) and the CRE group (p <0.01) than the C group separately.
CONCLUSION: Exercise and calorie restriction can improve the mitophagy and mitochondrial quality control in the skeletal muscle of aged rats. The mTORC1 signalling pathway involved in the regulation of promoting mitophagy, however, mTORC2 unlikely involved in it.

Invited symposia

IS-SH06 Sustainable sport tourism - Challenges for the future

THE CANADIAN BIRKEBEINER SKI FESTIVAL AND SUSTAINABLE HERITAGE SPORT TOURISM

REICHWEIN, P.

UNIVERSITY OF ALBERTA

Introduction
Winter festivals have long been events for sport and tourism (Abbott 1988; Poulter 2009; Hofmann 2012). Can they be sustainable tourism? The Canadian Birkebeiner Ski Festival began in 1985. Its focus on cross-country skiing and winter festivity for all became an enduring outdoor sport event in western Canada. The Festival was significant in the development of skiing and skiing landscapes, yet interactions between skiers and the environment call for more study particularly the question of sustainability. How did these traditions emerge? How did the event change skiing and landscapes? Did the event contribute to sustainability and what challenges lie ahead?
Methods
This paper analyzes how the Canadian Birkebeiner Ski Festival produced sporting landscapes, invented traditions, and winter sport tourism. Material from archives, interviews and previous research will be studied using theories of sporting landscapes (Bale 1994), invented traditions (Hobsbawm 1993), and sustainability (Pierce and Dale 1999). Events situated near Edmonton, Alberta, are the main examples with discussion of international influences from the Norwegian Birkebeiner and American Birkebeiner.
Results and discussion
The Canadian Birkebeiner loppets were indicative of fluid social relations and place making. Were they evidence of sporting landscapes and sustainable sport tourism? Social, economic, and environmental pillars supported a heritage sport tourism event involving skiers,

land holders, and diverse partners. Factors such as volunteers, loppet routes, weather, and land use management underscore the interplay of environmental and human agency in community development for the Festival. The co-production of the Birkebeiner events resulted in a sport festival and sporting landscape that shaped cross-country ski sport, trails, and parks in the short and long term. The Canadian Birkebeiner Festival had outcomes for nature sport in parklands made evident in community development and winter tourism as investments in mutual benefits and sustainability for locals and tourists in landscapes of sport. Winter sport participation and climate change are future challenges.

SEARCHING FOR THE PERFECT RIDE. A TENTATIVE STUDY OF HORSE TOURISM ON INTERNET

HEDENBORG, S.
MALMÖ UNIVERSITY

The aim of this presentation is to map out and analyze Internet marketing of horse riding tourism. Despite a growing interest for sport tourism in general and horse tourism in particular, studies of the marketing of horse tourism are scarce. The analytical framework is guided by marketing analysis of "story-telling", an understanding of the social construction of gender and human-animal studies. The source material consists of websites of three different horse travel agencies. The most popular tourism destination for the horse riders is Southern Europe, and Spain is utmost attractive. In addition, it is clear that trail riding is the most common offer. Horse and horsemanship are central in the story-telling. Furthermore, natural and cultural heritage and stories connected to the sea, the mountain as well as animal life, and traditional buildings are central. The narratives used for selling the horse riding trips are gendered. Previous research has pointed out that men and masculinity are closely connected to sport tourism and to travelling. Here women are represented as active and as participating in the sporting activities. In contrast, the guides are presented as male riders who belong to a traditional horse culture in which men and masculinity were central.

SPORT AN NATURE-BASED TOURISM IN NORWAY: SPORT/FRILUFTSLIV, TOURISM AND (MEDIATED) NATURE

RADMANN, A.
NORWEGIAN SCHOOL OF SPORT SCIENCES

Tourism in general and sport tourism in particular tourism is one of the fastest growing industries in the world. Norway has experienced a phenomenal increase in the number of Norwegian and foreign sport and nature- tourists in recent years. Nature in Norway constitutes an essential part of the Norwegian tourism product, and large parts of the tourism industry use precisely nature as a starting point for its products. Furthermore, tourism and especially sport and nature-based tourism are regarded as an increasingly important part of Norways future, a field many expect to give work and revenues in the future. The session will highlight how individuals (sport tourists) and organizations organize, experience and portray nature-based tourism. The main focus of the research project lies at the micro level where the individuals involved in nature-based tourism, and those responsible for facilitating the actual experience of nature-based tourism - the guides - are at the center. Thus, the goal is to increase the knowledge and understanding of nature-based tourism in Norway. This is done through four different sub-studies that explore nature-based tourism from a primarily micro- (and partly meso-) perspective. Sociological and pedagogical explanatory models form the theoretical basis for the study, while interviews, participatory observation and media analyzes form the methodology.
Keywords: sport tourism, nature-based tourism, friluftsliv, social media, sociology, pedagogy.

PL-PS03 Sport and brain injuries - A red flag for sport?

CHRONIC TRAUMATIC ENCEPHALOPATHY IN TOP ATHLETES

MCKEE, A.
BOSTON UNIVERSITY SCHOOL OF MEDICINE

Ann McKee, MD, is Professor of Neurology and Pathology at Boston University School of Medicine and Director of the BU CTE Center. Her research leads the field in the long-term effects of concussive injuries and Chronic Traumatic Encephalopathy (CTE) in contact sports athletes. She has published over 70% of the world's cases of CTE and created the world's largest repository of brains from individuals exposed to trauma (over 690) and neuropathologically confirmed CTE (over 400). She defined the spectrum of clinical and pathological abnormalities in CTE and developed the McKee criteria for the pathological diagnosis and staging of CTE. She was the first to report CTE in ice hockey, soccer, mixed-martial arts, baseball, high school and college football. She reported the youngest athlete ever diagnosed with CTE and the first case series of CTE in military veterans. She first reported the association between CTE and amyotrophic lateral sclerosis (ALS) and on the roles of microglia and inflammation. Her talk will include discussion of her work as well the resistance that she has met. McKee was named Bostonian of the Year 2017 by the Boston Globe, one of the 50 Most Influential People in Healthcare 2018 and one of the 100 Most Influential People in the World by Time magazine in 2018. She was recently awarded the Henry Wisniewski Lifetime

Achievement Award in Alzheimer's Disease Research by the Alzheimer's Association and was elected into the National Academy of Medicine.

SCHOOL'S RUGBY AS INSTITUTIONAL CHILD ABUSE

ANDERSON, E.

UNIVERSITY OF WINCHESTER

Eric Anderson holds the position of Professor of Sport, Masculinities and Sexualities at the University of Winchester, England. He is also the trustee of the Sport Collision Injury Collective, which is committed to examining and removing brain trauma caused by participation in contact sports, particularly within school settings. As a social scientist, Professor Anderson views sport-related head trauma as not only a medical, but a social problem. He argues that the only reason for the continuance of collision-based sporting activities among children is to privilege the history of a given sport, instead of privileging the children's health who currently play it. Professor Anderson highlights that meta-myths about the supposed, yet unfounded, health benefits of competitive sport prevent society from understanding the true danger within them; and that, particularly for boys, 19th and 20th Century notions of masculinity make policy-makers resistant to change. It is unsurprising that research shows that 91% of secondary schools that deliver contact rugby in England compel boys, from age 11-16, to play full-contact rugby. Additionally, these children are not required to be coached by qualified rugby specialists; nor are these PE teachers required to have any medical or concussion training whatsoever; nor even are they required to report a suspected concussion or injuries. In fact, injuries that occur in school sport are not even recorded. Thus, in this presentation, he will highlight how, according to the Rugby Football Union's own definitions of 'child abuse,' the playing of rugby as part of school's PE and school's clubs is just that—an institutional form of child abuse.

ATTITUDES TOWARDS OPPONENTS IN SPORTS

GRUSHKO, A., KOROBEYNIKOVA, E.

MOSCOW CENTER OF ADVANCED SPORTS TECHNOLOGIES

INTRODUCTION

In the chess fundamentals it is stated: «You can only get smarter by playing a smarter opponent», however, are athletes truly ready to outperform a strong and a well-known opponent in the face of the high pressure reality of sports competition? Nowadays, the large proportion of studies on attitudes towards opponents in sports primarily address to the acceptable/unacceptable patterns of behavior, and questionnaires are mainly aimed at game sports (Boardley, Kavussanu, 2007; Lazarević et al., 2014 etc). To this end, the questionnaire «Attitudes towards opponents in sports» (ATOS-q) was developed and initially validated.

METHODS

A diverse sample of competitive Russian athletes (novice, intermediate & elite) completed the ATOS-q (N = 274; 67% male; 32% female; Mean age ± SD = 19.25±4.81 y.o.), including game (22%) and combat sports (22%); endurance (30%) and complex coordinated sports (15%); shooting (4%), applied & multidiscipline sports (7%). The 1st version of the ATOS-q consisted of 107 items (in Likert Scale) developed according to the results of a) analysis of relevant studies; b) psychological counseling sessions (N = 60); c) expert analysis of the comprehensibility of the items (N = 16, 38% PhD, Mean work experience = 14.23 ± 8.06 yrs.).

RESULTS AND DISCUSSION

The 2nd version of ATOS-q consists of 84 items that assess 10 subscales: «external locus of control in relation to opponents success in sport»; «aggressive behavior towards opponents»; «fair play»; «good fellowship with the opponents»; «tactics development against a specific opponent»; «lack of confidence facing strong opponent»; «emotional coping»; «being judgmental towards opponents»; «perceiving teammates as opponents»; «readiness to compete with unknown opponent». The Cronbach alpha values were close to acceptable guidelines for the first six subscales. Construct validity analysis gathered by examining the relationship between the subscales of the ATOS-q and the subscales of the Russian version of the Mental Toughness Questionnaire, STAI & SMS revealed statistically significant bivariate correlations. In addition, attitudes towards opponents in different sports were compared: it was found out that game & combat sports athletes outperform other groups of athletes in tactics development and aggressive behavior towards opponents ($p<.01$); in complex coordinated sports athletes are likely to have a good fellowship with the opponents ($p<.01$); endurance sports athletes experience lack of confidence facing strong opponents ($p<.05$). Our findings suggest that ATOS-q can be applied in future psychological research and applied practice in athletes.

CHARACTERISTICS OF HARASSMENT BY COACHES IN JUNIOR HIGH SCHOOL, HIGH SCHOOL, AND UNIVERSITY IN THE JAPANESE SPORTS SETTINGS

HORIMOTO, N.1, KAWATA, Y.1,2, YAMAGUCHI, S.1,3, HIROSAWA, M.1,2, SHIBATA, N.1,2,3

1: GRADUATE SCHOOL OF JUNTENDO UNIVERSITY, 2: JUNTENDO UNIVERSITY, 3: JUNTENDO UNIVERSITY

Introduction

Harassment is defined as "abuse using superior status or position" (Kojien, 2009). Violence and verbal abuse are unpleasant experiences for athletes and considered as harassment in sports settings. Being ignored and being the subject of anger are recognized as har-

assment by coaches among elementary school athletes (Togo et al., 2017). However, the actual condition of harassment in junior high school, high school, and university sports settings has not been clarified. Specifically, the behaviors by coaches that athletes regard as harassment are still unclear. This study aimed to clarify the characteristics of harassment by coaches in Japanese sports settings.
Method
Ten Japanese university athletes (3 and 2 men belonging to team and individual sports, respectively, and 2 and 3 women belonging to team and individual sports, respectively; M age = 20.7 years) participated in semi-structured interviews. We asked the following question; "What experiences made you feel harassed/bullied by coaches in sports settings at junior high school, high school, and university?" We extracted parts of speech from dialogue data using KH Coder, and calculated the top 10 most frequently used words by external variable; by developmental stage (junior high school, high school, and university), and based on the sports characteristics (team sports vs. individual sports).
Results and Discussion
A comparison of the developmental stages revealed that at the junior high schools, "teacher," "advisor," and "coach" held top-ranking positions; then, "angry" was extracted. In high schools, "angry" was extracted following "teacher." In university, "coaches" and "sarcasm" were extracted. Junior high school and high school athletes seemed to have experienced being yelled at by coaches, but university athletes seemed to have experienced sarcastic comments. These experiences could be considered as harassment.
Regarding sports characteristics, in the team sports, "angry" was extracted following "coach" and "adviser." In individual sports, "sarcasm" was extracted following "teacher." In group sports, athletes seemed to have experienced being yelled at by coaches but, in individual sports, they seemed to have experienced sarcastic comments.
These findings show that the coach's behavior may be interpreted differently depending on the athletes' psychological maturity. To stop harassments in sports settings, coaches need to understand the behavioral features recognized as harassment by Japanese athletes.
Conclusion
In junior high school, high school, and team sports, guidance with anger may be perceived as harassment, but in university and individual sports, guidance with sarcasm may be perceived as harassment by athletes.

EXPLORING THE TEACHING STRATEGIES FOR TEACHING FILED GAMES FROM THE PERSPECTIVE OF CREATIVITY & CHARACTER EDUCATION

SHIN, K.

JEONJU NATIONAL UNIVERSITY OF EDUCATION

Introduction
Creativity & character education (CCE) in the regular school education has been recently introduced to the national curriculum for an attempt to foster a desirable human character which improves future and grows infinitely. Physical education is also no exception to this educational tendency. CCE is generally realized in substance through classes. Therefore it is necessary to inquire the substance and meanings of CCE in physical education based on the concrete cases of class. Thus the purpose of this study was to interpret the educational meanings of teaching strategies that applied in the competition activity instruction in physical education from the perspective of CCE.
Methods
This study used a qualitative research method. Participants were four 5th graders of the elementary school which is located in an urban area. They were chosen according to the purposeful sampling method by considering the difference of sex and skill level. Data were collected through participant observation and in-depth interviews of four elementary school students, and then categorized by the domain analysis and taxonomic analysis. Teaching strategies mainly focused on the strategies of making up game filed, grouping students, and utilizing teaching tools.
Results & Discussion
The results of this study were summarized in two aspects. First, the strategy of making up game filed showed two patterns as intentional variations to increase the learning effect and constructing game field by students. The educational meaning of teaching strategy was categorized as visual fuse leading participation, activity space with all participation, and expanding the channel forming the eye for games. Second, the strategies of grouping students also showed two shapes like expanding participating motivations and grouping for the multilateral game. The educational meanings of this strategy was categorized as forming motives and self-esteem, change of perception about game performance, and relaxation of exaggerative competition structure. Lastly, the strategies of utilizing teaching tools revealed two patterns as use of alternative materials and development of new materials. The educational meaning of this strategy was categorized as chance of revelation of responsibility and struggling between new and traditional norm.

IT'S HARDER TO PUSH WHEN I HAVE TO PUSH HARD! THE LEVEL OF CONCURRENT PHYSICAL EXERTION AFFECTS DECISION-MAKING ON HYPOTHETICAL MORAL DILEMMAS

WEIPPERT, M.1, RICKLER, M.1, BRUHN, S.1, LISCHKE, A.2

1: UNIVERSITY OF ROSTOCK, 2: UNIVERSITY OF GREIFSWALD

INTRODUCTION: During the 2017 Tour de France cyclist Peter Sagan was disqualified after determining an unfair attack against his opponent during the final sprint of the 4th stage. Sagan obviously accepted harming his opponent Mark Cavendish for winning the stage . In this example, moral decision-making took place during maximal physical exertion. From a scientific perspective it is surprising that acute effects of physical exertion and fatigue on moral decision-making have never been systematically investigated, despite their prevalence during special operations, sport or even daily life. To test the effects of physical exertion on moral decision-making, we administered a moral dilemma task before and during a moderate or high intensity cycling intervention. It was hypothesized that vigorous physical exertion facilitates non-utilitarian decision-making (involving intuitive thinking), while moderate physical exertion facilitates utilitarian decision-making (involving deliberative thinking).
METHODS: 32 healthy males volunteered in this study. Ten minutes cycling at light workload intensity (10% VO2peak) served as control condition and 25 min cycling at moderate (50% VO2peak) or high intensity (90% VO2peak) served as intervention. During the final

minutes of control and intervention participants had to decide on different hypothetical moral dilemmas. Two types of moral dilemmas were used, which differed in their directedness of harm. In personal dilemmas the agent is directly involved in the production of the proposed harm (e.g., pushing someone hard with ones' arms) and in impersonal dilemmas the agent is only indirectly involved in the production of the proposed harm (e.g., pushing a button with ones' finger). For all dilemmas, participants had to decide whether to sacrifices one individual to save the lives of five other persons (utilitarian decision-making) or not (non-utilitarian decision-making).
RESULTS: The change in moral decision-making was neither significantly affected by dilemma type [$F(28, 1) = 0.154$, $p = 0.697$, $\eta p2 = 0.005$] nor by exercise intensity [$F(28, 1) = 0.239$, $p = 0.629$, $\eta p2 = 0.008$] but by an interaction of dilemma type × exercise intensity [$F(28, 1) = 5.911$, $p = 0.022$, $\eta p2 = 0.174$]. Post hoc testing revealed differences in moral decision-making on impersonal [$p = 0.010$] but not personal [$p = 0.199$] dilemmas between participants of the two intervention groups. For the impersonal dilemmas, participants in the high intensity group showed a strong tendency for non-utilitarian moral decision-making, whereas participants in the moderate intensity group tended to utilitarian decision-making.
CONCLUSION: For the first time, it has been shown that physical exertion has an effect on decision-making in hypothetical moral dilemmas. Physical exertion may lead to limitations of executive resources, executive functioning and self-control that either alone or in concert account for changes in moral decision-making.

OTHER DOPING CONTROLS. ONE PROCEDURE VISION TO REVISION

MIRABET-AGULLED, R., GUERRA-BALIC, M., MARTÍNEZ–FERRER, J.O.

FPCEE BLANQUERNA - UNIVERSITAT RAMON LLULL

Introduction
Doping is a pursued practice in sports, and for that reason, regulations for its control, surveillance and eradication were established internationally (Martinez-Ferrer, J.O. and Pascual, A.J., 2011).
Many countries, the International Olympic Committee (IOC), the International Paralympic Committee (IPC) and many Olympic (O) and Paralympic (P) international sport federations (IIFF) have ratified the World Anti-Doping Code (WAC) valid since 2003, as well as its submission to the World Anti-Doping Agency (WADA) (Barbod S., Montero JA, 2002). All participants in the Olympic and Paralympic Games are mandatory signatories of the WAC and WADA partners, although there are non-participating federations (IIFF not O or not P) that are also voluntarily signatories.
Method
We have analyzed the web pages of 14 IIFF not O or not P as a visible sign of its commitment and compliance to the WAC, synthesizing the 19 Topic Code (WADA / AMA, 2014) in 14 items to determine its visibility on its web pages, where there is a link to the WADA Code, the availability of the prohibited substances list or therapeutic use exemptions (TUE) , the legal hearings and whereabouts, or the list of sanctioned athletes.
Results
We can highlight that among the 14 IIFF not O or not P, only 4 have direct access from the homepage to Doping Control and 8 of them indirect access. 12 refer to compliance with the WAC, although only 8 to the fact of being signatories. Likewise, all of them give access to the current prohibited substances list, but only 7 have an almost total visualization of the use of standard topics, and only 5 show their Doping Control program. 50% of these federations show the TUE procedure and use the Whereabouts locator system and the ADAMS notification system. Finally, only 4 of them expose the governing body and structure of Doping Control, and in 2 of them there is no reference to Doping control and / or its connection to WADA and WAC.
Conclusions
It does not exist in those 14 IIFF not O or not P a clear principle of visualization of the use of WADA standards, marked in its WAC of 2015. WADA should monitor compliance periodically, and avoid non-compliance of the WAC as WADA signatory partner organizations as it contributes to its depreciation.

RELATIONSHIP BETWEEN COMPETITION LEVEL, ANTI-DOPING LEARNING MOTIVATION, AND CONFIRMATION BEHAVIOR REGARDING PROHIBITED SUBSTANCES AMONG JAPANESE UNIVERSITY ATHLETES: A CROSS-SECTIONAL STUDY

MUROFUSHI, Y.1, KAWATA, Y.1,2, KAMIMURA, A.1,3, HIROSAWA, M.3,4, SHIBATA, N.1,3,4

1JUNTENDO UNIVERSITY, 2JUNTENDO UNIVERSITY, 3WAYO WOMEN'S UNIVERSITY, 4JUNTENDO UNIVERSITY

INTRODUCTION: Anti-doping (AD) education has mainly been imparted to elite athletes who may undergo doping control (DC). Japanese university athletes tend to have low AD knowledge, regardless of their competition level. Particularly, AD knowledge among national-level athletes, who may undergo DC, is lower than that among athletes at other competition levels (Murofushi et al., 2018). Thus, it is important to impart education in line with the World Anti-Doping Code 2015. However, the association between learning motivation (LM) and confirmation behavior (CB—checking whether medicines contain prohibited substances) regarding AD has not been clarified. Therefore, this study aimed to assess the relationship between the competition level, LM, and CB among individual Japanese university athletes, and discuss the direction of AD education.
METHODS: We collected data from 514 male and 629 female university athletes. LM was assessed with the question: "Do you want to learn and understand about anti-doping?" The response options were: 1, no; 2, not really; 3, somewhat; and 4, yes. CB was assessed with the question: "Have you confirmed whether the medicines you use contain banned substances specified in the anti-doping prohibition list?" The responses options were: 1, I did not think of checking; 2, I understand the importance but did not check; 3, I have checked some of them; and 4, yes. We compared LM and CB scores between individuals at the highest levels of competition (district, prefectural, national, and international level) using the Kruskal–Wallis test.
RESULTS: The overall median LM was 3 ($M = 3.08$) and CB was 1 ($M = 1.67$). At the competition level, there was a significant difference in CB ($p < .001$). This suggests that national-level athletes check for prohibited substances more frequently than do those at the district and

prefecture levels. Athletes at the international level checked the most frequently; the median CB of national-level athletes was 2 (M = 2.05) and that of international-level athletes was also 2 (M = 2.43).
CONCLUSION: Results revealed that competition level and LM are not related. "Somewhat" wanting to learn about AD (median = 3) is not a strong motivation. Thus, it is important to extend AD education beyond the national level. Though international-level athletes indicated that they understood the importance of checking for banned substances, they did not always confirm that there were none present (median = 2). This study revealed the importance of improving AD education to address athletes' insufficient motivation to learn about it and promoting CB in those who compete at a high level and are, thus, likely to undergo DC.

LIFELONG LEARNING: TO THE CORE OF DEVELOPMENT BETWEEN SPORT AND CULTURE OF SAFETY.

JOFFROY, S., GARNIER, S., MAURIEGE, P.

UNIVERSITÉ PAUL SABATIER : F2SMH AND INSTITUT TOULOUSAIN DOSTEOPATHIE

The dramatic increase in the level of sophistication and intensity of insecurity has led most developed countries in recent years to build resilience and to adopt national prevention strategies both in terms of body techniques and training directed towards citizens.
The recent strategic orientations are based on actions such as "anticipating, securing and reacting" and are one of the priorities of global strategies. Training in this area therefore takes an important place and is considered essential to remedy good behavior and especially to develop a culture of safety for all citizens. In this context, several training courses have been identified with a great diversity in terms of duration and in terms of training structures, ranging from higher education institutions to private training organizations. As far as higher education is concerned, the Management Master's degree in Sport Course ISSD is part of this area of expertise. Specific at a public in lifelong learning, its objective is to give employees of the public and private sectors of security, safety and defense, the means to take a step back from their experiences in the field. The main objective is to consider the field of science as a central aspect of training. This Masters degree thus makes it possible to respond to the two major actions of lifelong learning in the context of learning by integrating all the situations in which multiple skills are acquired: continuous training actions, professional activities, associative or volunteer involvement.
The purpose also aims to develop professional skills (through an operational immersion), so that professionals can expand their areas of expertise in the context of their duties and / or take the role of educational leaders, training managers or experts in the analysis of practices in the specific areas of security, safety and defense and meet the expectations of companies in terms of computer security, data protection. It is not uncommon to find within this training, among others, soldiers specializing in combat sports. Indeed the sport of the armies is TIOR (the Techniques of Close Operational Interventions). These techniques derive from other defense sports; from boxing to krav maga. The military can, thus, neutralize their adversaries using means adapted to the situation, with the help of stopping, grounding, riposte or dodge. In addition to defense techniques and / or prevention to attack specifically tailored to security professionals, the citizen must also be trained in emergency actions and take a behavioral attitude adapted to the situation. At this level, the state emphasizing the multiple new risks, has reaffirmed its objective target to train 80% of the population in the short term. "It must be done at school, in our companies, in our administrations".
Thus, whether it be for the actors of the security world or for the ordinary citizen, lifelong training in the field of security thus plays a fundamental role.

OCCUPATIONAL HEALTH AND SAFETY AWARENESS IN ELITE RUGBY

CHEN, Y., BUGGY, C., KELLY, S.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: The practical and theoretical significance of occupational health and safety awareness (OSH) as a construct derives from its capability to forecast the related outcomes (e.g., injuries and accidents) in a wide range of settings. However, no measurement instrument in elite rugby has been devised to evaluate OSH. In response to this OSH system gap in elite rugby, this study further explores key health and safety awareness indicators employing semi-structured interviews with rugby health and safety supporting staff.
METHODS: By using a snowball sampling strategy, 15 health and safety rugby supporting staff (e.g. coaching and medical staff) working in Ireland participated in individual interviews. Among these, 14 were conducted face to face, one was conducted via video communication. All of the interviews were digitally recorded in their entirety and the duration of the interviews ranged from 22 to 50 minutes with the consent. The approximate 11 hours of interview data was transcribed verbatim. Nvivo software was applied to all transcripts which were subsequently analysed using abductive analysis.
RESULTS: This presentation will show the key themes emerged from the inductive thematic analysis were grouped into 13 higher-order themes and subsequently combined into the following 6 categories: 1) Players' perceptions of management safety commitment; 2) Players' perceptions of management safety empowerment; 3) Safety ethics; 4) Players' safety value; 5) Safety communication, learning, and trust in teammate safety competence; 6) Health and safety awareness evaluation suggestion. Based on the initial themes emerged, a safety climate theory has been selected for the abductive analysis process to develop a framework on key OSH awareness components in rugby context.
CONCLUSION: This study aims to evaluate OSH awareness in context of elite rugby, the application of which, if successful, could point the way forward for application in a wider range of sports internationally. Specifically, the framework will then be tested in another cultural context. The responses of study cohorts in different environments will then be compared and contrasted in the context of the countries socio-economic and political systems.

GOOD REFEREES ARE NOT NICE. PERSONALITY EFFECTS ON FOOTBALL REFEREE DECISION-MAKING

GRÄFE, A., ELLERT, G.

MACROMEDIA UNIVERSITY

Problem. Personality has established itself as a way of predicting job performance in a wide variety of work areas. Research has shown that specific job positions require certain personality profiles of the candidates (Hough, 1992; Barrick & Steward & Piotrowski, 2002). Football refereeing is a very unique area of work, characterized by making decisions under high levels of uncertainty in short time, with

potentially large consequences for various types of stakeholders. The present study analyzes whether certain personality traits improve referee decision-making.
Methods. Seventy-five referees with different levels of expertise evaluated thirty tackle situations taken from international matches, after which they completed a Big Five personality test based on the Mini-IPIP (Donnellan, Oswald, Baird, & Lucas, 2006). Reference decisions provided by an expert panel served as benchmarks to assess accuracy (Spitz, Moors, Wagemans & Helsen, 2018).
Findings. Personality affected decision-making style and performance. More extroverted participants tended to make stricter decisions, while more agreeable participants tended to make softer decisions. With respect to performance, only agreeableness had an effect: participants who were more agreeable made less accurate decisions. Conscientiousness, Neuroticism, and Intellect neither affected decision-making style nor performance. The effects remained after controlling for expertise and sociodemographic variables.
Implications. The results can help to improve the education of referees by paying more attention to the analysis and targeted enhancement of the personality of referees. Specific selection procedures, as well as targeted personality development programs, could improve the accuracy of referee decision-making.

CP-MI10 Strength and power

RELIABILITY OF POWER AND VELOCITY VARIABLES COLLECTED DURING THE BENCH PULL EXERCISE

PÉREZ-DEL RÍO, A., GARCÍA-RAMOS, A., HÖLLRIGL, L., PÉREZ-CASTILLA, A., PATTERSON, C., RASCHNER, C.
UNIVERSITY OF INNSBRUCK

INTRODUCTION: Load-velocity and load-power relationships play a significant role in many modern training programs. Many studies have researched the reliability of power and velocity variables of different exercises such as the bench press or the vertical jump (1,2). However, no studies are available regarding the reliability of pulling movements. Therefore, this research aimed to examine the reliability of different power and velocity variables during the bench pull exercise performed with a Smith machine and with free-weights.
METHODS: Eleven male well-trained subjects (age 24.3±2.4 years, body mass 81.1±5.1 kg, height 182.9±2.4 cm., 1RM 100.6±9.6 kg.) performed four sessions of the bench pull exercise. In a counterbalanced order, participants completed in the first week 2 sessions of 2 repetitions with 5 incremental loads (50%RM, 60%RM, 70%RM, 80%RM, 90%RM) on a Smith machine and in another week two sessions with the same loads with free weights. The test was monitored by a linear position transducer (GymAware PowerTool, Australia). Mean velocity, peak velocity, mean power and peak power of the best repetition of each set were used for statistical analysis. Reliability was assessed through the coefficient of variation (CV) and a CV ratio of 1.15 was considered the smallest important ratio.
RESULTS: The Smith machine test was more reliable than the free-weights test (4.99% vs. 8.20%; CVratio = 1.64). Velocity values were more reliable than power values (5.34% vs. 8.08%; CVratio = 1.51). No significant differences in reliability were observed between the mean and peak values (5.82% vs. 6.00%; CVratio = 1.03).
CONCLUSION: These results support the use of a Smith machine and velocity variables for testing bench pull performance with a linear position transducer in well-trained subjects. From a reliability standpoint, mean velocity and peak velocity values can be used for assessing bench pull performance under several loading conditions.

LOAD DISTRIBUTION DURING SUSPENSION TRAINING EXERCISE

FUSCO, A.1,2, GIANCOTTI, G.F.1, VARALDA, C.3, CASTELLANI, L.1, CORTIS, C.1
1 UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE, CASSINO, ITALY; 2 UNIVERSITY OF SALZBURG, SALZBURG, AUSTRIA; 3 ITALIAN WEIGHTLIFTING FEDERATION FIPE, ROME, ITALY

INTRODUCTION: Suspension training (ST) uses body weight in multi-directional movements as a form of exercise and due to its feasibility promotes a large variety of workouts within a low space occupancy. However, only few studies (1,2) investigated the load distribution during ST, especially during pulling exercises. Therefore, the aims of this study were to evaluate body inclination and ground reaction force and to predict equations to estimate the training load distribution during ST static back-row at different length of the straps.
METHODS: Thirty volunteers (men=16, women=14; age=23.3±1.7years; body weight=63.9±13.3kg; height=167.9±9.2cm; Body Mass Index [BMI]=22.5±3.4kg·m-2) performed 14 static ST back-row (holding for 5s) at seven different lengths of ST device (148cm, 158cm, 168cm, 178cm, 188cm, 198cm, 208cm) ranging from the simplest to the most challenging, in 2 different elbow (flexed, extended) positions. A ST device (AINS ST FIPE, Italy) was anchored at 2.65m above a force platform. Subjects stood barefoot on the force plate, with their feet shoulder width apart positioned under the anchored point and visual reflective markers applied to subjects' left lateral malleolus and at the acromion process. The force platform was used to evaluate the ground reaction force, whereas a video camera was used to record all the trials. The recorded videos were then analyzed to calculate the body inclination angle with respect to the horizontal plane. Ground reaction force and body inclination were used to predict training load equations trough multi-level regression models ($P<0.05$).
RESULTS: Two multi-level regression models were created. In the first one, ground reaction force was used as dependent variable, whereas body inclination angle, body weight, height, BMI and elbow position were used as independent variables. Significant effects were found for all variables included in the model, with an Intraclass Correlation Coefficient (ICC) of 0.31. Analyzing the model, the follow-

ing equation to estimate the ground reaction force was extrapolated: Load=-132.9134+0.3724671·Angle-1.299028·Body weight+0.9844512·Height+3.675008·BMI-2.073684·Elbow.
In the second model (ICC of 0.37), the body inclination angle was replaced by the ST device's length. By analyzing this model, the following equation to estimate the ground reaction force knowing the length of the straps was extrapolated: Load=-69.80267-0.2199257·Length-1.281452·Body weight+0.8883487·Height+3.624841·BMI+5.188559·Elbow.
CONCLUSION: The proposed models could provide different methods to quantify the training load distribution, even if the use of the straps' length could result easier and faster than body inclination angle, helping practitioners and instructors to personalize the workout to reach specific purposes and provide load progression.

CORRELATION BETWEEN POWER CAPABILITIES AND TROWING PERFORMANCE IN FEMALE ATHLETES

DUCA, M., FORMENTI, D., TRECROCI, A., CAVAGGIONI, L., ALBERTI, G.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: In throwing events the power production capabilities can have a large impact on athlete's performance. This study aims to establish the relationship between parameters assessed in a jump protocol and performance in female athletes.
METHODS: 27 young regional and national level female throwers (age 18.9 ± 2.7 years, height 1.70 ± 0.09 m, body mass 78.7 ± 16.4 kg) were selected to take part to regional level training camps with a four-monthly cadence. During those camps, athletes jumping performance was assessed in the following tests: squat jump (SJ), countermovement jump with fixed arms (CMJ), countermovement jump with arms swing (CMJa) and multiple jumps with arms swing for 8 seconds (MJT). Jump height was computed from flight times measured by an optoelectric system (Optojump, Microgate, Bolzano, Italy)(Glatthorn et al., 2011). Additionally, relative power (Prel) and absolute power (Ptot) produced in MJT were computed (Landolsi et al.). Season's best performance for each participant was collected and standardized for discipline's world record (SBS). Correlations between performance parameters and SBS were tested using Pearson's product moment correlation coefficient.
RESULTS: SBS showed neither correlation with height reached in all jump test nor Prel in MJT. Otherwise, a significant correlation was established between SBS and Ptot (0.673; $p<0.001$) and SBS and Bodymass (0.717; $p<0.001$).
CONCLUSION: The results are in accordance with recent literature showing significant linear correlation between SBS performance and ability to generate power. Bourdin et al. (2010) did not found correlation between relative power measurements and SBS in male national level throwers, while half squat Ptot, bench press Ptot and body mass were significantly correlated. In that study, body mass showed a lower correlation with SBS ($r=0.540$; $p<0.001$) than our results, possibly suggesting a larger impact of body mass on performance for female subjects. In another study, while testing national level male shot putters, MJT absolute power showed significant correlation ($r=0.810$; $p<0.01$) with SBS whereas MJT relative power was not correlated (Landolsi et al., 2015). The present study widens current literature on the importance of power production towards throwing performance in female athletes. Thus, showing how body mass seems to play a key role for female athletes, training practice should be adapted accordingly.

CHANGES IN EMG ACTIVITY OF GLUTEUS MAXIMUS AND STRENGTH AFTER SQUAT MASTERING PROGRAM – CASE STUDY

CHUDÝ, J., KRCMÁR, M., ARGAJOVÁ, J., MUSILOVÁ, E., BUZGÓ, G.
COMENIUS UNIVERSITY IN BRATISLAVA

INTRODUCTION: There is a disagreement of previous studies about EMG activity of gluteus maximus muscle during squat exercise (1,2,3,4,6). It indicates potential impact of squat variations (3,4), movement experience (5) and bar placement (6) on the differences in EMG activity of muscles of lower extremities. In this study we track how the squat mastering program will change EMG activity of gluteus maximus and maximal isometric force.
METHODS: Two male subjects without previous experience with squat exercise were randomly divided into experimental (EXP) and control (CON) group (EXP: age, 20.8 years; height, 185 cm; weight, 81 kg; CON: age, 19.9 years; height, 182 cm; weight, 82 kg). EXP subject performed 3-weeks deep squat mastering program which consisted of eleven training sessions aimed on mastering the squat without any attention for strength development. Pre and post program tests were: maximal isometric force (ISOmax50°,90°) and rate of force development (RFD0-200ms;50°,90°), measured by dynamometric platform (Fitro Force Plate, SVK) in two different angles (50° and 90° of knee flexion). EMG activity (maximal value - EMGmax50°,90° and integrated EMG activity of full contraction - EMGint50°,90°) of gluteus maximus muscle of dominant leg was measured during the test by EMG Delsys Tringo Wireless System (UK). This paper was created with support of VEGA MŠVVaŠ SR and SAV č. 1/0333/18.
RESULTS: There were found changes of EMG activity and strength in EXP subject (followed squat mastering program) and CON subject (without squat mastering program intervention). ISOmax50° in EXP increased by 7.8 % (+129 N), ISOmax50° in CON increased by 3.1 % (+75 N), RFD0-200ms,50° in EXP increased by 31.4 % (+1,1 N.ms-1), RFD0-200ms,50° in CON decreased by 5.9 % (-0,2 N.ms-1), EMGmax50° in EXP increased by 151.8 % (+188 µV), EMGmax50° in CON decreased by 30.9 % (-26 µV), EMGint50° in EXP increased by 182.6 % (+126 µV.s-1), EMGint50° in CON decreased by 21.2 % (-11 µV.s-1), ISOmax90° in EXP increased by 9.5 % (+219 N), ISOmax90° in CON increased by 0.8 % (+21 N), RFD0-200ms,90° in EXP increased by 31.4 % (+1,1 N.ms-1), RFD0-200ms,90° in CON decreased by 6.3 % (-0.2 N.ms-1), EMGmax90° in EXP increased by 10.1 % (+28 µV), EMGmax90° in CON decreased by 32.9 % (-50 µV), EMGint90° in EXP increased by 35.3 % (+60 µV.s-1), EMGint90° in CON decreased by 31.2 % (-29 µV.s-1).

CONCLUSION: EXP subject who participated in the 3-weeks squat mastering program has greater increment in selected parameters. It suggests that squat mastering program has positive influence on EMG activity of gluteus maximus muscle and strength of lower extremities, but we recommend that a larger sample should be included in the research to reach valid conclusions.

POWER - MASS CURVE PARAMETERS IN DEEP SQUAT: ACCELERATION VS. CONCENTRIC PHASE OF MOTION

BUZGÓ, G., BALUN, M., NOVOSÁD, A., HALAJ, M.

FACULTY OF PHYSICAL EDUCATION AND SPORTS COMENIUS UNIVERSITY IN BRATISLAVA

INTRODUCTION: The character of movement (1), including the technical difficulty (2) and range of motion (3), affects the choice of the optimal resistance and the number of repetitions (4) in the development of speed-strength abilities. The effectiveness of individualisation of the loading in terms of these variables has already been monitored (5). Resistance size selection in the range of +90 % Pmax zone appears to be a suitable procedure (2). The strategy of power or speed evaluation (6) remains the subject of discussion. The aim of the paper is to compare the parameters of +90 % Pmax zone in terms of acceleration and concentric phase of movement in deep-squat.
METHODS: 57 subjects (23.7 y. ± 1.89) performed progressive loading diagnostic set in deep squat calf-rise by means of linear position transducer (FitroDyne Premium), until they reached their individual Pmax. Parameters for resistance corresponding with the highest power (Pmax) and the parameters of +90 % Pmax zone (i.e., the resistance range with power greater than 90 % of the Pmax value) were evaluated. All outputs were analysed in terms of acceleration and concentric phase of motion.
RESULTS: The average load Pmax-conc reached 90.4 kg ± 18.7 (P = 733.9 W ± 152.6; v = 82.1 cm.s-1 ± 8.4; ROM = 81.4 cm ± 6.5). Pmax-acc load was registered at 80.7 kg ± 17.5 (P = 869.2 W ± 189.4; v = 90.2 cm.s-1 ± 9.0; ROM = 62.6 cm ± 6.3). A significant difference was registered between Pmax-conc and Pmax-acc load (P<0.01, d = 0.533). The shape of the +90 % Pmax zone in terms of the concentric phase of motion appeared to be uniform (0.98 ± 0.08), similarly to the acceleration phase (0.97 ± 0.11). We did not register a significant difference between the zone shape values (n.s., d = 0.091). When evaluating the range of +90 % Pmax zone, we registered a smaller zone width of 32.6 kg (± 11.73) in the concentric phase of motion as opposed to acceleration phase 35.8 kg (± 10.85). There was a significant difference between the range of the zones (P<0.05; d = 0.278). This paper was created with financial support of VEGA MŠVVaŠ SR and SAV č. 1/0333/18.
CONCLUSION: Pmax-acc in comparison to Pmax-conc corresponds with a lower load with higher power and speed values, however with a smaller section of the overall ROM. The zone distribution is even, regardless of the diagnostic series evaluation method. The range of the zone appears to be broader in terms of the acceleration phase of motion. The overlapping of +90% Pmax-acc and Pmax-conc zones offers a compromise and a choice of load in terms of maintaining a load intensity in the range of 79.8 - 106.2 % of the resistance size at Pmax-conc (lower zone edge of +90 % Pmax-conc and Pmax-conc are a part of +90 % Pmax-acc).

WHICH ANTHROPOMETRIC AND LOWER BODY POWER VARIABLES ARE PREDICTIVE OF PROFESSIONAL AND AMATEUR PLAYING STATUS IN MALE RUGBY UNION PLAYERS?

JONES, T., KEANE, K., SMITH, A., DENT, J., MCSHANE, K., PAYNE, T., WILLIAMS, L., MAGUIRE, P., MARSHALL, S., GRAHAM-SMITH, P.

NORTHUMBRIA UNIVERSITY, NEWCASTLE FALCONS RUGBY CLUB & ASPIRE ACADEMY FOR SPORTS EXCELLENCE

INTRODUCTION: The purpose of this study was to compare anthropometric and lower body power measurements between current professional and amateur male Rugby Union (RU) players. The present study also sought to determine which anthropometric and physical performance variables were predictive of playing standard.
METHODS: Thirty professional and 30 amateur RU players performed Wattbike 6 s maximal effort (WB6S) and countermovement (CMJ) and squat jump (SJ) assessments, anthropometric measures were also taken. Dependant variables recorded and analysed included; body mass, stature, Σ8 site skinfolds, WB6S absolute and relative peak power, CMJ and SJ average concentric force, jump height, peak velocity, time to peak force, rate of force development (RFD) and absolute and relative peak force and power.
RESULTS: Professional players were heavier, taller and leaner than their amateur counterparts (P <0.05). Professional players performed significantly better in all physical performance measures except CMJ and SJ time to peak force, CMJ RFD and SJ relative peak force. Variables which were predictive of playing standard were; ∑8 skinfolds, CMJ peak velocity and WB6S absolute and relative peak power (P <0.05).
CONCLUSION: These findings indicate that the current body of male professional RU players are anthropometrically and physically superior to their amateur counterparts, although not all variables assessed here were predictive of playing standard. Data presented here indicate that ∑8 skinfolds, WB6S absolute and relative power and CMJ peak velocity are predictive of playing standard whereas other anthropometric and strength and power variables are not.

PREDICTION OF SHOOTING SPEED IN NATIONAL WOMENS HANDBALL TEAMS

SAAVEDRA, J.M.1, HALLDÓRSSON, K.1, KRISTJÁNSDÓTTIR, H.1, ODDSSON, H.R.1, ÞORGEIRSSON, S.1, STEFANSSON, A.2,3

1: PAPESH RESEARCH CENTRE, REYKJAVIK UNIVERSITY, ICELAND. 2: ICELANDIC HANDBALL FEDERATION , REYKJAVIK, ICELAND. 3: INNLAND NORWAY UNIVERSITY OF APPLIED SCIENCES, ELVERUM, NORWAY.

INTRODUCTION: The physical demands of team-handball (handball) are high, and players have to be able to perform various high-intensity actions such as sprints, jumps, and shoots (Gorostiaga et al. 2005). Since the aim of the game is to score goals, the shoot is one of its most important actions. To date, many articles have been published dealing with the population of male adult players, with less attention paid to female players. The objective of this study was therefore to develop a multivariate model that explains women players shooting speed as a function of their anthropometric and physical fitness parameters.
METHODS: Eighty women handball players (18.2±4.0 years in age) participated in the study. They belonged to the A-Team (n=23), under-19 (n=16), under-17 (n=20), and under-15 (n=21) Icelandic national teams. All were evaluated by basic anthropometry (height, weight), physical fitness tests (counter movement jump - CMJ, medicine ball throw, hand dynamometry, 10-m and 30-m sprints, yo-yo IR2 test), and handball shooting speed (from 7-m standing, and 9-m after three steps and a jump). Multiple linear regression (stepwise method) was used to predict the speed of each of the two shoots for each of the four teams. The ranges of the variance inflation factor for all the independent variables were between 1.00 and 1.13, indicating no collinearity. The Durbin-Watson statistic was calculated, and showed that there was no autocorrelation in the residuals (the values of the statistic ranged from 1.71 to 2.31).
RESULTS: The overall sample 7-m standing shoot model selected the variables medicine ball throw and height (ΔR^2=0.329; SSE=5.857, p<0.001), while the 9-m shoot after three steps and a jump model selected CMJ and height (ΔR^2=0.443; SSE=5.136, p<0.001). By age group, in the 7-m standing shoot, the selected variables were: height in the U19 team (ΔR^2=0.501; SSE=4.020, p=0.009); medicine ball throw and 10m sprint in the U17 team (ΔR^2=0.603; SSE=5.326, p=0.004); and yo-yo IR2 test in the U15 team (ΔR^2=0.386; SSE=5.243, p=0.044). For the 9-m after three steps and a jump shoot, only in the A-Team was a variable selected by the corresponding model: CMJ (ΔR^2=0.320; SSE=4.090, p=0.032).
CONCLUSION: Height was the only variable selected by both shoot-type models for the overall sample. This seems to confirm the relevance of this parameter for shooting speed (Shalfawi et al., 2014). The results need to be interpreted with some caution, however, since there did not seem to be any common pattern in what variables were selected for the different age groups.

CP-MI13 Swimming

ANALYSIS OF THE INFLUENCING FACTORS OF LEG EXTENSION DURING THE WALKOUT MOVEMENT IN ARTISTIC SWIMMING

KAHO, M.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: Artistic swimming (AS) requires the ability to freely manipulate the body in an unstable and resistant underwater environment. The basic movements in AS include walkout, which is a movement that involves drawing a large arc with the right leg from the posture opened back and forth on the water surface, and aligning it with the extending left leg. This movement is aimed at not only increasing hip joint range of motion of the lower limbs but also extending it greatly back and forth; however, only a few swimmers can perform this extension. We conducted a study to identify the muscles involved in leg extension during the walkout motion and to determine whether the extent of extension depends on the athlete's competitive level.
METHODS: We targeted six AS players (age, 20.8±2.2 years) who provided informed consent and had 10.8±3.2 years of competition history. Three of the six athletes were national-level swimmers; the other three athletes had won university championships. The movement of the subjects were evaluated using radio electromyography (DL-5000 analytical software, mBiolog S & ME) and three photography cameras on land. Each subject performed walkout with normal and lower limb extensions 5 times. The test muscles were the left and right gluteus maximus and inner hamstrings. The analysis items were the opening angle at the start position of the motion, length of both legs in the anteroposterior direction, value obtained by dividing the height of the apex of the arc during walkout by the length of the leg (walkout index [WI]), and percentage of the integrated electromyography reading.
RESULTS: The opening angle was 141.43°±8.31° in the normal position and 144.54°±6.61° at extension, which showed a significant difference (p<0.05). Two subjects, both of whom had a high competitive level, actually extended their lower limbs. The WI was 1.07±0.04 cm normally and 1.08±0.06 cm at extension. The gluteus major muscle activity on the right was higher in the 3 athletes with high competitive levels than in those with low competitive levels. Increased left and right gluteus major muscle activities were observed at extension as compared with those in the normal position in the athletes with high competitive levels.
CONCLUSION: The walkout movement is a technique for obtaining high scores by performing a larger motion by enlarging the arc. For this reason, athletes are often given instructions on site on "more extension." The 3 athletes with high competitive levels showed that the left and right gluteus major muscle activities were higher at the time of extension than in the normal position. By contrast, the athletes with low competitive levels normally had increased right gluteus major muscle activity, without any change in activity at the time of extension. Therefore, training that involves moderate activities of the right gluteus major muscle is important.

THE SESSION RPE BREAKPOINT CORRESPONDING TO INTENSITY THRESHOLDS IN OPEN WATER SWIMMERS

IENO, C.1, BALDASSARRE, R.2, BONIFAZI, M.2,3, PIACENTINI, M.F.1

1: UNIVERSITY OF ROME, FORO ITALICO, ROME, ITALY, 2: ITALIAN SWIMMING FEDERATION, 3: DEPARTEMENT OF MEDICAL, SURGICAL AND NEURO SCIENCES, UNIVERSITY OF SIENA, SIENA, ITALY.

INTRODUCTION: Recent literature (Seiler & Kjerland, 2006) has pointed out that endurance athletes adopt a polarized training model (76±4 % in zone 1, 6±5 % in Zone 2, 18±7 % in zone 3) based on the quantification of training performed in each intensity zone (Zone 1 training performed below the first ventilatory threshold (VT1), zone 2 between VT1 and the second ventilatory threshold (VT2), while zone 3 above VT2). In order to verify that each athlete trains in the prescribed training zone, different methods can be used, such as heart rate (HR) response or blood lactate concentrations ([LAT-]) (VT1= 2mM, VT2=4mM), or utilize the session rating of perceived exertion (sRPE) method. A whole session is allocated to Zone 1 when the RPE value lies below 4, in zone 2 for RPE values of 5 and 6 and zone 3 for RPE values > 7 (Seiler 2006). This seems the easiest method to monitor training load in swimmers as reported by Baldassarre et al (2019), because of the objective difficulty in using technological support. Therefore, the aim of the present study was to evaluate the correspondence between sRPE breakpoint with VT1 and VT2 in elite open water swimmers (OWS).
METHODS: Six international level OWS (4 females and 2 males ; 26 ± 2 yrs, 176,5 ± 9,95 cm, 66,25 ± 11,62 kg) specialized in distances between 5 and 25-km participated to the study. The group includes the best swimmers of the Italian Team including an Olympic Medal and two World Champions. The OWS performed a 6x500m incremental swimming step test during which HR, [LAT-], split times, and RPE were collected. VT were calculated both at 2 and at 4 mM and as described by Pallarés (2016). The highest workload not associated with a rise in [LAT-] above baseline was considered VT1 and a rise of 2mM above [LAT-] corresponding to VT1 was considered as VT2. VT1 and VT2 were used to delineate the 3 intensity zones.
RESULTS: With fixed [LAT-] at 2 and 4 mM, the RPE intensity zones resulted as follows: Zone 1 ≤4, Zone 2 between 5 and 7 and Zone 3 ≥8. By calculating the VT according to Pallarés et al the RPE intensity zones resulted as follows: Zone 1 ≤3, Zone 2 between 4 and 7 and Zone 3 ≥8.
CONCLUSION: From the results of this pilot study on elite OWS, using the sRPE method to quantify training intensity, zone 2 is larger than previously reported which confirms what observed by Baldassarre et al (2019), that OWS, compared to marathon runners, spend more time in zone 2 than in zone 3.

SLEEPING HIS WAY TO AN ASIAN GAMES MEDAL

TAN, A.

CHANGI GENERAL HOSPITAL

INTRODUCTION: Sleep is an essential component of optimal health (1) and post exercise recovery to realise training adaptations (2). Poor sleep is considered detrimental to athletic performance (3) and it results from various training and lifestyle factors (4). Despite risk of sleep disordered breathing (SDB) being high among collision sport athletes (5), there is a paucity of literature exploring SDB among both Asian athletes and racing sports, including swimming. The aim of this case study is to increase awareness of the importance of sleep and screening for SDB among elite athletes.
METHODS: Subject
The subject was an 18-year-old male swimmer competing at a national level for Singapore, and specialising in the sprint freestyle event, who gave written informed consent to participate in this study.
Presentation
The athlete presented to sport science staff complaining of persistent fatigue, poor recovery from training, and poor physical development. Sleep history revealed excessive daytime somnolence, nightly snoring and sleep interrupted frequently by apnoea and choking episodes. He reported an average total sleep time (TST) of 7 hr / night. Actigraphy monitoring confirmed frequent awakenings and a sub-optimal TST < 7 hr / night.
RESULTS: Physical examination showed maxillary retrusion and high arched palate. Nasoscope revealed bilateral enlarged turbinates and narrowed retroglossal space. Sleep study showed elevated respiratory disturbance index (pRDI = 21.0) with low apnoea-hypopnea index (pAHI = 1.0) and upper airway resistance syndrome was diagnosed.
The subject started continuous positive airway pressure (CPAP) treatment during sleep. Intranasal steroids and antihistamines were prescribed and he was educated on sleep hygiene and sleep apnoea exercises. On CPAP he reported improved sleep and subjective feelings of alertness, post exercise recovery and swim performance. The subject's swimming time improved and he won an Asian Games Bronze medal for the 4x100m freestyle team event.
After the Asian Games, the subject underwent tonsillectomy and modified uvulopalatopharyngoplasty. Post operation, nasal airflow improved and actigraphy variables normalised during sleep.
CONCLUSION: Sleep science is gaining importance in elite sport to promote optimal athlete health and performance. Swimmers are at risk of poor sleep and may experience SDB. Elite sport environments should routinely assess athletes for poor sleep and develop a process for treating sleep issues, including qualitative and quantitative monitoring, referring for a medical diagnosis when required. This case study adds to the current body of knowledge on athlete sleep disorders and management within the context of a high-performance environment.

COMPARISON OF SWIMMING START IN 100 M EVENTS AMONG GENERATIONS OF JAPANESE COMPETITIVE SWIMMERS

SUITO, H.1, IKUTA, Y.2, IKEGAMI, Y.3

1: AICHI GAKUIN UNIVERSITY, 2: OSAKA KYOIKU UNIVERSITY, 3: AICHI SHUKUTOKU UNIVERSITY

INTRODUCTION: During competitive swimming races, the elapsed time of the start phase (start time) contributes significantly to the total race time, especially during shorter races (1). Moreover, start and turn phases are one of the important factors to determine a race time in

100 m events (2). Therefore, decreasing start time is necessary to enhance swimming performance in shorter races. However, little is known about the effects of age on the start phase. The present study aimed to compare the start phase among the generations of Japanese competitive swimmers.
METHODS: In 2018, swimmers' displacements during 100 m swimming events at the Japanese national (Japan) and inter-college (IC), inter-high school (IH), inter-junior high school (IM), and national junior (JO) swimming championships were videotaped, using two digital camcorders set at 60 frames per second. The present study evaluated 64 swimmers at Japan, 32 male and 32 female, and 64 swimmers at IC, 32 male and 32 female, 64 swimmers at IH, 32 male and 32 female, 64 swimmers at IM, 32 male and 32 female, 64 swimmers at JO, 32 male and 32 female. Time data were collected in all preliminary heats and in two finals (B-final and final), during 100 m freestyle swimming events.
The start phase corresponded to the period between the starting signal and reaching the 15 m line. The elapsed time of the start phase was calculated from the frame rate (the resolution of the time resolution is 0.017 s). To clearly detect the start phase from the swimmer's head position, markers were placed at the 15 m point of the poolside. The total and reaction times were obtained from the official record.
RESULTS: The reaction time in male JO butterfly swimmers was significantly lower than that of male Japan butterfly swimmers. On the other hand, no significant differences were found in the reaction time of female swimmers.
The elapsed times of male backstroke swimmers' start phase differed significantly between Japan and JO. However, no marked differences were found between Japan and IC regarding the time of freestyle, butterfly, and breaststroke, both in males and females.
CONCLUSION: Reaction time is not significantly affected by generation; however, the start phase time decreased in all events both in males and in females. Although, females undergo growth period earlier than males, no marked differences were observed between JO and IM in other events except freestyle in female swimmers. The results suggest that the growth period exerts a profound effect on the start time.

EFFECT OF BODY COOLING ON PERFORMANCE IN TRIATHLON COMPETITIONS ~DOES PRECOOLING SWIMMING IMPROVE PERFORMANCE? ~

NAKASHIMA, D.

HIROSHIMA UNIVERSITY HOSPITAL

INTRODUCTION: Core body temperature was increased after swimming in a triathlon competition. The dehydration rate at the time of swimming was also unknown. In addition, no study has investigated the preventive and suppressive effects of body cooling during swimming on heat stroke and performance deterioration, respectively. Therefore, in this study, we investigated the effect of body cooling before swimming (precooling) on core body temperature, dehydration rate after swimming, and swimming performance.
METHODS: Seven healthy male athletes (age, 21.3 ± 2.8 years; height, 1.74 ± 0.05 m; body weight, 67.6 ± 6.1 kg) participated in this study. The subjects took a pill sensor in order to measure core body temperature at 6 hours before swimming and ingested 7.5 g/kg tepid fluid (TF; 31°C) or ice slurry (IS; -1°C) 20 minutes before swimming. The protocol was two sessions of a 750-m freestyle swimming time trial (TT) after a 400- m warm-up swim (W-up) at the 25-m pool. The core body temperature and body weight were measured before ingestion of drink, before and after W - up, between TT for 2 minutes, and after TT. We measured the swimming time every 50 m. For a crossover test, measurements were performed on a different day for each condition.
RESULTS: The rate of body weight loss of the IS condition was significantly lower than that in the TF condition after swimming (0.69 ± 0.24% VS 0.64 ± 0.23%, $p < 0.05$). TT time was not different between the first and second halves of the TT, but the total time in the IS condition was significantly shorter than that in the TF condition (21'16" ± 2'26" VS 21'05" ± 2'23", $p < 0.05$). The core body temperature of the IS condition was significantly lower than that in the TF condition from after ingestion in the first half of the TT (TF/IS: 37.6 ± 0.4/37.4 ± 0.4% at rest, not significant; 37.6 ± 0.5/32.7 ± 4.6% after ingestion, $p < 0.05$; 37.9 ± 0.4/36.3 ± 1.3% after W-up, $p < 0.05$; 38.5 ± 0.3/38.0 ± 0.5% after the first half of the TT, $p < 0.01$; 38.9 ± 0.3/38.7 ± 0.4% after the latter half of the TT, not significant). The mean heart rate was significantly lower in the IS condition than in the TF condition in the first half of the TT, but not in the latter half of the TT. The water temperature was 31.3°C. No adverse event occurred after IS ingestion.
CONCLUSION: Compared with the total time in the TF condition, that in the IS condition was shortened, which suggests that the performance was improved by the ingestion of IS. Although the time difference between the condition was small, the actual race could greatly influence the subsequent development. The increase in core body temperature was suppressed by the ingestion of IS, the increase in skin blood flow rate would be inhibited, and the heart rate in the first half of the TT was decreased by the increase in stroke volume. Suppression of dehydration during swimming may improve the performance not only in the swimming but also in the transitions and biking and running segments of the triathlon competition in the heat.

THE EFFECT OF DIFFERENCE ACTIVE RECOVERY PROTOCOLS ON BLOOD LACTATE CLEARANCE IN YOUNG SWIMMERS

CHAIPATPREECHA, N.

SPORTS AUTHORITY OF THAILAND

INTRODUCTION: The purpose of this study was to investigated the effect of difference active recovery protocols on blood lactate clearance in young swimmers.
METHODS: Twenty young sprinters and middle distance swimmers of Thailand national team
(males 13 and females 7; age 16.26 ± 0.86 yrs; 61.80 ± 9.29 kg of body mass ; 169.40 ± 8.68 cm of height; 174.93 ± 11.00 cm of arm span ; 21.38 ± 2.08 km/m2 of BMI ; 20.23 ± 5.07 % fat mass by bioimpedance ; 20.23 ± 5.07s of 50m performance time; 60.74 ± 2.92s of 100m performance time and 131.40 ± 5.98 of 200m performance time) engaged on a regular basis in regional- and national level competitions volunteered to participate in this study. Three experimental sessions with one day intervals between sessions were organized during in season training period. Swimmers were performed a maximal speed replicating their competition pacing and strategy in 100, 50 and 200-m front crawl with dive start. Following the race paced swim swimmers were assigned either a self-paced continuous swim of 20 minutes (coach-prescribed) or a 20 minute land-based recovery consisting of light intensity walking, skipping and stretching (land-based). Capillary blood samples was measured by using Lactate scout from the ear lobe after warm-up (Pre), after 100, 50 and 200 m maximal speed (from 1, 3, 5, and 7m in, or until La- peak was identified) and during the middle and post of active recovery. Heart rate is also used to measure the intensity of swimming race pace. Descriptive statistics and two way analysis with repeated measurement were

use run to determine the effect of different recovery protocols over time on blood lactate concentration, complemented with the Bonferroni correction post-hoc test with a significance level of $p < 0.05$.
RESULTS: There were a statistically significant interaction between recovery protocols and time on blood lactate concentration in all distances
($p < .01$). Therefore, simple main effects were run. The post-race maximal lactate concentration was not statistically significantly different in the coach-prescribed trial compare to the land-based trial in all distances ($p=0.879$, $p=0.975$ and $p=0.810$ for 50,100 and 200m, respectively). Blood lactate concentration during mid of active recovery (10 min) of 50m race was statistically significantly different ($p < .01$) in coach-prescribed (3.54 ± 0.62 mmol.L-1) compare to the land-based recovery (4.05 ± 0.54 mmol.L-1). Blood lactate concentration of the end of active recovery (20 min) were statistically significantly different ($p < .01$) in the coach-prescribed (1.81 ± 0.31, 1.87 ± 0.24, 2.65 ± 0.39 mmol.L-1) compared to the land base recovery race (2.41 ± 0.25, 2.40 ± 0.25, 3.01 ± 0.33 mmol.L-1) in all distances.
CONCLUSION: The active recovery protocol using coach-prescribed by swimming recoveries removed more blood lactate than the land-based recovery particularly in 50m - 200m freestyle swimming.

EFFECT OF 6-WEEK INSPIRATORY MUSCLE TRAINING ON DIAPHRAGM AND ACCESSORY RESPIRATORY MUSCLE FUNCTIONS IN ELITE SWIMMERS

ANDO, R., OHYA, T., KUSANAGI, K., KOIZUMI, J., OHNUMA, H., KATAYAMA, K., SUZUKI, Y.
JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: It has been suggested that the respiratory muscle training is beneficial for swimmers (Thomaidis et al., 2009) and that inspiratory muscle training enhances inspiratory muscle strength (Romer et al, 2002). However, the mechanism for increase in inspiratory muscle strength has not been well understood. The purpose of this study therefore was to elucidate the changes in contributions of diaphragm and accessory respiratory muscle (i.e., sternocleidomastoid: SCM and intercostal muscle: IC) to inspiratory muscle strength by 6-week inspiratory muscle training.
METHODS: Twenty Japanese male college swimmers (Age: 19.4±0.9 yr., Height: 174.0±5.2 cm, Body mass: 69.0±7.5 kg, FINA point: 773±49) were randomly assigned to training (n=10) and control (n=10) groups. Training group performed 30 maximum inspirations at load resistance of 50% maximal inspiratory pressure (PImax). They conducted two sessions on a day and six days a week. Both groups maintained their usual swim and strength training. Before and after the 6-week training period, PImax, shear modulus of diaphragm and electromyograms of SCM and IC during PImax were estimated. Shear modulus was measured using ultrasound shear wave elastography, and root mean square (RMS) was calculated from electromyogram signals.
RESULTS: Both groups significantly increased PImax (Training: 129±18 cmH2O to 163±22 cmH2O, Control: 136±20 cmH2O to 153±22 cmH2O), but relative change was greater in training (27±19%) than control (13±9%) groups. Shear modulus during PImax significantly increased in both training (198±38 kPa to 249±64 kPa) and control (178±69 kPa to 255±63 kPa) groups after six weeks. RMS of SCM increased in a training group (0.09±0.03 to 0.17±0.05) after training period, whilst no change was observed in a control group (0.11±0.03 to 0.14±0.05). RMS of IC did not change between before and after six weeks in both groups (Training: 0.02±0.01 to 0.02±0.02, Control: 0.01±0.01 to 0.02±0.01).
CONCLUSION: These results suggest that 6-week inspiratory muscle training improves function of SCM, which could be one of mechanisms for increase in inspiratory muscle strength by training. That is, improved function of SCM, rather than diaphragm, may contribute to increased inspiratory muscle strength.

DIFFERENCES OF INTER-LIMB COORDINATION BETWEEN SYNCHRONIZED SWIMMERS AND NON-SYNCHRONIZED SWIMMERS: A PILOT STUDY

VATHAGAVORAKUL, R., GONJO, T., HOMMA, M.
UNIVERSITY OF TSUKUBA

INTRODUCTION: Synchronized swimmers are required to perform a very complex coordination task where they need to synchronize their body movement with teammates and music and stabilize their body to achieve maximum performance and aesthetic of the show. In synchronized swimming, the motion of body segments above the water is required to be synchronized with music, but the motion of under-water segments need to maintain a certain frequency to keep a required above-water height of the swimmer. This imply that the movements of arms and legs of synchronized swimmers might not have the same rhythm. Therefore, it was hypothesized that synchronized swimmers have a higher inter-limb coordination ability fewer entrainment than athletes in other sports. The aim of this research was to analyze the inter-limb coordination ability of synchronized swimmers during underwater eggbeater kick with arm motion.
METHODS: Two synchronized swimmers and one non-synchronized swimmer participated in the experiment. Participants were asked to perform eggbeater kicks while a preferred arm was above water for 20 seconds. Another arm was instructed not to support the body in the water. The leg frequency was collected and defined as a natural leg frequency. The leg frequency (bpm) was the average of an inverse of each leg cycle duration. A leg cycle was determined from the right ankle range of motion in the transverse axis. Then, the participants were asked to perform three tasks where they were required to synchronize a circular motion of the preferred arm with metronome beats of 80, 100, and 120% of their natural leg frequency while performing eggbeater kicks. After 8 beats of the sound, the participants continued the arm and leg movements without metronome for another 20 seconds. The swimmers were required to maintain their natural leg frequency throughout the trial at all testing conditions. The order of the three tasks was randomized. A motion capture system with 6 underwater cameras and 3 above water cameras were used to collect the duration of arm and leg cycles. A cycle of an arm movement was determined from the wrist range of motion in the transverse axis.
RESULTS: When the participants performed with metronome beats, all participants were able to synchronize arm movements with the metronome beats in all conditions. However, when the participants were asked to continue arm and leg movements without the metronome beats, the results varied and only one synchronized swimmer could maintain the frequency of arm and leg movements in all conditions. The other two participants (one synchronized swimmer and one non-synchronized swimmer) were not able to maintain their leg movements with the 100% of their natural frequency.
CONCLUSION: It is inconclusive whether synchronized swimmers have smaller entrainment than non-synchronized swimmers. Further investigation with more numbers of participants is required.

COMPARISONS OF GENDER-RELATED HEMATOLOGICAL, HORMONAL AND FITNESS INDICES IN YOUTH SWIMMERS

QIU, J., CAI, G., CHEN, S., PAN, Q.L., SHEN, X.Z.
SHANGHAI INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: This study was to evaluate gender differences in hematological and fitness parameters among youth swimmers and to explore relationships between erythrocyte indices and aerobic and anaerobic capacity.
METHODS: 308 youth swimmers including 137 girls and 171 boys aged 8 to 16 volunteered to participate in this study, and they were divided into three (Beginner, intermediate and advanced) groups based on their training experiences. Blood samples were obtained to determine red blood cell counts, hemoglobin concentration, hematocrit, and serum erythropoietin and testosterone levels. VO2max was assessed using a submaximal cycle protocol. 76 girls and 102 boys also undertook a Wingate test to determine their peak anaerobic power. One-way analysis of variance (ANOVA) was used to compare gender differences in hematological indices hormonal indices and aerobic and anaerobic capacities. Two-way (gender × training) ANOVA was used to analyze the interactive effect of gender and training on hematological variables.
RESULTS: Boys had higher ($p<0.05$) means than girls for all hematological variables except for erythropoietin and values demonstrated an increase with training in boys. The average VO2max in l·min-1 and peak anaerobic power in watts were also higher in boys (2.91±0.08 and 547±28, respectively) than girls (2.25±0,07 and 450±26, respectively). Modest but significant ($p<0.05$) correlations were found between VO2max and red blood cell counts ($r=0.252$), hemoglobin concentration ($r=0.345$), or hematocrit ($r=0.345$) and between peak anaerobic power and red blood cell counts ($r=0.304$), hemoglobin concentration ($r=0.319$) or hematocrit ($r=0.351$).
CONCLUSION: This study revealed relatively lower yet age- and gender-appropriate erythrocyte indices and aerobic and anaerobic capacity in youth swimmers with boys demonstrating higher values than girls in most of these variables. Boys also exhibited a greater training response in erythrocyte indices than girls. The gender-related differences in erythrocyte indices seem unrelated to EPO and may be explained by the higher serum testosterone levels seen in boys. Given that these children are trained regularly and many of them have erythrocyte indices near the lower end of the normal range, regular screening of hematological variables for youth athletes is necessary. The fact that RBC, Hb, and Hct correlated to both aerobic and anaerobic capacity suggests that these erythrocyte indices may be used as part of talent identification for sports.

CP-SH10 Team functioning and leadership

COACHES' LEADERSHIP PROFILE IN TRADITIONAL ROWING: TRAINERAS

LEÓN GUEREÑO, P.
DEUSTO UNIVERSITY

Introduction
Coaches' behaviours are a key factor when leading a team successfully and they are directly connected to athletes' satisfaction (León-Guereño et al. 2018) and team's task cohesion (Huéscar Hernández et al. 2017). Traditional rowing or trainera boats are crewed by 13 rowers and a coxswain (León-Guereño, 2014). Since each sport is considered unique and specific context is important, (Urra Tobar, 2018), the aim of this research was to define the leadership profile in traditional rowing, so that future intervention plans could be designed and carried out in order to improve the performance of coaches.
Methods
370 elite sportsmen (26.3 ± 5.9 years), and 14 formal coaches (39.0 ± 8.2 years) completed the three surveys of the Leadership Scale for Sports (Chelladurai & Saleh, 1980), in its Spanish adaptation (Sánchez Bañuelos, 1996). The three perspectives and their congruence on coaches' leadership were assessed at mid-season. (congruence among athletes' preferences and perceptions about their coaches, and the coaches' self-perceptions).
Results
The results showed statistical differences between athletes' preferences and perceptions ($p<0.001$) in the six dimensions. Two dimensions showed significant differences between coaches' self-perception and rowers' preferences: Instruction and Management of the group ($p<0.05$) and Individual Attention ($p<0.05$). Coaches' self-perception and athletes' perception showed statistical differences in Social Support ($p<0.001$) and Management and Forecast ($p<0.05$)
Discussion
The main results are in agreement with previous studies developed regarded to rowing teams (León Guereño, 2014; León-Guereño et al. 2018). Rowers see their coaches with much fewer behaviours than they would desire. At the same time, coaches perceive themselves with better behaviours than their athletes do. These differences are associated with athletes' dissatisfaction and performance; therefore, and having evidence that an intervention plan can improve coaches' behaviours (Urra Tobar, 2018)
we see the need to create a plan. The plan requires to get athletes' preferences and coaches' real behaviours aligned. This approach will meet the required leadership profile in this sport, thus improving managers' performance.

PERCEIVED COACH LEADERSHIP STYLE AND PSYCHOLOGICAL WELL-BEING AMONG SOUTH AFRICAN NATIONAL MALE WHEELCHAIR BASKETBALL PLAYERS.

JOOSTE, J.

TSHWANE UNIVERSITY OF TECHNOLOGY

Background: An understanding of psychological welfare in sport is essential for the advancement of coach development frameworks and practices to meet the needs of contemporary disabled athletes.
Objective: This study investigated the perceived coach leadership style and psychological well-being (PWB) of South African senior national level male wheelchair basketball players (n = 16, M age = 32.13, SD = 6.62 years).
Methods: An exploratory, quantitative cross-sectional study design was employed in which the Leadership Scale for Sport, Subjective Vitality Scale, and Ryff's Psychological Well-being Scale were utilised to collect the data. Descriptive and inferential statistics were applied to describe and analyse the data respectively.
Results: Players exhibited high levels of subjective vitality and overall PWB. The perceived coach leadership style was strongly represented by the exhibition of training and instruction, and positive feedback behaviour which were also moderately and significantly associated with players' subjective vitality scores and various dimensions of PWB. Moderate and strong negative associations were also noted between players' positive relations with other and the coach's exhibition of democratic, and autocratic leadership behaviour respectively. Essentially, hierarchical multiple regression analyses revealed that components of perceived coach leadership style were not found to predict PWB.
Conclusion: Although further investigation on national level disabled athletes is warranted, it was concluded that aspects of coaches' leadership style in conjunction with athletes' national level experience could contribute to athletes' professed states of PWB in their sport environment. This study represents essential yet persistently understudied information on selected social settings in sport.

IMPLEMENTING A SHARED LEADERSHIP PROGRAM IN INDIVIDUAL SPORTS AN INTERVENTION STUDY MEASURING THE EFFECTIVENESS OF SHARED LEADERSHIP IN ATHLETICS GROUPS

BULTHEEL, M., GYSELAERS, J., FRANSEN, K., DE CUYPER, B., MERTENS, N.

CATHOLIC UNIVERSITY LEUVEN

Background.
Leadership in sports teams may be empowered by employing a shared leadership structure, in which responsibilities in task, motivational, social and external domains are distributed amongst athlete leaders.
Objective.
The present study aimed to identify potential benefits of shared leadership in individual sports, both for group-level and athlete-level outcomes.
Methods.
Fourteen athletics training groups, totalling 209 athletes and coaches, were distributed between intervention and control conditions. In the intervention condition, we conducted the 5RS Shared Leadership Program to identify and appoint the best athlete leaders, and subsequently to develop their leadership qualities, by teaching them to nurture a shared group identity.
Results.
We observed significant improvements in group-level outcomes, such as collective efficacy, motivational climate, and team resilience. However, most individual outcomes were not significantly improved. Coaches reported higher perceived performance, both at individual and group level. Athlete leadership quality was reported by coaches to be improved, but no improvement in team identification was observed.
Conclusion.
The 5RS Shared Leadership Program is effective in athletics groups at harnessing athlete leadership to improve group processes. However, the program didn't elicit improvements in individual athletes. Since no objective performance measurements were performed, further research is needed to uncover potential performance benefits.

A NETWORK APPROACH TO UNDERSTANDING TEAM WORK IN AUSTRALIAN FOOTBALL

YOUNG, C.

DEAKIN UNIVERSITY

INTRODUCTION: ocial Network Analysis (SNA) has been applied widely in soccer and basketball to assess the how a team share possession of the ball. SNA can be used to determine whether the characteristics of team work are related to match outcome. To date, this approach has not been applied to assess team work in Australian Football (AF). The aims of this study were 1) to asses if measures of team work varied between teams and between seasons, 2) identify whether there are differences between winning and losing performances, 3) determine whether team work is related to score margin and 4) to determine whether team work is also related to whole-of-season performance.
METHODS: Data from each match in the 2009–2016 Australian Football League (AFL) seasons were analysed. A total of Seven network measures (i.e. team work measures) were calculated for each team for every match. T-test and correlation analyses were used to identify differences between winning and losing teams and the relationship between network measures and score margin.
RESULTS: There were significant differences ($p < .05$) for all network measures, between teams that won and lost matches, and moderate relationships with score margin. Edge count held the strongest positive relationship ($r = .58$, $p < .001$) and Average path length had the strongest negative relationship ($r = -.51$, $p < .001$) with score margin.
CONCLUSION: This work provides novel insights regarding the optimisation of team work in AF that are not captured by analyses of traditional team performance indicators (kicks, handballs etc.). Key tactical performance indicators (Edge count, Edge density, Average path length, Transitivity and Eigenvector centrality) can be used to assess effective team work tactics. AFL teams should aim to maximise their effective disposal count with an even contribution from all players.

CONFLICTS OF TEAM BUILDING IN THE SPORTS ENVIRONMENT

NÉMETH, ZS.

UNIVERSITY OF PÉCS, FACULTY OF SCIENCES, INSTITUTE OF SPORT SCIENCE AND PHYSICAL EDUCATION

Introduction
Nowadays the team building programs become increasingly popular not only in business sector, but in sport environment too. The aim of team building programs is to know, to accept and to trust each other. In this process it is natural, that sometimes conflicts appear in the surface. The aim of our study is to map the reasons of conflicts in the different process of team building.
Methods
From the qualitative research methods we chose the focus group analysis. In the sample, we selected consciously the coaches: 2 football, 1 baseball, 1 basketball, 2 handball, 1 volleyball and 1 water polo. The average age was 35 years. The gender ratio was the same, so 4 women and 4 men participated in the study. Some of them were at the beginning, middle and end of their coaching career, with an average practical experience of 17 years. My questions focused on the most common locations, causes, and methods of conflict management strategies during the process of the team building. The focus group study took place on January 23, 2019.
Results
It turned out, that one of the main reason of the conflicts was the competition for the position.
Another common reason was that the player was talented in other areas, such as in the music and so on. In addition, the play time of the substitute players and the parents' different views on their children' position caused conflicts. In these cases generally the coaches used the problem solving conflict management strategy.
Conclusion
The teams success is largely influenced by team building, which is based on mutual trust and cooperation. During the team building process the coaches have to consider the age-specific carasteristics and personality of the players and personal performance too. Coaches have to find the best position for each player with the agreement of the players and their team members. They have to use the situation based leadership-, communication- and conflict management styles. Coaches during the team building process have to create an atmosphere where they minimize the apperance of conflicts. In the process of conflict management not the number of conflicts, but the quality of solutions is the most important.

MEASURING ROLE PERCEPTION IN TEAM SPORTS: THE VALIDATION OF THE CHINESE VERSION OF ROLE AMBIGUITY SCALE (RAS)

HO, W.J., LIAO, C.M.

NATIONAL TAIWAN SPORT UNIVERSITY

Measuring role perception in team sports: the validation of the Chinese version of Role Ambiguity Scale (RAS)
Ho, W-J. and Liao, C-M.
National Taiwan Sport University (Taiwan)
Introduction
The purpose of this study was to test the validity of the Chinese version of Role Ambiguity Scale (RAS). According to Carron and Eys (2012), role ambiguity refers to team members' lack of information about their roles on the team and has been found to be related negatively to team cohesion, intra-team communication, and positively to competitive state anxiety. Beauchamp, Bray, Eys, and Carron (2002) developed RAS to measure role ambiguity of members in athletic teams, its reliability and validity have been supported by data from North America, Greece, Sweden, and Spain. However, it has not been systematically tested in a non-Western culture. In this study, RAS was translated to Chinese language and administrated to athletes from Chinese culture, i.e. Taiwanese.
Methods
Items of RAS (English language, a total of 20 items in 4 sub-scales) were translated into Chinese language (traditional font) with a back-translation procedure. 180 Taiwanese collegiate athletes from 8 different sports and 8 universities (division 1= 99, division 2= 52, recreational= 26; male= 110, female= 69; mean age= 20.71, SD= 1.55) with an average of 6.46 years of sports experiences (SD= 3.55, range= 0.08-15) filled in the scale. Exploratory factor analysis (EFA) and item analysis were conducted.
Results and discussion
EFA and item analysis revealed a single-factor structure with a total of 67.17% variance accounted (Cronbach's alpha=.94). This result was not in line with the four-dimension structure of the original RAS. It appears that the factorial structure of role ambiguity of athletes from Taiwan is different from that of athletes from Western cultures. In spite that our data showed a high level of total variance accounted and internal consistency, this scale should be used with caution. A translated Chinese version of RAS may not be suitable for athletes from Chinese culture. Further research based on a grounded theory approach is warrant to conceptualize role ambiguity of athletes from Chinese culture.

PSYTOOL: SPORT PSYCHOLOGY AS A THEORETICAL FRAME TO PROMOTE A POSITIVE ATTITUDE IN GRASSROOT SPORTS

SÁEZ DE VILLARREAL, E., JAENES, J.C., CASADO-ALDA, A., CALVO, A., GONZÁLEZ-JURADO, J.A., FLORIA, P.

UNIVERSITY PABLO DE OLAVIDE

Discrimination, inequality, sexual harassment, aggression, insults and other negative attitudes are common in grassroots sports in particular (Nogueira, Molinero, Salguero del Valle, Lucidi&Márquez, 2017; Jaenes, Peñaloza, Méndez-Ruiz, Ponce- Carbajal&Jaenes-Amarillo, 2017). Sport Psychology (SP) offers theoretical frames with enough scientific evidences to cope with and also to educate young

players and coaches in values greatly appreciated in our field. PSYTOOL, an European Erasmus + Program conducted by Universidad Pablo de Olavide, is an educational platform for training to promote positive behaviors based on the principles of SP (www.psytoolspot.eu). Part of PSYTOOL is the creation of Agents of Change (AoCs) (N=155). These agents received a special training in regards to detecting negative situations. In this paper, researchers tried to evaluate Program Efficacy between coaches and football players.
Instrument
Disposition to Change Questionnaire (Miller&Johnson, 2008) adapted to the grassroots sports evaluates three dimensions: Disposition, Reasons to change, and Behaviors to be changed: No Changes, Cognitive and Metacognitive Changes, and scores it from 0 to 5.
Participants
Sixty-three Agent of Changes; 56 males and 7 females; aged 21-58 years old, Men: 32,39; SD: 9,02; Experience: Mean: 9,02; SD: 7,68.
Results
In Disposition to Change, subjects score mean 4,5 SD: 0,41; Reasons to Change: mean 4,71; SD: 0,42; and Behaviors Made: mean 4,54; SD: 0,54. Questionnaires was filled out by AoCs and analyzed through their content categories: No Change: 4,8%; Metacognition: 14,3%; Cognition: 88,3%. Researchers evaluated 18 different categories of Topics of Cognitive Changes considered by the AoCs, and results demonstrate more changes in Personal Development and Training Competencies (14,3% each); Violence (13,1); Fair Play (10,7) and Discrimination (10,1%).
Conclusions
According to the results, PSYTOOL Educational platform demonstrates its capacity to modify behaviors and attitudes in Agents of Change, who took the ten lesson and activities course. Most of the changes detected from the AoC are on the cognitive level, highlighting the topics that have been detected as targets. The most outstanding points of change are the Personal Growth, Coaching Skills, Violence and Discrimination between players. The results provide objective data on the direct and indirect impact of the program that will be useful for the design of future PsyTool developments and interventions with coaches and players.

THINK ALOUD: UNLOCKING DUATHLETES THOUGHT PROCESSES

MCEWAN, H., GRAHAM, S.
UNIVERSITY OF THE WEST OF SCOTLAND

Think Aloud: Unlocking duathletes' thought processes
Introduction
Cognition is an under-researched area in sport. Further understanding athletes' thought processes has inferences for both athlete and coach performance. Many of the methods used to investigate thought processes rely on reflection on-action, which may result in distorted recall. Ericsson and Simon's (1980) Think Aloud (TA) protocol is a method that allows reflection in-action. TA has been described as "eavesdropping on someone's thinking". The method has been applied in diverse disciplines from teaching to medicine and involves participants thinking aloud as they perform a set of specified tasks. The aim of the present research was to apply the TA method in sport by exploring duathletes' cognitions during a duathlon (run-cycle-run).
Methods
Participants were 6 duathletes (5 female, 1 male), age range 31-59 years with 3-8 years duathlon experience. Participants trained for a minimum of 6 hours per week. A three-stage procedural model was used which consisted of a pre-TA protocol workshop, followed by a mini duathlon using the TA protocol (2.5km run, 5km cycle and 2.5km run) in a laboratory setting. Participants were required to verbalise (TA) their though processes whilst undertaking the mini duathlon. The research concluded with post-protocol interviews to investigate the prospective use of TA to support reflection in-action during duathlon. All participant verbalisations were recorded and subject to a thematic analysis.
Results and discussion
During the mini duathlon participants thoughts pertained to 3 main themes: pace and distance, technique, and pain and discomfort. Within these themes there are examples of adaptive and maladaptive thinking, and a focus on task relevant and task irrelevant thoughts. Overall TA was reported prospectively as a difficult, but useful task for self-monitoring within endurance sport. The findings support the potential utility of TA to study the decision making processes in endurance athletes.

HIGH LEVEL FOOTBALL PLAYERS' ABILITY TO USE IMPLICIT INFORMATION AS AFFORDANCES FOR ACTION

BEAVAN, A.1,2,3, FRANSEN, J.L.3, SPIELMANN, J.4, SKORSKI, S.1, MAYER, J.4, HAUSER, T.2, MEYER, T.1
1: ISPM , 2: DFB-AKADEMIE , 3: UTS , 4: TSG1899

Introduction
Response times in athletes have commonly been assessed using simple motor tasks and is reliant on a participant's ability to detect and process explicit sources of information. Yet, an athlete is constantly processing the surrounding environment to guide his/her subsequent actions, known as affordances (Gibson, 1979). However, not all this information is perceived explicitly. This translates into an athlete receiving both explicit and implicit information that together, shapes their knowledge about prospective opportunities before they need to act, which in turn improves response time. This study used a new assessment (Precued Choice Response Time Task: PCRTT) that measures the impact of implicitly perceived visual information on response times.

Methods
Seventy-four male soccer players from four age groups: U12 (n = 15; Age = 10.3±0.6; years of playing experience (Exp) = 6.4±1.7), U13 (n = 17; Age = 11.2±0.5; Exp = 7.6±1.7), U17 (n = 21; Age = 15.2±0.3; Exp = 11.6±2.5) and U19 (n = 21; Age = 16.7±0.5; Exp = 12.9±2.2) representing a German 1st league club were tested. Player's conducted one session consisting of twenty-four trials, where a small dot was presented in the centre of one of four stimulus circles 86 ms before the stimulus circle turned yellow, for a duration of 43 ms on a screen. In half of the trials, the dot appeared in the same circle as the stimulus circle (congruent), and in the other half, the dot appeared in a different circle (incongruent). Participants were required to press the button on a panel associated with a stimulus circle as fast and accurate as possible.
Results
A repeated measures ANOVA did not reveal a significant interaction effect of congruency*age group ($F(3,74) = 0.33$, $p = .80$, ES = 0.01). However, a significant within-subjects effect of congruency ($F(1,74) = 51.32$, $p < .001$, ES = 0.41) and a significant between-subjects effect of age group ($F(3,74) = 4.30$, $p = .008$, ES = 0.15) was observed. Post-hoc analyses demonstrated in congruent trials, the U12 group was significantly slower than the U19 group; while in incongruent trials, both younger (U12-13) groups were significantly slower than the U19 group.
Conclusion
The results demonstrated that response times are shorter in older players, which is a well-established result of the development of the central nervous system with age. Yet, the absence of an interaction between congruency and age may signify that high-level athletes indeed use implicit advanced sources of information to inform their actions, but the ability to do so does not change with increasing age or experience in football. This implies that a better ability to detect or suppress implicit, non-sport specific information may not be related to playing experience, and future studies should compare these findings with more sport-specific information.

SELF-TALK, AUDITORY DISTRACTION, AND PERFORMANCE ACCURACY IN BASKETBALL FREE THROW SHOOTING

WARREN FRIEDRICH, K., SEVDALIS, V.
AARHUS UNIVERSITY

Introduction: Self-talk has been shown to be effective for facilitating performance in sports. For this study, a self-talk intervention for basketball players was introduced, with a view to improving accuracy in a free throw shooting task, as well as helping counter an auditory distraction.
Methods: A within-subjects design was applied. Basketball players were individually tested in a basketball court, and performed 64 free throws. Two independent variables were introduced in the experiment: an auditory distraction, and a self-talk intervention. In the first part of the experiment, the participants performed free throws with and without auditory distraction. In the second part of the experiment, a self-talk intervention was introduced, and the participants continued to shoot free throws with and without distraction, while applying the self-talk intervention. The dependent variable was performance accuracy (i.e., scoring or missing a free throw).
Results: The results indicated that the self-talk intervention had a significant performance enhancing effect, as the shooting accuracy increased after the self-talk intervention was introduced. Performance accuracy improved across trials both before and after self-talk (i.e., from low to high accuracy in both conditions), indicating practice effects. The auditory distraction did not have a detrimental effect on performance, as performance accuracy was similar under auditory distraction and no distraction conditions. No relationships were found between performance accuracy and individual differences in players' experience (e.g., years of experience and hours of practicing).
Conclusions: This study supports previous literature indicating that self-talk is beneficial for performance, and encourages the use of self-talk as a strategy employed by sport practitioners.

CAN YOU REACH IT? THE INFLUENCE OF TENNIS EXPERIENCE ON PERIPERSONAL SPACE

ZAVADSKA, A., BIBI, M., BRINKSCHULTE, M., HEISLER, S., VAN HAAREN, E., LIEPELT, R.
GERMAN SPORT UNIVERSITY COLOGNE

Introduction: There is a myriad of sport types and many of them require the athlete to use a tool, which is essential for its performance. The frequent use of one of these tools over a long period of time can affect the so-called peripersonal space of an athlete. Peripersonal space is defined as the space just surrounding the body and its representations are highly plastic as a function of experience (Làdavas & Serino, 2008). Therefore, the purpose of the study was to find out if the frequent use of a tennis racket has an influence on the peripersonal space of tennis experts compared to novices in terms of reaching distance estimation due to experience. It is assumed that the estimated reaching distance will differ between tennis experts and novices, which means that tennis experts will overestimate their reaching distance to a greater degree than novices due to their frequent use of a racket over a long period of time.
Methods: The sample consisted of 24 participants (age: M = 25.21, SD = 2.43; sex: 8 females, 16 males). Two groups were tested, an expert group with tennis players (nexperts = 12, with at least 3 years of experience) and a novice group (nnovices = 12, not experienced in playing racket sports at all). Participants were asked to sit on a chair, place their head on the chin support, and place their right hand on a mark at the edge of the table. The experiment consisted of 4 blocks. In each block, one of the bars was placed in front of the participant and a tennis ball was moved closer to or farther away on thirteen different marks in a randomized order. Each time the tennis ball was moved, the participant was asked to estimate if the ball was reachable or not. In 2 blocks, the last reachable mark was farther away from the participant (far condition), and in 2 blocks, the last reachable mark was closer to the participant (near condition).
Results: Descriptive analysis of the reaching estimation showed that in 31.29 % (experts) and 23.52 % (novices) of all trials, participants overestimated their reaching distance. This difference was not significant. In less than 2 % of all trials, the participants underestimated their reaching distance (experts: 0.35 %, novices: 1.92 %).
Discussion: The findings of this study showed that experts overestimated their reaching distance more often than novices and so perceive their peripersonal space to be bigger. Furthermore, no differences between the conditions were found. It is assumed that reaching estimation did not depend on reference cues in the environment. To better understand the influence of tool use on peripersonal space, it could be valuable to additionally assess body ownership in tennis players.

EFFECT OF MICROGRAVITY ON BEHAVIORAL AND NEURONAL PERFORMANCE

WOLLSEIFFEN, P.

DEUTSCHE SPORTHOCHSCHULE KÖLN

INTRODUCTION: Physical exercise is of particulary importance for astronauts under the extreme conditions of spaceflight in order to counteract the deconditioning of the musculosceletal and the cardiovascular systems. As previous research indicates, exercise might in addition maintain mental fitness and therefore contribute to mission safety and succes. So far it has not been distinguished between a primary effect of weightlessness and a secondary effect of isolation and confinement while living in space. When isolating the gravitational effects in short periods of weightlessness (20sec) during parabolic flight manoeuvres, previous research has shown reaction time to be enhanced. The more the complexity of the task increased, the better the cognitive performance was in 0G. The aim of this study was to compare behavioral performance (reaction time) and neuronal performance (event related potentials analysis, ERP) in a complex task within 1G and 0G.
METHODS: 17 participants were presented a complex arithmetic task in combination with an auditory-oddball task during the 1G and 0G-phases in a parabolic flight. Reaction time as well as event related potentials (ERP, N200 and P300) were assessed.
RESULTS: Results revealed a reduced reaction time ($p < .05$) for solving the mental arithmetic task during 0G. No differences in reaction time could be obtained between 1G and 0G for the oddball paradigm. Error rate in 1G compared to 0G with no difference neither for arithmetic task nor oddball paradigm. The Amplitude of the neurocognitive markers N200 and P300 was significantly reduced during 0G. Latency remained unaffected in both gravity conditions for P300, but was lower in 0G for N200 amplitude.
CONCLUSION: Previous studies have demonstrated no or a small negative impact, of space flight on cognitive performance (1), albeit were not able to distinguish between primary effects of weightlessness and secondary effects of stress and confinement. Data presented here suggest that microgravity is more likely to enhance neuro-behavioral performance. It is assumed that the weightlessness induced fluid shift to the brain is positively affecting neuro-behavioral performance (2).

THE EFFECT OF COMBINED COGNITIVE AND EXERCISE TRAINING ON WORKING MEMORY PERFORMANCE AND BRAIN SIGNAL COMPLEXITY

GUO, G.W., YANG, C.T., LIANG, W.K., WANG, C.H.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: The efficacy of brain training has been debated in recent years. In contrast, physical exercise has been consistently associated with benefits to a wide range of cognitive abilities, beyond the well-known physiological and health improvements. Several groups have investigated the potential for a combination of physical exercise and cognitive training to maximize cognitive improvements, yet little is known about the interaction of the two components at the neural level.
METHODS: Here, we used multiscale entropy (MSE)—a measure of brain signal complexity—to better understand the influence of multimodal training on working memory performance. Young adults took part in a 20-day randomized controlled trial including two conditions: a dual n-back training combined with acute bouts of moderate-intensity aerobic exercise, and the same dual n-back training combined with a control condition (i.e., reading). Before and after training, all participants completed a feature-binding working memory task with concurrent electroencephalographic (EEG) recording.
RESULTS: For the behavioral data, we subtracted working memory performance in the pre-test from the post-test session for each participant to compute training gain scores. Pairwise comparisons on gain scores for each condition showed a significant group difference for the Shape and Binding conditions ($p = .005$, and $p < .001$, respectively), but not for the Color condition ($p = .78$), together with greater changes in cognitive modulations on brain signal complexity (qs <.05, FDR corrected).
CONCLUSION: Overall, our findings are consistent with the claim that multimodal intervention may facilitate cognitive improvements, and suggest that the addition of physical exercise to the brain training program could enable wider, more robust improvements.

EFFECTS OF ACUTE AEROBIC EXERCISE ON DELAYED FREE-RECALL PERFORMANCE

KAMIJO, K.1, EDA, N.2

1: UNIVERSITY OF TSUKUBA, 2: WASEDA UNIVERSITY

INTRODUCTION: A growing number of investigations have examined the effects of acute exercise on memory. These studies suggest that the effects of acute exercise are likely to differ depending on the timing of exercise relative to memory encoding, consolidation, and retrieval phases. Several studies have shown that retrieval improved when exercise was done before or after the encoding phase (Roig et al., 2013). By contrast, stress studies have suggested that the elevation of cortisol before the retrieval phase is likely to result in impaired memory (Schwabe & Wolf, 2013), which suggested possible negative effects of acute exercise on delayed memory retrieval. This study was designed to examine whether acute aerobic exercise before a retention test would improve or impair delayed free-recall.
METHODS: Young adult participants ($n = 28$) completed rest and exercise conditions in a within-participants design with a counterbalanced order. The rest condition consisted of 30 min of sitting, whereas the exercise condition consisted of exercise on a cycle ergometer (70-75% VO2max). Delayed free recall of a wordlist learned 24 hours previously was tested 15 min after each intervention. The delayed free-recall performance was defined as the percentage of correctly remembered words compared to the immediate free-recall performance of the previous day. Saliva was collected before and after the intervention to assess cortisol levels.
RESULTS: Salivary cortisol after exercise was higher than after rest. Delayed free-recall performance did not differ between the rest (53.5%) and exercise (54.8%) conditions.
CONCLUSION: The exercise intervention used in this study caused an elevation in cortisol. Nonetheless, delayed free-recall performance was not affected by acute aerobic exercise, which is inconsistent with the results of stress studies (Schwabe & Wolf, 2013). Many studies have shown that acute aerobic exercise improves a variety of brain functions including information processing, attention, and executive function (Chang et al., 2012). The underlying mechanisms of acute exercise on brain functions are not well understood. However, the

results of this study suggest that beneficial effects of acute aerobic exercise on memory performance might cancel the adverse effects of cortisol elevation.

INFLUENCE OF EXPERTISE AND GAME TIME ON FOOTBALL REFEREE DECISIONS

GRAEFE, A., ELLERT, G.

MACROMEDIA UNIVERSITY

Problem. Referees need to make quick decisions in situations that involve high uncertainty. Thereby, critical decisions (e.g., sending a player off) can have a decisive impact on the outcome, particularly early in the game, which increases pressure. We analyzed the influence of referees' expertise on decision accuracy and investigated a potential moderating influence of game time.
Methods. Referees (N=198) with different levels of expertise assessed thirty tackle situations taken from international matches through an online survey. Thereby, the displayed game time for each video (early, medium, late) was experimentally manipulated. Decision accuracy was assessed by comparison to an expert panel decision.
Findings. Expertise improved decision accuracy. The difference in the percentage of correct predictions between the high (45%) and low (41%) expertise group was four percentage points. The effect remained after controlling for the rigidity of decisions (+), foul severity (-), game time (0), and sociodemographic variables (0). Referees with higher levels of expertise were better equipped to deal with uncertainty. Although game time did not affect accuracy, referees made more rigid decisions later in the game.
Implications. Referees may be too soft in their application of the Laws of the Game for tackle situations, which would put the players' safety at risk. The Laws may not serve as a high-quality decision aid, particularly in situations involving uncertainty. Future research should further evaluate the quality of the Laws of the Game as decision aids for referees and assess potential needs for improvement.

EXPOSURE-ADJUSTED INJURY INCIDENCE RATES IN OLYMPIC COMBAT SPORTS: A COMPARATIVE STUDY OF THREE CONSECUTIVE OLYMPIC GAMES

LYSTAD, R.P., ALEVRAS, A., RUDY, I., SOLIGARD, T., ENGEBRETSEN, L.

MACQUARIE UNIVERSITY

INTRODUCTION: There is a high risk of injury in full-contact combat sports (Lystad, 2015). Direct comparisons of injury risk across combat sports has been hampered by methodological heterogeneity (e.g. operational injury definitions, measures of exposure, and context of injury surveillance) across studies. In the present study, the challenges with heterogeneity are overcome by using data from official tournament records and the International Olympic Committee injury surveillance system (Junge et al., 2008). Specifically, this study aims: (1) to determine the incidence, severity, and pattern of injuries in Olympic combat sport athletes; and (2) to compare exposure-adjusted injury incidence rates across Olympic combat sports.
METHODS: This study used injury and exposure data from three consecutive Olympic Games (i.e. Beijing 2008, London 2012, and Rio 2016). Exposure data were obtained from publicly available tournament draw sheets, while injury data were obtained from on-site injury surveillance. Competition injury incidence rates were calculated per 1000 athlete-exposures (IIRAE) and per 1000 minutes of exposure (IIRME) and presented with 95% confidence intervals (CI). Subgroups were compared by calculating their rate ratio (RR) with 95% CI.
RESULTS: The overall IIRAE and IIRME were 40.98 (95%CI 36.58–45.75) and 7.85 (95%CI 7.01–8.77), respectively. The IIRME was slightly higher for females (8.27 [95%CI 6.63–10.02]) than males (7.70 [95%CI 6.74–8.77]); however, the difference was not statistically significant (RR 1.07 [95%CI 0.84–1.37]). The highest IIRME were observed in judo (9.58 [95%CI 7.74–11.73]), boxing (9.16 [95%CI 7.62–10.92]), and taekwondo (7.92 [95%CI 5.73–10.67]), while the injury rate in wrestling (4.79 [95%CI 3.61–6.24]) was significantly lower than for the other three combat sports. Overall, 30% of injuries were moderate or severe (i.e. resulting in >7 days lost from participation in training or competition). The proportion of moderate and severe injuries was higher in wrestling (40%) and judo (36%) than in taekwondo (31%) and boxing (21%).
CONCLUSION: There is a substantial risk of injury in Olympic combat sports, with athletes sustaining, on average, 1 injury for every 30 minutes of competition. The risk of injury varies across combat sports, with the highest incidence rates observed in judo and boxing. The injury severity appears to be greater in grappling styles (i.e. wrestling and judo) than in striking styles (i.e. taekwondo and boxing). Greater efforts to prevent injuries in Olympic combat sports are warranted.

VERIFICATION OF POSTURE IMPROVEMENT EFFECT OF PHYSICAL FUNCTION IMPROVEMENT TRAINING AND POSTURE LEARNING

KUDO, S.1, TAKAHIRA, N.2, OFUSA, M.2, SAKAI, K.1

1: KITASATO UNIVERSITY GRADUATE SCHOOL, 2: KITASATO UNIVERSITY

INTRODUCTION: Bad posture in the elderly is related to locomotive syndrome and falls, and it becomes one of the necessary care factors. Meanwhile, bad posture in young people, such as students and office workers, causes cross syndrome. To treat bad posture and cross syndrome, you need to improve your physical function such as muscular strength and ability to stretch, learn to maintain the ideal pos-

ture, and increase awareness. Therefore, the purpose of this study was to examine the effects of habitual training, which improves physical function and helps learn the ideal posture, on posture improvement.
METHODS: The subjects were 40 females aged between 20 and 30 years. They were randomized: training group (wall-side squat and wall-side stretching; n=10), the posture learning group (stand upright against the wall, and when sitting, place the back half of the buttocks on a rolled towel to support the pelvis neutral; n=10), combination group (training and learning to maintain the ideal posture; n=10), and control (n=10). They were instructed to intervene 3 days a week, 3 sets per day, using rolled towels for at least 1 hour daily except on day 2, and the intervention period was 4 weeks. By using the body tilt angle measuring device HORIZON, trunk anteroposterior inclination, left / right flexion angles, pelvic anteroposterior inclination, left / right inclination, left / right rotation angle, and vertebral kyphosis angle were evaluated as the main aspects of posture. The ideal posture was measured before intervention; the difference between the ideal posture and the usual posture was taken as the change amount, and it was used as the primary outcome.
RESULTS: In the trainings group, the trunk anteroposterior inclination angle, the pelvic anteroposterior inclination angle, and vertebral kyphosis angle significantly improved with single intervention. In the posture learning group, single intervention led to a significant improvement only in the pelvic anteroposterior inclination angle. At the same time, the posture learning group significantly improved pelvic anteroposterior inclination angle compared to the training group. However, there was no significant difference between the two groups with regard to the sustained effect of single intervention on posture improvement. After 4 weeks of intervention, all subjects in the combination group improved in all posture evaluation items.
CONCLUSION: An improved posture can be achieved by focusing on posture holding muscles that are not normally used, stretching shortened muscles, and posture learning. Therefore, we suggest that these interventions are necessary to maintain the ideal posture.

PREVALENCE OF LUMBAR DISC DEGENERATION IN COLLEGIATE RUNNERS

KUBO, Y.1, KOYAMA, K.1, NAKAZATO, K.2, TAHARA, Y.3, MIZUNO, M.2, MIN, S.K.4, HIRANUMA, K.2

1: TOKYO ARIAKE UNIVERSITY OF MEDICAL AND HEALTH SCIENCES, 2: NIPPON SPORT SCIENCE UNIVERSITY, 3: MEIJI GAKUIN UNIVERSITY, 4: KOREA INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: In many sports, lumbar disc degeneration (LDDG) is a frequent injury among athletes. The prevalences of LDDG in collision and non-collision sports were 43.2% and 29.1%, respectively. In particular, the prevalence of LDDG in track and field athletes was low (22.7%) (1). Furthermore, the prevalence of LDDG in runners (25.6%) was almost the same or even lower compared with that of LDDG in non-athletes (31.4%) (2). However, in these previous studies, the subjects' running preference (sprinter or long-distance runners) was unclear. Thus, the type of running that is beneficial for preventing LDDG was also unclear. Therefore, this study aimed to investigate the prevalence of LDDG in sprinters and long-distance runners.
METHODS: A total of 102 collegiate sprinters (86 men and 16 women), 91 long-distance runners (78 men and 13 women), and 45 non-athletes (17 men and 28 women) as controls were included in this study. The average sport-related experiences of the sprinters and long-distance runners were 7.0 ± 2.4 years and 6.6 ± 2.0 years, respectively, and all athletes in this study were ranked at the intra-national and/or international levels. LDDG was evaluated using T2-weighted magnetic resonance imaging. To assess whether running distance was associated with LDDG, logistic regression analyses were performed with adjustments for athletic event, sex, and weight. The significance level was accepted at $p < 0.05$.
RESULTS: The prevalences of LDDG in sprinters, long-distance runners, and non-athletes were 16.7%, 3.3%, and 17.8%, respectively. A logistic regression analysis with the control reference group revealed that the prevalence of LDDG among long-distance runners (adjusted odds ratio, 0.20; 95% confidence interval, 0.04–0.90) was significantly lower than that of LDDG among non-athletes.
CONCLUSION: In this study, the prevalence of LDDG in sprinters was similar with that of LDDG in non-athletes, as reported previously (2). However, the prevalence of LDDG was significantly lower in long-distance runners than in non-athletes, suggesting that long-distance running is beneficial in preventing LDDG. However, running at least twice a week in early adulthood has been associated with LDDG (3). A possible reason for this contradiction could be that the subjects in this study were well-trained collegiate runners. The impact on the lumbar disc while running is surely dependent on the running form. We speculated that the impact while running in long-distance runners might be lower than that in novice runners. Overall, the prevalence of LDDG was lower in long-distance runners than in non-athletes. Although a biomechanical approach is necessary, the load on the lumber disk during long-distance running might be very low or even beneficial in preventing LDDG.

EFFECT OF A 3-DIMENTIONAL COMBINED EXERCISE INTERVENTION PROGRAM FOR THE REDUCTION OF SCOLIOSIS ANGLE IN PATIENTS WITH ADOLESCENT IDIOPATHIC SCOLIOSIS

AHN, S., JEONG, S., KIM, K., SEONG, C., KIM, M., LEE, S., HWANG, M., KANG, N., YOON, K., LEE, S., JEON, K.

INCHEON NATIONAL UNVERSITY

INTRODUCTION: Scoliosis of the spine is typically defined as complex spinal deformities of sideways curvature and asymmetry in the ribs with a Cobbs angle of ≥10° detected on spinal X-ray (Weinstein et al., 2013). Idiopathic scoliosis is particularly prevalent in adolescents between the ages of 11 and 17, among whom more than 80% have structural scoliosis caused by intrinsic structural factors (Weiss and Goodall, 2008). Accordingly, it is important to determine the effects of continuous and repeated treatment with an established intervention on reducing spinal curvature. Therefore, this study aimed to investigate the effect of a 3-dimensional combined exercise intervention program consisting of static muscle exercises and Schroth exercises in reducing spinal curvature in adolescents.
METHODS: Thirty-four female elementary school students (age 11.18±.39 years, height 141.97±4.97 cm, weight 36.29±6.05 kg) presenting with scoliosis in whom 3-D spinal structure analysis (Formetric 4D, DIERS Biomedical Solutions, Germany) showed a Cobbs angle of ≥10° were included. A combined exercise intervention program consisting of static muscle exercises (30 minutes) and Schroth exercises (30 minutes) was completed by the subjects two times a week for a total of eight weeks. The intervention program was composed of static muscle exercises (Form roller, Gym ball, 3D wedge, and Balance board), with a focus on the strengthening and coordination of the spine, and Schroth exercises (Physiologic, 3D made easy, Fifty times, and Muscle cylinder) for body alignment. Pre- and post-intervention spinal curvature, pelvic tilt, torsion, and rotation were measured using a highly spinal structure. Data were analyzed using SPSS 25.0 (SPSS Inc.,

Chicago, USA). For each variable, mean and standard deviation were computed, and the values before and after the completion of the intervention were compared using the paired sample t tests. The level of statistical significance was set at .05.
RESULTS: Pelvic tilt and torsion angles did not significantly differ before and after the intervention program; however, pelvic rotation (p=0.003), trunk torsion (p=0.020), and scoliosis angle (p=0.000) were significantly different after the intervention program.
CONCLUSION: This study demonstrated that the exercise intervention program performed to reduce spinal curvature in adolescent idiopathic scoliosis patients was effective in decreasing pelvic rotation, trunk torsion, and scoliosis angle.

CROSS-CULTURAL ADAPTATION, TRANSLATION IN FRENCH AND VALIDATION OF THE

KAUX, J.F, BORNHEIM, S., REMY, G., VAN BEVEREN, J., REGINSTER, J., BRUYERE, O., DARDENNE, N., BUCKINX, F.
UNIVERSITY OF LIÈGE

INTRODUCTION: Anterior knee pain is common in sports and especially among sportswomen. Moreover, early sport specialization in female adolescents is associated with increased risk of anterior knee-pain disorders. The "Anterior Knee Pain Scale" was developed (in English) for the evaluation of the severity of symptoms and sports ability in individuals with anterior knee pain. Our purpose was to linguistically and cross-culturally translate the Anterior Knee Pain Scale into French and to evaluate the reliability and validity of this translated version of the questionnaire.
METHODS: The translation part was performed in six stages, according to international guidelines: (i) two initial translations from English to French; (ii) synthesis of the two translations; (iii) backward translations into the original language; (iv) expert committee to compare the backward translations with the original questionnaire; (v) pre-final version testing and (VI) expert committee appraisal. To validate the French version of the Anterior Knee Pain Scale, we assessed its validity, reliability and floor/ceiling effects. To do this, volunteer patients from the French part of Belgium and from France, with patellofemoral pain were asked to answer the French version of the Anterior Knee Pain Scale at baseline and after 7 days, as well as the generic SF-36 questionnaire.
RESULTS: The Anterior Knee Pain Scale was translated without any major difficulties. A total of 101 subjects aged 34.5 ± 11.4 years (58.4% of women) were included in this study. Results indicated an excellent test-retest reliability (Intra-class correlation coefficient (ICC) = 0.97, 95%CI: 0.96-0.98), a high internal consistency (Cronbachs alpha = 0.87), a consistent construct validity (high correlations with the SF-36 questionnaire were found with domains related to physical function (r = 0.80), physical role (r = 0.70) and pain (r = 0.64)) and low or moderate correlations with domains related to mental health (r = 0.26), vitality (r = 0.32) and social function (r = 0.41). Moreover, no floor/ceiling effects have been found.
CONCLUSION: A valid French version of the Anterior Knee Pain Scale is now available and can be used with confidence to better assess the disease burden associated with patellofemoral pain. It was successfully cross-culturally adapted into French. Implications for rehabilitation The results on psychometric properties of the French Anterior Knee Pain Scale are comparable with six validated versions obtained for the Finnish, the Turkish, the Chinese, the Dutch, the Thai and the Persian populations. The French translated version of the Anterior Knee Pain Scale is a reliable and valid instrument for assessing the functional limitations associated with patellofemoral pain. The test-retest reliability of the French Anterior Knee Pain Scale was excellent, the internal consistency was high and the construct validity was consistent. There were no floor/ceiling effects.

REVIEW OF SCAPULAR MOVEMENT DISORDERS AMONG ADULTS WITH FORWARD HEAD POSTURE

ANGIN, E., DEPRELI, Ö., KIRMIZIGIL, B.
EASTERN MEDITERRANEAN UNIVESITY

INTRODUCTION: Forward head posture (FHD) results in a posture in which the extended head and upper cervical, and the lower cervical vertebrae flex. This increases the length of the external moment (the arm) by moving the gravitational center (the head) ahead of the load bearing axis. Scapular dyskinesis, which is known as altered scapular motion and position, is a musculoskeletal disorder that affects upper extremity. The purpose of this study to compare scapular movement disorders among adults with forward head posture.
METHODS: As a result of power analysis, 150 adults were included in this study. FHP was assessed with photography method and the craniovertebral (CV) angle that was formed by the horizontal line through C7 and the line connecting C7 with tragus was measured, if the angle was less than 50˚, then a participant was referred to the study with FHP. Lateral Scapular Slide Test (LSST) was used for assessing scapular dyskinesis. The test involves three positions (placement of the shoulder in glenohumeral joint neutral, with 45˚ of shoulder abduction in the coronal plane and with 90˚ of shoulder abduction in the coronal plane). The position of the scapula is detected by measuring the distance between the inferior angles of the scapula to the spinous process of the thoracic vertebra bilaterally in all 3 ways and difference is greater than 1.5 cm, it indicates that scapular asymmetry is abnormal.
RESULTS: A total of 150 individuals who were 62.7% female and 37.3% male participated in the study while 65.3% of them with FHP. Mean of age, height, weight and BMI values were 41.9 ±7.7 year, 167.5±72.9 cm, 72.9±16.2 kg and 25.8±4.2 kg/cm2 respectively. The averages of LSST 1 and 3 position among the participant with FHD posture have been found statistically significant difference ($p < 0.05$).
CONCLUSION: This study provides evidence that adults with FHP was more affected scapular movement disorders. The FHP is known as an internal factor that causes dysfunction with shoulder and neck, therefore scapula kinematics should be evaluated in postural disorders.

THE EFFECTS OF COMPETITION LEVEL ON THE PREVALENCE OF LUMBAR DISC DEGENERATION IN GYMNASTS

KOYAMA, K.1, NAKAZATO, K.2, HATAKEDA, Y.2, SEO, K.2, NAKASE, T.2, KUBO, Y.1, TEJIMA, R.1, HIRANUMA, K.2
1. TOKYO ARIAKE UNIVERSITY OF MEDICAL AND HEALTH SCIENCES 2. NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: Several magnetic resonance imaging (MRI) studies have shown that gymnasts have a high prevalence of lumbar disc degeneration (LDDG). Some risk factors contributing to LDDG are age, obesity, genetic factors, and excessive physical loading. An MRI study of 33 competitive female gymnasts showed that 9% of the pre-elite, 43% of the elite, and 63% of the Olympic-level gymnasts had spine abnormalities (1). However, in that study, only female gymnasts and certain types of spine abnormalities were considered with a small sample size. Thus, the prevalence of LDDG in gymnasts depending on different levels of competition has not been clarified. The purpose of this study was to determine the prevalence of LDDG at each competitive level in Japanese collegiate gymnasts.
METHODS: The subjects were 298 Japanese collegiate gymnasts (203 men and 95 women). According to the competitive level, the gymnasts were divided into 3 groups: 43 athletes in the pre-elite group, (sporting experience, 8.2 ± 4.1 years); 219 athletes in the elite group (sporting experience, 13.7 ± 3.0 years); and 36 athletes in the international group (sporting experience, 14.4 ± 3.2 years). LDDG were

evaluated using T2-weighted MRI. The grading system for the assessment of LDDG was based on the Pfirrmann classification, with grades 3, 4, and 5 being considered as degeneration. The prevalence of LDDG and each level of competition were compared between the 3 groups using the chi-square test or Fisher exact probability test.
RESULTS: The prevalence of having 1 or more degenerated discs in the pre-elite group, elite group, and international group was 44.2% (19/43), 44.3% (97/219), and 50.0% (18/36), respectively (P = .810). The prevalence of LDDG was not associated with the level of competition. With regard to the spinal level, comparison of the prevalence of LDDG at each level between the 3 groups revealed that the spinal level of L1/L2 was significantly more frequently degenerated in the international group (P = .027).
CONCLUSION: We showed that the prevalence of LDDG was significantly high at the level of L1/L2 in the international gymnasts. A previous study reported that the prevalence of LDDG in elite swimmers was significantly higher than in recreational swimmers at the L5/S1 level (2). Therefore, we speculate that a specific motion might be considered to occur at the L1/L2 level during performance that causes mechanical stress at this level among international gymnasts. Notably, the prevalence of 1 or more degenerated discs was not associated with the level of competition in the present study. In conclusion, although the prevalence of 1 or more degenerated discs was not associated with the level of competition, the prevalence of LDDG was significantly high at the level of L1/L2 in international gymnasts.

PREVALENCE OF CHRONIC ANKLE INSTABILITY IN COLLEGIATE ATHLETES: THE INTERNATIONAL ANKLE CONSORTIUM DIAGNOSED CRITERIA

UDOMPANICH, N.1,2, HUNSAWONG, T.1,2, PHADUNGKIT, S.1,2, TIPSORN, W.2, SOPARAK, B.2, JAROONRAK, S.2

1: BNOJPH , 2: KKU

INTRODUCTION: Chronic ankle instability (CAI) is a result of recurrent lateral ankle sprains (LAS) and thereby leading to an early onset of ankle osteoarthritis (Gribble et al., 2014). Over the last 2 decades, an inconclusive definition and diagnosed criteria of CAI was conducted in the previous study resulting in an inconsistent prevalence of CAI with a range from 23 to 58% among athletic populations (Tanen et al., 2014; Simon et al., 2014; Mehta et al., 2015). Therefore, in 2014, The International Ankle Consortium provided a standard minimum of diagnosed criteria for CAI (Gribble et al., 2014). However, there is a lack of study observed the prevalence of CAI under the current criteria and there is no report demonstrated whether the difference in diagnosed criteria affects the prevalence of CAI. Hence, the present study determined the point prevalence of CAI using the standard minimum of diagnosed criteria and compared the finding with the previous reports.
METHODS: A cross-sectional study was conducted on collegiate athletes including soccer, running, volleyball, basketball and badminton players (mean age 21 ± 1.56 years). Participants completed a demographic data sheet, history of LAS and the Cumberland ankle instability tool (CAIT). Participants who met the following criteria including 1) had multiple LAS, 2) had the history of first LAS at least 12 months, 3) had the latest LAS at least 3 months, and 4) have a score < 24 on CAIT were diagnosed CAI (Gribble et al., 2014). One sample proportion test was used to compare the prevalence of CAI with the recruited previous reports.
RESULTS: Among a hundred participants, 9 participants have developed CAI estimated as 9% prevalence from the total participants (95% CI: 3.29-14.7). The highest prevalence of CAI was found in running, volleyball and soccer players, respectively. However, CAI was not found in basketball and badminton players. There were 3 previous reports recruited for analysis (Tanen et al., 2014; Simon et al., 2014; Mehta et al., 2015). The prevalence of CAI in this study was significantly lower than that in all previous reports ($p<0.05$).
CONCLUSION: Regarding the diagnosed criteria among the studies, the present study used the standard minimum diagnosed criteria of The International Ankle Consortium. While the previous study (Simon et al., 2014; Mehta et al., 2015) applied only a questionnaire such as CAIT and Identification Functional Ankle Instability (IdFAI) for diagnosing CAI. The present findings suggest that the variation of diagnosed criteria among the studies affect the prevalence of CAI. Therefore, further study should apply the standard minimum of criteria for providing more consistent characteristics of CAI participants to enhance the strength of research in CAI population.

THE CHONDROPROTECTIVE EFFECT OF EARLY PASSIVE MOTION COMBINED WITH INTRA-ARTICULAR PLATELET-RICH PLASMA (PRP) INJECTIONS ON ARTICULAR CARTILAGE AFTER ACUTE ANTERIOR CRUCIATE LIGAMENT RUPTURE

CHUNHAO, L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Anterior cruciate ligament (ACL) rupture is a common injury on athletes. Upon ACL rupture, it causes dramatic inflammation in in-situ knee joint and may further develops posttraumatic osteoarthritis (PTOA). Therefore, how to prevent PTOA is critical. Use of early continuous passive motion (CPM) may offer an enhanced chondroprotective effect. Platelet rich plasma (PRP) also may be a method for cartilage repairs due to containing growth factors for tissue regeneration. However, it remains to be investigated whether using CPM, with or without additional intra-articular PRP injection, in early ACL injury might provide chondroprotective effects and thereby further reduce the risk of PTOA.
METHODS: The rabbits were equally and randomly allocated to four groups: I) sedentary group (SED group), rabbits just kept in the cage. II) CPM group, rabbits performed the CPM exercise for continuously 7 days after ACLT. III) PRP group, rabbits were injected leukocyte-rich PRP (LR-PRP) once per week in ACLT one week later. IV) CPM+PRP group, rabbits performed the CPM and followed by PRP injection in the following three weeks once weekly. All animals sacrificed at week 4, lateral condyle(LC), medial condyle(MC), lateral tibial plateau(LTP), medial tibial plateau(MTP), patella trochlear groove (PG), and retro patella (RP) were taken out for gross appearance, histological stainings including hematoxylin and eosin for surface and chondrocyte alignment; Alcian blue for glycosaminoglycan content.
RESULTS: The PRP platelet concentration was significant higher 5-6 fold than whole blood (baseline). Leukocyte concentration was also higher than 2 fold, indicating LR-PRP.

Overall, the CPM groups and CPM+PRP group provided protective therapeutic effects in all compartments. With regards to gross appearance, the SED group resulted in irregular surface abrasion. Regarding histological analysis, compared to SED group, the CPM group had significantly better histological OA scores in lateral compartment (LC
CONCLUSION: Early CPM with or without additional intra-articular PRP injections shows a promising strategy for reducing the occurrence of PTOA after ACL injury. However, PRP containing with different leukocyte concentration warrants to be investigated.

ACUTE EFFECTS OF SELF-MYOFASCIAL RELEASE WITH FOAM ROLLING ON FLEXIBILITY, ARTERIAL STIFFNESS AND AUTONOMIC NERVOUS SYSTEM FUNCTION IN WOMEN

LEE, C.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Many individuals perform self-myofascial released(SMR) using a foam roller before/after sport, exercise. Myofascial release can improve the flexibility and range of motion of muscles, tendons, ligaments, and fascia by releasing tension in tight muscles of fascia. Stretched muscle fibers elicit cardiovascular adjustments through parasympathic activation and sympathetic deactivation. However, the effect of SMR of on arterial stiffness and autonomic nervous system is unclear. This study investigates the acute effect of SMR using a foam roller on arterial stiffness, autonomic nervous system and flexibility in women.
METHODS: Ten healthy young women(age, 23.20±0.59 y) and ten middle age women (age, 44.50±0.91y) performed SMR using a foam roller for 30 minutes. The participants performed SMR of the cervical vertebra, trapezius, lumber, glutes, hamstrings, quadriceps, adductor, iliotibial band and soleus. Brachial ankle pulse wave velocity(baPWV), augmentation Index(AIX), autonomic nervous system(ANS) and flexibility were measured before and after SMR.
RESULTS: In the middle age women group, AIX, which is associated with cardiovascular disease, significantly decreased (from 22.10±3.43 to 14.65±1.71) after SMR. (P=0.0259).
In both groups, the flexibility of shoulders and the flexibility of lower extremities significantly increased (P<0.0001).
In both groups, the changes of baPWV, RMSSD and SDNN were not statistically significant.
CONCLUSION: This study suggests that SMR using a foam roller decreases AIX and increases the flexibility. However, SMR does not affect baPWV and autonomic nervous system.

CP-MI16 App and method development

VALIDATION OF SMARTPHONE APP VOICE RECOGNITION PHYSICAL ACTIVITY SYSTEMS USING TRI-AXIAL ACCELEROMETER

NAMBA, H.

NIHON UNIVERSITY

INTRODUCTION: Online or Web-based measurement systems have been proposed as easy methods for collecting physical activity data. Smartphone applications and wearable devices are developing remarkably in recent years. We developed a physical activity assessment method using Web-based measurements systems in the past, but it took time to input as it was necessary to choose behavior. Therefore, we developed the voice recognition application for measurement of physical activity. This application collects daily behavior records using the voice and converts it into METs. The purpose of this study was to examine the validity of the voice recognition application physical activity using the tri-axial accelerometer.
METHODS: Twenty healthy subjects (18-24years, 14 male and 6 female) participated in this study. The behavior of all participants was recorded using a smartphone APP voice recognition physical activity systems over 1 week. At the same time, a triaxial accelerometer (Active style PRO HJA-750C, Omron) was attached to the waist. The metabolic equivalents (METs) for the participants was assessed everyday using the triaxial accelerometer (ACC) and compared with the respective METs estimated using the APP voice recognition systems (APPV). The criteria for the data to be analyzed by APP and ACC were set to 8 hours or more per day.
RESULTS: The mean METs estimated using the APPV was 1.72 (SD 3.10), while the mean METs from the ACC was 1.47 (SD 0.28). The Pearson's correlation METs between the two methods was r = 0.815 (P < .01). The Bland–Altman 95% limit of agreement was 0.15 to 0.33 between the two methods. The Pearson's correlation METs between the two methods was r = 0.259 (P = .282). The average time of voice action record to APP was 10 hours 58 minutes. On the other hand, the average wearing time of ACC was 13 hours and 8 minutes.
CONCLUSION: Average METs per day by APPV showed high correlation with accelerometer. However, the average METs suggested the possibility of overestimating on the basis of accelerometer. Diary methods for the assessment of physical activity have been used since the 1960s. In the system we made in the past, validity was high by verifying with the DLW method and ACC, but the behavior record method required time-based recording, which I equested the user input time and effort. In recent years, the technology of speech recognition has made remarkable progress, and in this research, we attempted to record behaviors by voice of themselves. The result of this research is to reduce burden on users even if poor compliance of wearing of devices, and to evaluate simultaneous physical activity of many people.

DEVELOPMENT OF A MACHINE LEARNING METHOD TO EVALUATE KARATE SKILLS FROM INERTIAL SENSOR DATA

SHIMPEI, A.1,2, HIROYASU, I.2

1: JAPAN INSTITUTE OF SPORTS SCIENCE, 2:WASEDA UNIVERSITY

INTRODUCTION: Our research aimed to develop algorithms to evaluate the quality of karate motions. Kata is the representation of karate's self-defense techniques strung together into a performance routine. Kata is judged based on several technical and physical criteria including speed, strength, focus, breathing, balance, and rhythm. For this reason, evaluation of karate motions is challenging. Here, we

complied a dataset of karate movements from inertial sensors. We then developed a machine learning method to evaluate these karate motions.
METHODS: A. Dataset creation
The subjects were 22 members (15 males, seven females, age 20 ± 1.3 years) of Waseda University's Karate club who competed at the international and regional level. Inertial sensors were attached to five body parts (forearms, lower legs, and waist) and the subjects performed fundamental movements in karate (reverse punch, upper level block, and front kick) as the target actions. Subjects performed 30 trials for each action. The quality of each action was scored by an official referee as the ground truth. Also, the quality of each action was scored by subjects self-assessment as the comparison. Finally, the resulting data was distributed into the learning dataset and the evaluation dataset.
B. Development of the evaluation method
We developed a classifier that evaluates the quality of each action in the learning dataset in three stages. First, the importance of each feature was judged using ensemble learning (1, 2). The classifier then evaluated the karate motions using handcrafted features of high importance. Finally, the classifier constructed strong classifiers by combining weak classifiers.
RESULTS: Our evaluation method was applied to the test dataset. The matching rate of the estimated value and the ground truth was 0.830 ± 0.067 (Mean ± SD). Also, the accuracy of self-assessment was 0.326 ± 0.040. Also, there was significant difference at the 1%.
CONCLUSION: We created a novel dataset of referee scores and inertial sensor data of karate movements. We then developed a machine learning method for evaluating karate motions using this dataset. The proposed method could judge the movement with significantly higher accuracy than the subjects self-evaluation. We confirmed the possibility of expressing the tacit knowledge of the referee by applying machine learning to sensor data. We aim to develop a system to support improvement of karate skills using this technology.

A MOBILE APPLICATION FOR HOME-BASED EXERCISE INTERVENTION FOR PEOPLE LIVING WITH HIV

PLEBANI, M., BRAMBILLA, E., TURRINI, F., VITOBELLO, C., GIORDANI, A., MELONI, A., GALLI, L., LA TORRE, A., MERATI, G., CINQUE, P., BONATO, M.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Dropout from exercise interventions could be higher in people living with HIV than in patients with other chronic diseases. The aim of this study was to assess improvements of physical fitness and metabolic parameters in people living with HIV exercising with the support of a smartphone application, as compared to a control group wit
METHODS: This was a two-armed, parallel group, randomized controlled trial in which HIV-infected subjects were enrolled and assigned to either an experimental group (EG), which trained with a smartphone application, or a control group (CG), which trained with a hard copy training program. Physical activity program included an initial coach-supervised period of 4 weeks, followed by 12 weeks where participants were instructed to train independently. The program consisted of walking or jogging three times/week for 60 minutes. At baseline (BL) and after 16-weeks (W16), patients underwent measurement of peak oxygen consumption (VO2peak), body composition (%fat mass and %fat free mass by bioimpedentiometry), and metabolic parameters (total-, HDL-, LDL-cholesterol). Results are given as number (%) or median (IQR) values. Intention-to-treat analysis regarding an improvement of the 15% of VO2peak was performed with a Chi-Square test. Percentage changes between BL and W16 regarding EG and CG were assessed by Wilcoxon matched-pairs signed rank test.
RESULTS: Forty-eight participants were screened and 38 were eligible: 20 were allocated to the APP group and 18 to the No-APP group. The two groups did not significantly differ in demographic and BL laboratory parameters [overall: 27 males (71%), median age: 50 (IQR, 45-56) y-o, BMI: 24.8 (22.5-27.4) kg/m2, current CD4+: 672 (579-846) cells/µl; nadir CD4+: 289 (228-418) cells/µl]. All patients were cART treated with undetectable HIV-RNA. Two APP and two No-App participants were not included in the analyses because they missed W16 evaluation. The remaining 34 participants had a median training adherence of 100% (IQR: 91-100%) during the initial coach supervised period with no differences between groups. During the autonomous training period (week 5-16), median adherence was 60% (IQR: 50-80%) and 54% (IQR: 31-76%) in the APP (based on app reports) and No-App (self-reported) participants, respectively (p=0.517). ITT analysis showed a W16 improvement of >15% of VO2peak in 13 of 18 (72%) APP participants, but only in 3 of 16 (19%) No-APP participants (p=0.025), and significant change differences in VO2peak, %FM, %FFM, total-, LDL-cholesterol, and triglycerides between groups. Significant W16 changes from BL were observed in APP but not in No-APP participants in VÀO2peak, %FM, %FFM, total-, LDL-cholesterol, and triglycerides. No significant change differences were observed in the other parameters.
CONCLUSION: In conclusion, the use of an app may be useful to motivate patients to perform a proper amount of physical activity, therefore improving health status.

VALIDITY AND RELIABILITY OF A SMARTPHONE MOTION ANALYSIS APP FOR LOWER LIMB KINEMATICS DURING RUNNING

MOUSAVI, S.H., HIJMANS, J.M., MOEINI, F., RAJABI, R., FERBER, R., ZWERVER, J., VAN DER WORP, H.

UNIVERSITY OF GRONINGEN

INTRODUCTION: Smart-phone applications (SPAs) are increasingly used to measure kinematics both in the field and laboratory setting. However, there is no evidence to support validity and reliability of SPAs for lower limb kinematics during running. The aim of this study is therefore to investigate the validity and reliability of a SPA for selected lower limb kinematics during running.
METHODS: Twenty healthy female recreational runners ran twice on a treadmill at a self-selected speed. Two video and three Vicon cameras were utilized to capture body movement for the sagittal and frontal plane when running on a treadmill. Sagittal plane lower limb kinematics and rearfoot in/eversion at touch down (TD) and toe off (TO) were measured using a 3D gait analysis system and a SPA, coach's eye app (CEA) installed on the smartphone (Samsung Note5, android). Intraclass correlation coefficient (ICC) was used to determine the test-retest, intra- and interrater reliability. ICCs and paired t-tests were used to establish criterion validity of CEA.
RESULTS: Results of ICC for criterion validity of SPA were excellent for in/eversion at TD (0.794) and fair to good (0.513 to 0.735) for other kinematics except for hip flexion at TD (0.356) being poor. Significant differences were found between the CEA and 3D measures for ankle angle at TD and knee angle at TO ($P<0.05$). Test-retest (0.8 to 0.917), intra-(0.949 to 0.985) and interrater (0.868 to 0.936) ICCs were excellent for all selected kinematics measured using CEA. The standard error of measurement (SEM) ranged from 0.81 to 1.90 for test-retest, from 0.43 to 1.1 for intrarater, and from 0.68 to 1.6 for interrater reliability. The minimum detectible change (MDC) ranged from 2.25 to 5.27 for test-retest, from 1.19 to 3.04 for intrarater, and from 1.9 to 4.44 for interrater reliability.

CONCLUSION: Excellent test-retest, intra- and interrater reliability measures of running kinematics were derived using the CEA. CEA is not a valid instrument for measuring ankle angle at TD, knee angle at TO or hip angle at TD during running, when compared to 3D motion capture system measures. However, the criterion validity was excellent for rearfoot in/eversion at TD. Therefore, the use of the CEA in clinical practice is proposed if it is utilized to compare the results in the pre- and post-intervention trials but cannot be utilized to compare those results with 3D measures in the cases of not being valid.

FAT CONTENT AND MUSCLE QUALITY OF THE QUADRICEPS MUSCLE ASSESSED BY ELECTRICAL IMPEDANCE MYOGRAPHY: CORRELATIONS WITH ULTRASOUND MEASUREMENTS

LONGO, S., CÈ, E., CORATELLA, G., DORIA, C., RAMPICHINI, S., SHOKOYAR, S., BORRELLI, M., LIMONTA, E., ESPOSITO, F.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Electrical Impedance Myography (EIM) has been proposed as a non-invasive approach for the assessment of fat content (FM) and muscle quality (MQ) [1]. A new portable device (Skulpt®Chisel) has been developed to estimate these parameters. The device is portable, battery-operated, and connected to a smartphone via Bluetooth®. The present study aimed to assess FM and MQ in a population of healthy young participants and to correlate them with FM and MQ measured by ultrasound.
METHODS: Twenty-five participants (12M, 13F; mean±SD: age=24±4.3yrs; stature=1.71±0.09m; body mass=63.0±10.0kg) underwent two EIM measurements over the quadriceps muscle at 50% of the femur length. FM and MQ were assessed by Skulpt (Skulpt®Chisel). EIM involved high-frequency (50KHz), low-intensity electrical alternating current applied to the muscle belly using 12 surface electrodes. Thereafter, the same area was scanned by ultrasound in the transverse plane. Six snapshots were taken with the same brightness and contrast parameters. Subcutaneous fat, muscle thickness (FT and MT, respectively) and echo intensity as muscle quality index (MQei, grey scale) were measured offline as average of 6 measures. EIM and ultrasound parameters were then correlated.
RESULTS: Significant correlations were found between: FM and FT ($r=0.94$, $p<0.01$), FM and MQei ($r=0.53$, $p<0.01$), and MQ and MQei ($r=0.47$, $p<0.05$). No correlation was found between MQ and MT ($r=0.29$, $p>0.05$).
CONCLUSION: FM and MQ assessed by EIM were correlated to subcutaneous FT and MQei obtained by ultrasound. Therefore, it seems that Skulpt can provide an index of fat percentage and muscle quality within the area of measurement in a quick and cheap manner. Further studies are needed to assess these correlations in other muscles and to check the applicability of Skulpt in monitoring training-induced changes in FM and MQ at local level.

CONTINUOUS MEASUREMENT OF ACETONE RELEASE DURING CYCLING AS A BIOMARKER FOR PHYSIOLOGICAL METABOLIC STATE; A PILOT STUDY.

KUPERS, B.A.M.1, SOER, R.1,2, DAMEN, C.1, REENALDA, J.3,4, OOSTERVELD, F.G.J.1

SAXION UNIVERSITY OF APPLIED SCIENCE

INTRODUCTION: Acetone is a substance being released through the skin during katabolic metabolism of free fatty acids in mitochondria. As such, it might be a valuable biomarker to detect physiological metabolic changes during sports and is hypothesized to be correlated to exercise intensity. Up to now, continuous measurement of acetone during sports have never been studied before. At Saxion University of Applied Sciences, a prototype device (based on optical interferometry) to measure acetone release via the skin has been further developed. One of the first steps of the project was to test a to compare acetone release with the relationship between exercise, heart rate and metabolism. We have done measurements to test this relationship with another sensor ('Dognose' with a Taguchi-sensor)
In the present study preliminary measurements have been carried out of the acetone release as a function of exercise intensity during a submaximal aerobic test. We hypothesized that acetone release in subjects would increase in the begin of the test and would decrease, after reaching a maximum level, within the range of 60-70% of estimated maximum HR (220-age).
METHODS: Healthy subjects were submitted to a cardiopulmonary exercise test (CPET) test with breathing gas analyses. In parallel gas samples released from their skin were collected and analyzed using a home-built acetone detector, based on Taguchi gas sensors. All subjects were asked to cycle at 60RPM with a stepwise increase in load of 2.5W/kg for men, and 2W/kg for women, until 80% of max estimated HR was reached. The first ventilatory threshold (VT1), the point after where carbohydrates are assumed to be catabolized dominantly, was determined after the test. Results were analyzed qualitatively to detect changes in acetone release.
RESULTS: Ten healthy volunteers participated in this study (4 men, 6 women). In 2 cases the data was severely affected by movement artifacts, leading to difficulties in interpretation. Results of 8 subjects could be analyzed and show that during and shortly after reaching VT1, for 5 of them acetone release decreased compared to the earlier stages of the test.
CONCLUSION: Continuous measurement of acetone detection on the skin during sports activity has not been performed before. The setup used in this study showed large artifacts whenever movement was too large during the test. This was to be expected when using the Taguchi sensor. When artifacts were deemed small, we could observe trends within most subjects that confirm the hypothesis that during exercise acetone mighty be an indicator for physiological metabolic state. Better controlled and larger studies, with a more stable optical sensor should be carried out to confirm this hypothesis.

NIRS ON A FUNCTIONAL SCALE OF 0-100%: ESTABLISHING PRACTICALITY OF THE MOXY MONITOR FOR SPORT SCIENCE

FELDMANN, A.1, SCHMITZ, R.2, ERLACHER, D.1

UNIVERSITY OF BERN,(1), FORTIORI DESIGNS LLC, US (2)

INTRODUCTION: Near-infrared spectroscopy (NIRS) has become readily available technology to monitor muscle oxygenation (SmO2) in applied sport settings. However, the technology is limited by its inability to convey quantifiable values, but rather offers relative change of oxy- and deoxyhemoglobin (O2Hb, HHb). In order to generate robustness for inter-individual and inter-location analysis and comparison an arterial occlusion method (AOM; 1) can be applied to generate a functional scale of 0-100%. On this scale 0% represents a maximally deoxygenated state defined by a disappearance of O2Hb in relation to the sum of O2Hb and HHb, and 100% a maximally oxygenated

state and the disappearance of HHb to the sum. The purpose of this study is to examine the practicality and reliability of an a priori determined 0-100% scale by a commercially available NIRS device, the Moxy Monitor (Fortiori Designs LLC, US), using the AOM.
METHODS: 22 participants completed a series of tests to scrutinize the a priori 0-100% scale modeled by the device. First, reliability was tested with AOM in back to back weeks. Then the feasibility of the 0-100% scale was tested firstly by comparing the AOM during passive and active conditions, and secondly by comparing the results for minimally and maximally obtained SmO2 (SmO2min and SmO2max) to a priori defined limits from invasive measurement results of mixed venous oxygen saturation (SvO2). Four devices were mounted on participant's legs.
RESULTS: The reliability test resulted in significant equivalency between all trials for SmO2min, TOST: -5.38 to 4.62, $t(54) = 4.85$, $p < 0.001$, and SmO2max, TOST: -6.13 to 3.87, $t(55) = -3.5$, $p < 0.001$. The 0-100% functional scale showed a good dynamic range for all muscle groups (Mmin = 10.1%±5.7; Mmax = 78.1%±6.0). During active and passive conditions the results for SmO2min were significantly equivalent, TOST: -7.69 to 2.32, $t(39) = 2.77$, $p = 0.004$. Tested against the a priori defined limits of SvO2, SmO2min was significantly lower than the SvO2 limit of 26% (2), $t(54) = -20.69$, $p < 0.001$; as was SmO2max, $t(54) = -8.53$, $p < 0.001$, for the SvO2 limit of 85%(3), as predicted.
CONCLUSION: The device exhibits an appropriate a priori defined functional scale between 0-100% that can be consider reliable and functional for application in sport.

SENSOR-BASED OBJECTIVE MEASUREMENT OF PHYSICAL ACTIVITY IN SWISS ARMED FORCES

OESCHGER, R., ROOS, L.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM

INTRODUCTION: For many recruits and recruits of the Swiss Armed Forces, the physical demands of daily military life are greater compared to civilian daily life. A study by Wyss et al. (2012) investigated total energy expenditure (TEE) and distance covered on foot in different occupational specialties of the Swiss Armed Forces during basic military training (BMT). They observed that average TEE decreased significantly from week 2 to week 8 of BMT (Wyss et al. 2012). In recent years, the Swiss Armed Forces reorganized BMT with now progressively increasing intensities in daily activities and physical training. The aim of this study was to assess TEE and distance covered on foot in armored infantry and communication intelligence today.
METHODS: All male recruits from one company of two occupational specialties of the Swiss Armed Forces were asked to volunteer for the study. Twenty volunteers from each BMT school were chosen to participate after they gave written consent to participate in the study. Participants wore a heart rate (HR) monitor (Rhythm24; Scosche Industries Inc., Oxnan CA, USA) on the upper arm, one accelerometer (Axiamo PADIS 2.0, Axiamo GmbH, Biel, Switzerland) on the hip and another accelerometer on the backpack during each day of weeks 2-9 during BMT. The sensors were worn from getting up in the morning until going to bed in the evening and placed on the non-dominant side of the body. The sensors were programmed to store HR, hip acceleration, step count and backpack acceleration data at 2s epoch time. Energy expenditure estimations and distance covered on foot were based on algorithms developed by Wyss et al. (2010, 2011 & 2012). Resting energy expenditure (REE) was calculated with the formula developed by Mifflin et al. (1990).
RESULTS: The 40 participants were 20.0 ± 1.5 years old, 179.6 ± 6.8 cm tall and weighed 71.7 ± 9.9 kg. As in the study of Wyss et al. (2012) only days with data greater than 480 min were included in the analysis. Recruits of the armored infantry and the communication intelligence had a TEE of 20.2 ± 2.5 MJ and 22.0 ± 2.4 MJ per day, respectively, and covered a distance of 13.9 ± 3.6 km and 9.5 ± 1.4 km per day , respectively.
CONCLUSION: The recruits of the armored infantry had a similar TEE such as the data reported by Wyss et al. (2012). Communication intelligence' recruits TEE was greater in this study (22.0 ± 2.4 MJ compared to 15.4 ± 1.8 MJ per day). Daily distance covered on foot was lower in armored infantry (13.9 ± 3.6 km) compared to the study eight years ago (15.6 ± 1.9 km) (Wyss et al. 2012). Distance covered on foot by the communication intelligence' recruits was 7.7 ± 1.5 km per day, in the present study the daily distance was increased by 1.8 km. Sensor-based objective measurement provides important information about daily physical activity in BMT. However, currenty monitoring systems must be improved further, to steadily record data over several days and minimize data loss due to technical problems as much as possible.

THE ESTIMATION OF CALORIC CONSUMPTION ON A NEW ELLIPTICAL MACHINE

FEDELE, G.1, CUZZOLIN, F.1,2, SENNI, S.1, ZOFFOLI, L.1,3, NICOLETTA, R.1, ZANUSO, S.1,4

1. TECHNOGYM SCIENTIFIC DEPT., CESENA, ; 2. UNIVERSITY OF PADOVA, ITALY; 3. UNIVERSITY OF URBINO, ITALY; 4. UNIVERSITY OF COVENTRY, UNITED KINGDOM

INTRODUCTION: When exercising on a cardio equipment, oxygen (O2) consumption and caloric expenditure related to a given exercise intensity can be estimated by means of specific metabolic equations (ME). Aim of this study was to create a new ME to predicts on the new Technogym Elliptical Machine (TE) O2 consumption and caloric expenditure from the external power output. The TE is an aerobic machine that has been developed to carry out a movement on the sagittal plane along an elliptical trajectory that can be changed in inclination. The equipment is moved applying alternatively a force on two pedals connected and synchronized with two upper levers. To estimate on TE the O2 consumption related to a given external power output it was not possible to refer on previously developed ME
METHODS: A group of 32 healthy individuals (19 male and 13 female; age 35.7 + 8.3; BMI 23.7 + 4.1) were enrolled in the study. All subjects familiarized with TE on two sessions.
They executed three separate sessions in non-consecutive days. On day one subject executed an exercise protocol where the load was gradually increased to obtain 4 different Rate of Perceived Exertion (RPE) levels corresponding to 8, 10, 12, 14 of the 6-20 RPE scale. Intensity was changed by increasing the external resistance without modifying the inclination set at 15°.

After two days of rest each subject executed four steady state steps at the external intensity (expressed in watts) corresponding to the RPE 10 of day one. At that intensity ramp inclination was set at 5°, 15°, 20°, 35°.
On day three, after other two days of rest they executed four steady state steps at the exercise load (expressed in watts) corresponding to RPE 12 of day one modulating the ramp inclination at 5°, 15°, 20°, 35°.
Each step lasted 5 mins to obtain a steady state condition; resting time between steps was of 5 mins. O2 consumption was continuously monitored with a metabolic cart (Cosmed Quark CPET, Rome Italy).
Overall, 362 steady state points were collected; at each steady state point both the related O2 consumption and the external load (expressed in watts) were recorded
RESULTS: The steady state VO2 at the four steps ranged from 13.1 to 51.3 (ml02.min-1.kg BW-1). For each of the 362 steady state points, the following variables were considered: O2 Consumption (ml02.min-1.kg BW-1); External Workload (Watts); Body Weight (kg); Gradient (%). By using those variables, the equation that better predicted the actual O2 consumption was: VO2 = 0,13 * Watt + 1090,28 / Body Weight + (0,0085*(Gradient)^2)-(0,2821*(Gradient))+1,13. Applying this equation, the correlation with the VO2 measured with the metabolic cart was r2=0,8493.
CONCLUSION: The ME developed by Technogym to predict the oxygen consumption and caloric expenditure based on external workload, subject's body weight and ramp inclination, provides a good estimate of the actual values.

CP-SH12 Exercise, cognition and performance II

EFFECT OF DIFFERENT COGNITIVE TASKS ON DUAL-TASK PERFORMANCE

ZHANG, L.1, SUDO, M.2, ANDO, S.3, KATAYAMA, K.1, ISHIDA, K.1

1: NAGOYA UNIVERSITY, 2: PHYSICAL FITNESS RESEARCH INSTITUTE MEIJI YASUDA LIFE FOUNDATION OF HEALTH AND WELFARE, 3: THE UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: When motor and cognitive tasks are performed simultaneously, the performance of one or both tasks should be affected by the dual-task interference. However, it is unclear that changing the type or difficulty of the cognitive task should affect each or both motor-cognitive dual-task performances. The aim of this study was to elucidate the effects of different types and difficulty of cognitive tasks on each performance.
METHODS: Ten young participants completed 5 cognitive tasks which were different in type and difficulty under rest condition for 2 min (single cognitive task; CT) in a random order. Thereafter, they pedaled on a cycle ergometer at the cadences which were 7.5 rpm faster than their preferred cadences as constant as possible. After the warm-up cycling for 5 min, they performed 5 cognitive tasks (dual-task; DT) in the same order preceded by cycling only task for 2 min (single exercise task; ET). Exercise intensity was adjusted to their 40% heart rate reserve. Trail Making Test-B (TMT; working memory and attention function), short memory task (memory function) and visual searching task (attention function) were used as the cognitive task. The difficulty of the last two tasks was adjusted to easy and hard levels by changing the target number or symbol of the cognitive task.
RESULTS: The coefficient of variation of pedal cadences during DT showed a significant increase during short memory task and TMT task as compared with that during ET. Under the DT condition, the average cadence tended to become slower than that during ET, but there was no significant difference between DT and ET conditions. As for the cognitive task performance, error rates during DT increased significantly in hard visual searching task (25±11.9% vs 32.1±5.9%) and TMT task (3.1±0.3% vs 8.7±5.2%) as compared with that during CT. However, reaction times during DT did not show any significant change as compared with those during CT. Furthermore, easy and hard level cognitive tasks also showed no significant difference in reaction times.
CONCLUSION: Cognitive task performances should decrease during cycling with cognitive task in visual search task and TMT task. Additionally, motor performances should decrease during cycling while doing short memory task and TMT task. As for the effects of different types of cognitive task, our results suggested that cognitive performance tends to be affected by cognitive task in which attentional function is involved. On the contrary, motor performances should decrease during cycling while doing cognitive task related to memory function. As for the effects of different level of cognitive task, our results suggested that the difficulty of cognitive task has little influence on the interference of dual-task.
It is concluded that motor and cognitive performances during DT should be reduced depending on the type of cognitive task, regardless of the difficulty of the task.

FUNCTIONAL CAPACITY, ISOKINETIC LEG STRENGTH AND SLEEP QUALITY CORRELATE WITH COGNITIVE FUNCTION IN MULTIPLE SCLEROSIS PATIENTS

GIANNAKI, C.1, ARISTOTELOUS, P.1, PATTICHIS, C.2, PANTZARIS, M.3, STEFANAKIS, M.1

1: DEPARTMENT OF LIFE & HEALTH SCIENCES, UNIVERSITY OF NICOSIA, CYPRUS, 2: UNIVERSITY OF CYPRUS, NICOSIA, CYPRUS, 3:THE CYPRUS INSTITUTE OF NEUROLOGY AND GENETICS, NICOSIA, CYPRUS

INTRODUCTION: Cognitive impairment is very common in Multiple Sclerosis (MS) patients (Jongen et al., 2012). Recent evidence suggests an association between functional capacity and cognitive function, at least in older adults (Yang et al., 2018). However, it is still not clear whether such an association exists also in MS patients. The aim of this cross-sectional study was to examine the relationship between cognitive function, functional capacity, isokinetic strength of knee flexors and knee extensors, sleep quality, handgrip strength and fatigue in MS patients.
METHODS: Fifty-one relapsing-remitting MS patients (age: 38.4 ± 7.1 y; female= 30) were recruited and agreed to participate to this study. Cognitive function was assessed by the Paced Auditory Serial Addition Test (PASAT). Functional capacity was examined using various functional tests such as the Timed Up and Go (TUG) test, two sit to stand tests (STS-5 and STS-60), and the six minutes walk test (6MWT). Maximal voluntary leg strength was assessed using an isokinetic dynamometer. Isometric handgrip strength was assessed by a dynamometer. Finally, the patients' sleep quality was evaluated using the Pittsburg sleep quality index and fatigue levels were evaluated using the fatigue severity scale.
RESULTS: A moderate correlation was found between the PASAT score and the score in various functional capacity tests such as the TUG test, the 6MWT and the STS-5 test ($p < 0.050$). On the other hand, a weak but statistically significant correlation was found between the

PASAT score and isokinetic strength of knee extensors and knee flexors (p <0.050). Sleep quality was negatively correlated with the PASAT score (r= -0.334, p=0.017). The regression analysis revealed that the performance on the STS-60 test was a significant predictor of cognitive function.
CONCLUSION: The results from the current study show a relationship between cognitive function, functional capacity and sleep quality in MS patients. Performance on the STS-60 test emerged as the best predictor for cognitive function among this sample of MS patients. It is still not clear whether improvement or maintenance of adequate levels of functional capacity could delay or prevent cognitive decline in MS patients. On the other hand, the association between sleep quality and cognitive performance revealed in the present study confirms existing literature. Functional capacity should be considered as a main contributing factor for impaired cognitive function in the MS patients.

THE RELATION BETWEEN PERCEPTUAL-COGNITIVE SKILLS AND COGNITIVE FUNCTIONS IN YOUTH VOLLEYBALL PLAYERS

DE WAELLE, S., BENNETT, S.J., LENOIR, M., DECONINCK, F.J.A.
GHENT UNIVERSITY

INTRODUCTION: Volleyball is a fast ball sport and – consistent with similar sports – we know that elite players outperform their less-skilled counterparts on tests for perceptual-cognitive skills such as anticipation and decision making. What remains unclear, however, is how these perceptual-cognitive skills develop in youth players, and to what extent this development relates to core cognitive functions. Therefore, this study aims to examine the relationship between perceptual-cognitive and cognitive functions in youth volleyball players.
METHODS: 145 Female volleyball players between 7 and 16 years old were recruited. Anticipation and decision making were assessed using video-based occlusion tests as a measure of sport-specific perceptual-cognitive skill. In these tests participants were to predict the direction of a pass (anticipation) or to decide the most optimal attack zone (decision making) as quickly and as possible using an adapted keyboard. As a measure for generic perceptual-cognitive function, a multiple object avoidance task was administered, i.e. a videogame where participants had to avoid multiple moving objects, using the computer mouse. Selected tests from the Cambridge Brain Sciences test battery were used to assess cognitive function. The selected tests measured core executive functions (inhibition, working memory, switching), higher level executive functions (planning, reasoning, problem solving) and attention.
RESULTS: Canonical correlation analysis demonstrated a significant relation (Rc=0.541; Wilks's Lambda=0.630; F(35,540.877)=1.797; p=0.004) between the set of perceptual-cognitive functions and the set of cognitive functions. The amount of shared variance was 37%. All variables in the perceptual-cognitive function set were valuable contributors to the canonical function, while the tests for reasoning, switching, planning and visual-spatial working memory were the main contributors for cognitive function.
CONCLUSION: These results show that the association between perceptual-cognitive and cognitive functions is already present in youth volleyball players. It is interesting to note that both sport-specific and generic perceptual-cognitive function contribute independently to this relationship. Furthermore, core executive functions (switching and visual-spatial working memory) as well as higher order executive functions (reasoning and planning) play a crucial role in this relation between cognitive and perceptual-cognitive function. Future research is warranted to examine how both perceptual-cognitive and cognitive function develop and how the relation might change with age. However, these results already give a strong indication for the consideration of perceptual-cognitive as well as cognitive functions in talent identification and development programs.

DOES A MENTAL TASK CAN INFLUENCE YOUR PHYSICAL PERFORMANCE? THE NEGATIVE EFFECT OF THE CONTROL CONDITION

MANGIN, T., ANDRÉ, N., BENRAÏSS, A., AUDIFFREN, M.
UNIVERSITÉ DE POITIERS

INTRODUCTION: There is a wide literature about acute mental fatigue, also called ego depletion, and its effect on physical performance. However, this effect seems to be inconsistent through the literature. Some experiments or meta-analysis find an effect (Bray, et al., 2008; Hagger et al., 2010), other have difficulties to find it (Carter and McCullough, 2014). In the current presentation, we hypothesized first that a long exerting mental task should produce an ego depletion effect in comparison to mental control group. Second, we hypothesized that the control condition can also produce negative effect on the participants.
METHODS: For the first experiment, using the sequential task paradigm, 118 young adults (age=20.42) completed two sessions. During the first session, participants realized an endurance handgrip task at 13 percent of their maximal voluntary contraction. One week later, during the second session, participants had to realize a mental task that last 30 minutes, a modified Stroop task or a congruent Stroop task (CST) for the control condition. Right after, they realized the handgrip task again.
In a second experiment, the control task used in the first experiement was compare to another control task (video) by 20 young adult participants. We compare on both task boredom, emotion and tiredness. We also compare the self-reported mental capacities used during the tasks.
RESULTS: The ego depletion effect was not replicated. Control and experimental group squeezed the handgrip during the same time between sessions and conditions F(1, 116)=0.03, p=.85. Complementary analysis using covariables will be presented.
For the second experiment, we found that the CST induced boredom, tiredness and negative change in emotion (all p<.05), whereas those effects were not observed in the video condition. No difference was observed concerning the mental capacities used in both conditions.
CONCLUSION: Only the second hypothesis was validated. The CST is often used as a control condition in the ego-depletion paradigm. However, as we presented here, this task is not as neutral as we could think. The replication's crisis and the debate about the ego depletion effect could be partially explain by the control task used.

ASSOCIATION BETWEEN LOCOMOTIVE SYNDROME AND COGNITIVE FUNCTION IN COMMUNITY-DWELLING OLDER ADULTS IN JAPAN

FUJITA, K.

OSAKA UNIVERSITY

INTRODUCTION: Cognitive function is an important component of health and quality of life in older adults. The Japanese Orthopaedic Association defined locomotive syndrome (LS) as a condition in which people may have high risks of requiring long-term care services due to locomotive impairment. Presence of LS is considered to be associated with cognitive function decline because of the reported relationship between cognitive impairment and sarcopenia, which has many factors in common with LS; however, such a relationship has not been shown in LS. Therefore, this study aimed to determine the association between LS and cognitive decline in community-dwelling older adults.
METHODS: Study participants included 3,751 community-dwelling elderly people (1,914 men and 1,837 women; mean age, 71.9 ± 5.7 years) who completed the 25-question Geriatric Locomotive Function Scale (GLFS-25) of the 14,906 people who responded to the questionnaire on care prevention distributed by the local government in Japan between 2014 and 2016. LS stage was assessed using total GLFS-25 scores (non-LS: scores ≤ 6; Stage 1: scores ≥ 7; and Stage 2: scores ≥ 16). The risk of cognitive function decline was assessed using applicable numbers of 3 cognitive-related items in the care prevention questionnaire (risk 1: applicable number ≥ 1; risk 2: applicable number ≥ 2). Univariate and multivariate logistic regression analyses adjusted for sex, age, motor function, nutritional status, and oral function were used to calculate the odds ratios (ORs) of LS stage for risk of cognitive function decline.
RESULTS: In the univariate logistic regression model, participants with Stage 1 and Stage 2 LS had higher ORs for risk 1 of cognitive function decline than those without LS (Stage 1: OR = 1.96, 95% confidence interval [CI] = 1.63-2.35 and Stage 2: OR = 2.43, 95% CI = 1.87-3.13); p for trend < 0.001). Similar tendencies were observed in the multivariate logistic regression model, although the association weakened (Stage 1: OR = 1.52, 95% CI = 1.25-1.84 and Stage 2: OR = 1.63, 95% CI = 1.22-2.15; p for trend < 0.001). Similar results were observed for risk 2 of cognitive function decline. The ORs of LS stages for risk 2 of cognitive function decline were as follows: a) univariate logistic regression model, LS Stage 1: OR = 2.14 (95% CI = 1.46-3.09); LS Stage 2: OR = 3.63 (95% CI = 2.28-5.64), (p for trend < 0.001) and b) multivariate logistic regression model, LS Stage 1: OR = 1.51 (95% CI = 1.01-2.24); LS Stage 2: OR = 2.07 (95% CI = 1.23-3.42), (p for trend < 0.01).
CONCLUSION: This study showed that LS stage had a significant positive association with relative risk of cognitive function decline in older adults, and this association strengthened with increase in cognitive function decline. Our results suggest that LS might be an independent factor for cognitive function decline in community-dwelling elderly people. A longitudinal survey for clarifying the causal relationship between LS and cognitive function is needed.

SOMATOSENSORY DYSFUNCTION IN CHILDREN WITH DEVELOPMENTAL COORDINATION DISORDER

TSENG, Y.T.1, CHEN, Y.W.1, LIU, C.C.1, TSAI, C.L.2, CHEN, F.C.3

1: NATIONAL TSING HUA UNIVERSITY, 2: NATIONAL CHENG KUNG UNIVERSITY, 3: NATIONAL KAOHSIUNG NORMAL UNIVERSITY

INTRODUCTION: Developmental coordination disorder (DCD) is a neurodevelopmental disorder characterized by poor motor skill learning and uncoordinated movements. It has been suspected that proprioception and haptic perception, two submodalities of the somatosensory system, underlie the motor problems in DCD. Yet, current evidence of somatosensory dysfunction in children with DCD and how it relates to their motor function are unclear. This study pursued the following aims: 1) To obtain objective measures of somatosensory function (wrist position sense and haptic perception) in children with DCD, and 2) To investigate the relationship between somatosensory and motor function in children with and without DCD.
METHODS: Nineteen children with DCD (Mean age ± SD: 10.53 ± 0.61 years; 9♂, 10♀) and nineteen typically developing (TD) children (Mean age ± SD: 10.37 ± 0.83 years; 10♂, 9♀) were recruited and screened using Movement Assessment Battery for Children (MABC-2). The DCD group had total MABC-2 score below the 5th percentile, and the TD group was above the 25th percentile. All participants performed two parts of somatosensory task: a wrist position discrimination task measuring position sense acuity, and a haptic curvature discrimination task measuring haptic acuity. With vision occluded, children were asked to discriminate two wrist positions or two curvature blocks. The test stimuli were generated using an adaptive algorithm (Ψ-marginal method), and psychophysical just-noticeable difference (JND) thresholds were obtained by fitting a logistic Weibull function to the response data.
RESULTS: First, in comparison to TD children, children with DCD exhibited significantly elevated position sense JND thresholds ($p < 0.001$), and higher haptic JND thresholds ($p < 0.001$). Second, position sense thresholds correlated significantly with MABC-2 manual dexterity ($r = -0.43$) and balance scores ($r = -0.57$). Third, children who had elevated haptic JND thresholds also showed higher position sense JND thresholds ($p < 0.05$, $r = 0.41$).
CONCLUSION: This study documents that DCD is associated with somatosensory dysfunctions (combined proprioception and haptic perception), which likely contributes to the motor problems in children with DCD.

MEDIATION OF GLOBAL SELF-WORTH ON THE RELATIONSHIP BETWEEN DEVELOPMENTAL COORDINATION DISORDER AND INTERNALIZING PROBLEMS IN GRADE 3 CHILDREN

LI, Y.C.1, TSENG, Y.T.2, CHEN, Y.W.2, LIU, C.C.2, NIEH, W.Y.2

1: CHINA MEDICAL UNIVERSITY, 2: NATIONAL TSING HUA UNIVERSITY

INTRODUCTION: Children with Developmental Coordination Disorder (DCD) are at greater risk for internalizing problems, such as anxiety or depression. As the underlying mechanisms behind this relationship were not clear, the Environmental Stress Hypothesis was developed by synthesizing the existing evidence to explain the possible mediating pathways from DCD to internalizing problems, through physical and psychosocial health (Cairney et al., 2013). Although this hypothesized framework has been widely examined and some of mediating pathways have been supported, it has not been tested in eastern cultural context. Therefore, the purpose of this study was to examine the mediating pathways proposed by the Environmental Stress Hypothesis in Grade 3 Taiwanese children.

METHODS: This was a cross-sectional study recruiting 127 children aged between 8 and 9 years. All participants were required to complete a survey regarding their physical activity, global self-worth, perceived social support from classmates/friends, and internalizing problems. The Movement Assessment Battery for Children – 2nd edition was used to evaluate their motor coordination. Children who scored below the 15th percentile were identified as probable DCD (n = 12, 11.8%). Based on the Environmental Stress Hypothesis, four specific sequential mediating pathways through physical activity/body mass index (BMI) and global self-worth/perceived social support were tested using the PROCESS macro for SPSS.
RESULTS: There were no differences in demographic variables (e.g., height and weight) between children with and without DCD. Compared to typically developing (TD) children, children with DCD also had similar levels of physical activity, BMI, perceived social support, and internalizing problems (all p's >.05). However, children with DCD have a significantly lower level of global self-worth ($p < .05$). It is worth noting that no sequential mediating pathway was identified in this study. Interestingly, when we further tested the single mediator pathways, there was a significant mediating effect of global self-worth on the relationship between DCD and internalizing problems (Effect = .4572, SE = .3056, 95% Bootstrap CI = .0121 - 1.1792).
CONCLUSION: Younger Taiwanese children (i.e., Grade 3) with DCD may have a lower level of global self-worth, compared to TD children, which could consequently lead to higher levels of anxious and depressive symptoms. Therefore, in order to improve these children's mental health, the enhancement of global self-worth should be integrated into conventional interventions or programs of motor coordination.

THE EFFECT OF ENVIRONMENTAL CONDITIONS ON DECISION MAKING OF FOOTBALL REFEREES'

SCOOT, C., STRÖMBERG, M., GAOUA, N.
LONDON SOUTH BANK UNIVERSITY

INTRODUCTION: Referees need to make sure the laws of the game are fairly and consistently applied. A top referee faces high psychological demands, with around 137 observable decisions made per match (Helson & Bultynck, 2004). It is well known that cognitive performance decreases under various stressors including, heat and altitude (Taylor et al., 2016; Asmaro et al., 2013). The aim of this study was to investigate the effect of heat and altitude on referees' decision making performance.
METHODS: Five healthy qualified referees (M = 25.8, SD = 4.8y; M = 80.8, SD = 10.2kg; M = 180.9, SD = 7cm) completed the study. Following a familiarisation, referees performed a Go-No-Go cognitive task and a 'referee specific video decision making task' during 90mins of intermittent treadmill exercise (Clarke et al., 2011). The protocol was completed under three conditions; normoxia (21 degrees C, sea level, CON), heat (30 degrees C, HOT) and hypoxia (3800m, HYP). The exercise protocol consisted of two 45-minute halves separated by a 15min break. During CON & HYP muscle and cerebral oxygenation were measured using near-infrared spectroscopy. During CON & HOT skin temperature was recorded. In all conditions, subjective levels of comfort, using visual analogue scales were obtained. Measures were analysed at four-time points, at the start and end of the first half (T1, T2) and the second half (T3, T4).
RESULTS: There was no significant effect of condition on decision making performance in the Go-No-Go task or video decision-making task at any time ($p>0.05$). Comfort and muscle oxygenation were also not affected by condition ($p>0.05$). Cerebral oxygenation was significantly different between CON and HYP ($F(1-4) = 52.21$, $p<0.05$) with a significant progressive decrease from T1 to T2 ($p=0.037$); T2 to T3($p=0.009$) and T3 to T4 ($p=0.019$). There was a significant increase in skin temperature from CON to HOT ($F(3, 15) = 31.79$, $p < 0.01$).
CONCLUSION: Exposure to hypoxia and heat individually did not have an impact on the decision making of referees in a match simulated exercise protocol. A decrease in cerebral oxygenation across the protocol could have been counteracted by the beneficial effects of exercise on cognitive performance. Alternatively, as suggested by Binks et al (2008), in hypoxic conditions, blood containing vital oxygen may be diverted to deeper structures of the brain to maintain executive function. For the heat condition as previously suggested by Gaoua et al (2011), the task was not complex enough to induce a decline in performance under heat stress. This protocol used a simulated environment attempting to replicate that of a referee; in a real match the pressure on referees is far greater and therefore the effects of environmental stress upon their performance could be more pronounced. Further investigations using more ecologically valid methods and bigger sample size are warranted to further explore these effects.

FINGER AND BALL MOVEMENT AT RELEASE IN RELATION TO ACCURACY IN BASEBALL PITCHING

KUSAFUKA, A.
THE UNIVERSITY OF TOKYO

INTRODUCTION: In baseball pitching, a pitcher is required to deliver a ball with high velocity and accuracy to the target located at about 20 m distance. This throwing movement is performed with the effectively coordinated whole-body motion, which is regarded as one of specific motor skills obtained after certain period of motor practice. Although numerous studies have succeeded to understand mechanical characteristics of baseball pitching, it is unknown how the baseball pitcher attains such higher pitch accuracy especially from the neurophysiological perspective. Therefore, we focus on the particular part of the pitching motion that needs fine adjustment to understand the pitching accuracy. It is known from previous studies that the accuracy of pitch location depends largely on variability in the timing of onset of finger opening, which is determined by back force from the ball. Pitch location is also thought to be related that opposing the back force, pitchers produce the flexion of finger. However, the relationship between pitching accuracy, flexion of finger, and the relationship between finger and ball at release is not entirely clear. Thus, in this study, we aimed to figure out the state of the finger and ball at release, and its influence on the pitch location.
METHODS: Baseball pitching to three different target courses of the professional pitchers was captured using 2 high-speed cameras (1000Hz) placed behind and on the side of the pitcher, and the three-dimensional positions of balls and index fingers for several tens of milliseconds near ball release were calculated by the DLT method.
RESULTS: Calculating each joint angle of finger and comparing it with pitch location, it was found that the pitch location tended to be higher and on the dominant side as distal interphalangeal joint at ball release was more flexed and the distal phalanx was more inclined in the elevation direction with respect to the horizontal plane. Moreover, creating an indicator showing where the finger touches the ball at release, it was shown that the finger tended to be at the lower part of the ball, when the pitch location was high.

CONCLUSION: It can be considered that greater flexion of the joint occurred, because the back force the finger received from the ball was small when the finger touched the lower part of the ball at release compared with when it touched the higher part. Probably as a result, the pitching angle was directed to the upward on the dominant side and the ball reached as it was. Since the differences were shown in these values, when comparing for each target course, it can be considered that pitchers may make some fine adjustment depending on the target position. This study is expected to contribute to understand the neural mechanisms underlying the accurate ball control skill in well-trained baseball pitchers.

PERFORMANCE ANALISYS IN PROFESIONAL ICE HOCKEY: USING TRACKING DATA TO COMBINE TACTICAL AND PHYSIOLOGICAL ANALYSIS

KOMAR, J.1, GIRARD, J.2, BROWNLEE, T.E.3, MCROBERT, A.P.3

1.NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY, 2. UNIVERSITY OF ROUEN, 3. LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Ice hockey is a sport that requires repeated, high-intensity bouts of skating, interspersed with on-ice gliding and rest between bouts, leading to high rotations between players (i.e., every 40 seconds in average) (1). Although heart rate (HR) has been used to assess the fitness demands of such an intermittent activity (2), in the present research we sought to investigate the HR of players in relation to actual time on ice versus time in activity and time at rest.
METHODS: During a whole regular season and during the playoffs (quarter-final to the final) of the French National Hockey League, the HR of every player was recorded during all the games using a Firstbeat® wireless system. This allowed physiological tracking of players specific to periods spent in activity (on ice with the clock running) and resting periods. Both time series were subsequently synchronized. In addition to regular measurement (HRmax, time above 80%HRmax, time above 90%HRmax, see (2)), "rate of recovery" was calculated as the exponential decrease of HR during the 60 s from the end of each bout of play. The sampling rate of all measurement was set at 1Hz.
RESULTS: Time on ice varied between players during a single game (mean = 12.4min, std = 4.6). Players performed 22.2 (std = 2.3) bouts on the ice during a game, therefore around 22 exponential decrease indexes were computed for each player per game. The average exponential coefficient was 0.0051, with a range between 0.0029 for the slowest and 0.0124 for the fastest recovery. In average, the rate of recovery appeared significantly slower during the playoffs compared to the regular season. Interestingly, for some players, the rate of recovery was faster during the last third of the game compared to the first one.
CONCLUSION: Combining time on ice and heart rate allows the assessment of player recovery rates in-between each bout. Due to the high-level of player rotations in ice-hockey, this indicator can be used to determine physical demands. Also, the investigation of individual dynamics within the game seemed relevant for future investigation.

QUANTIFYING COLLECTIVE PERFORMANCE IN RUGBY UNION.

SAULIÈRE, G., DEDECKER, J., MOUSSA, I., TOUSSAINT, J.F., SEDEAUD, A.

INSEP

INTRODUCTION: The aim of this study was to quantify collective experience based on cumulative shared selections of players and to assess its impact on team performance in international rugby union.
METHODS: Scoresheets of all games involving at least one of all 10 nations participating at the Rugby Championship and the Six Nations Championship were collected from the end of the 1999 Rugby World Cup (RWC) up to the 2015 RWC final. A single indicator quantifying the cumulative shared selections (CSS, e.g. the number of selections that each player has shared with the other ones) was computed for each match as a key collective experience indicator. The World Rugby Ranking points of each nation and the percentage of victories were used to estimate team performance. The study period was divided into sequences of 4 years; each sequence corresponds to the period between two consecutive RWCs. For each sequence and nation, slopes and intercept of CSS trends were computed along with victory percentage and mean ranking points. Multiple linear regression analysis was used to establish the associations between team performance and experience.
RESULTS: Mean number of games played by the 10 nations over a sequence is 45.9 ± 6.9, involving an average of 62.1 ± 7.6 different players. Regarding the experience indicators, mean number of CSS over a sequence is 860.4 ± 284.9 and it evolves, on average, with a slope of 7.9 ± 8.1 and an intercept of 677.0 ± 287.5. Regarding performance indicators, the ten nations completed the sequences with mean ranking points of 82.21 ± 5.59 and a mean victory percentage of 55.27 ± 18.95. In multiple linear regressions, CSS slope is found to be significantly associated with both ranking points (p Value = 0.042) and victory percentage (p Value = 0.001), adjusted on the CSS intercept.
CONCLUSION: For the first time, a single estimator (CSS) allows to relate the evolution of a team's experience and its performance through time. This study reveals the potential of this indicator. It would be captivating to transpose this methodology to other team sports and other competition formats, such as a championship. Investigating more precisely the links between players through social network analyses would also make it possible to discretise relationships and detect key individuals or groups of individuals. National managers need to create the most competitive squad for each competition. They have to decide what to do with the time and few games to play that are given to them. The number of cumulative shared selections is a parameter that could help them in the decision making process.

DOES DIFFERENT FACIAL DIRECTION INFLUENCE THE SWIMMER'S HORIZONTAL POSTURE?

MORIYAMA, S.1, WATANABE, Y.2, KURONO, T.1, MIZUKOSHI, H.1, WAKAYOSHI, K.3, SHIBATA, Y.4, OGITA, F.5

1: TOKYO GAKUGEI UNIVERSITY, 2: SENDAI UNIVERSITY, 3: OSAKA UNIVERSITY OF ECONOMICS, 4: TEIKYO UNIVERSITY OF SCIENCE, 5: NATIONAL INSTITUTE OF FITNESS AND SPORTS

INTRODUCTION: Breathing styles and/or body shapes in water are affected by the positions of center of mass (CM) and center of buoyancy (CB) associated with horizontal posture (2). The differences in CM and CB affects the leg-sinking torque and the energy cost during

swimming, and consequently, the swimming performance. In the present study, we examined whether the different facial directions, seen during respiration while swimming, influences the position of CM and CB associated with horizontal posture in water.
METHODS: Twelve participants maintained the horizontal posture with both arms raised (streamline) on land and in water. In this study, the participants turned their face in two direction, one is the neutral condition without flexion or extension on their neck (NSL), the other is the extensional condition of neck with their face forward (FSL). The total length of the participants was defined as the distance from the foot (lateral malleolus) to the hand (center of the fist) of each participant. CM and CB were expressed as distance from the participant's foot. CM was measured by the reaction board method which used the force plates (1). CB was calculated using the force exerted on a vertical direction with two load cells attached to the hands and feet, respectively. On measuring CB, a snorkel was attached to each participant's head and they were instructed to breath once every 10 seconds (5-s maximal inspirations, 5-s maximal expirations) (3). CB were expressed as the values of zero buoyancy obtained from the regression line of the inspiratory volume and buoyancy during the CB measurement in each participant and compared between different facial directions. The distance between CB and CM were determined as the difference between them.
RESULTS: The total length of the streamline position in NSL (207.4±6.2 cm) were significantly longer than the length of FSL (206.3±6.5 cm) ($p < 0.05$). Both CM and CB of NSL（CM, 103.10±3.49 cm; CB, 104.80±3.61 cm） were significantly higher than the CM and CB of FSL (CM, 104.50±3.65 cm ; CB, 102.75±3.56 cm), respectively ($p < 0.05$). There were no significant differences in inspiratory volume (NSL, 2.34±0.68 ℓ; FSL, 2.46±0.68 ℓ) and the distance between CB and CM (NSL, 1.70±0.29 cm; FSL, 1.75±0.22 cm) between the two postures ($p > 0.05$).
CONCLUSION: As reported earlier (3), the difference in CM could be attributed to the difference in the total length of the body. Additionally, no significant difference was observed in the inspiratory volume between NSL and FSL. However, the average inspiratory volume in FSL was larger by 0.12 ℓ compared to the volume in NSL. Therefore, the difference in CB might be influenced by the small amount of air in the lungs. In conclusion, it is suggested that different facial directions would change the CM and CB of horizontal posture.

ANALYSIS OF FACTORS INFLUENCING THE HEIGHT OF THRUST MOTION IN ARTISTIC SWIMMING

MURO, O.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: Artistic swimming (AS) is an event that is scored on the basis of acrobatic lift motion in addition to underwater artistry and synchronicity. The skill of raising the legs high above the surface of water vigorously is called thrust under the basic operation of AS. This thrust motion requires a pike position underwater, floating using buoyancy, movement in a segmental extension (unroll) of the pelvis and trunk, movement by scratching the water with the hands, and positioning the legs high on the water surface. The teaching method for this movement and the learning ability of athletes differ. The optimal teaching method and necessary physical function have not been elucidated yet. In this research, we aimed to analyze factors that influence the height of the thrust motion.
METHODS: Six AS athletes (age, 20.83 ± 2.19 years), who provided informed consent, were included in the study. Of the six players who competed at the national level, three obtained medals at international conventions and the other three were athletes at university championship victory level. The subjects performed underwater thrust motion, which was analyzed using three-dimensional motion analysis equipment (Venus3D, Motive; Novitec) and recorded using 7 underwater motion capture cameras. The analyzed items were the height of the thrust (determined by measuring the distance the outer malleolus marker surfaced out of the water (thrust index [TI])); the angles of the trunk and lower limbs at the start of the thrust; the maximum rotational speed of the pelvis; and the maximum pelvic, and hip joint flexibility. The correlation between these items and the value obtained by dividing the height of the thrust by the length of the lower limb was determined.
RESULTS: The mean TI of the subjects was 92.92 ± 11.83 cm, which was higher for Japanese national team players. The angle between the trunk and lower limbs at the start of the thrust was 44.27° ± 9.28°, the maximum rotation angular velocities of the unroll in the pelvis was -340.23° ± 205.76°/s, and the flexibility of the pelvic and hip joints was 55.33° ± 9.36°. These items and TI were most correlated with the pelvic, and hip joint flexibility and the angular velocity of the unroll -0.79 and -0.68, respectively.
CONCLUSION: Thrust motion is important for pelvic, and hip joint flexibility as well as unrolling speed. However, these objective numerical quantifications have not been elucidated owing to the technical problems of performing three-dimensional motion analysis in water. This study revealed that the athletes who had high competition levels also had high thrust ability. Further, it clarified that pelvic, and hip joint flexibility was the most important influencing factor of thrust height. Beyond providing technical guidance when teaching thrust, training to ensure these physical functions is important.

ASYMMETRIES OF MUSCLE STRENGTH IN LOWER LIMB MUSCLE TWITCH DURING STRETCH-SHORTENING CYCLE MOVEMENT IN COLLEGIATE ALPINE SKIER

KASHIWAGI, Y.1, HIRANO, T.2, SOMA, M.3, FUJITO, Y.2, HAKAMADA, N.4, TAKEGOSHI, M.2, FUNATO, K.2

1:SENSHU UNIVERSITY INSTITUTE OF SPORT, 2:NIPPON SPORT SCIENCE UNIVERSITY, 3:JUMONJI UNIVERSITY, 4: JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: In alpine skiing competition, repeating the continuous turn the gate are assumed as made of the stretch-shortening cycle in lower limb musculature. As the competition race course is not a constant slope change, symmetry of lower limb muscle strength is important for athletes in order to react on various course situations. Repetitive jump training is one of the most used training methods because it is close to the alpine skiing movement style. Since skiing is a falling movement, it is important to select lower limb function properly in eccentric contraction phase (ECC) and concentric contraction phase (CC). The purpose of this study was to investigate mechanical lower-limb muscle strength asymmetry on difference contractile characteristic during jump movement in collegiate alpine skier.
METHODS: Twenty-one collegiate alpine skiers including national team athlete (male n=14, female n=7) were participated in this study. Before the jump test, the muscular strength of the knee and the power of the lower limb were measured. Subjects performed squat jumps (SQJ), counter movement jump (CMJ) and repeated five times squat rebound jumps (SQRJ) on dual force plate system (Kistler inc. Switzerland) that was capable of simultaneously measuring the vertical ground reaction force (Fz) recorded at 2kHz sampling frequency

during the jumps. The velocity of the body center of mass (CM) was obtained by time integration of the instantaneous acceleration signal calculated from Fz. From the velocity of the CM, the eccentric deceleration phase was defined as the time interval from the maximum negative velocity to zero velocity (deepest squatting position), whereas the concentric phase was defined from this instant of zero CM velocity to the instant of jump takeoff. The CMJ and SQRJ total kinetic impulses for the right and left limb were then calculated separately for the eccentric phase and concentric phase by time integration of the force–time curve. The knee extension-flexion muscle strength, leg press power and jump kinetic impulse asymmetry index (AI:%) was calculated from Impellizzeri F. M. et al. (2007) for each contraction phases. All statistics analysis was used by two-way ANOVA (Jump condition×contraction phase) performed on selected means to detect significant differences (effective P<0.05, SPSS ver.25 IBM).
RESULTS: AI of muscle strength and power of lower limbs were 7.2±5.9% (Knee extension), 7.0±8.0% (Knee flexion) and 7.4±5.6% (Leg power) respectively. The average AI of the concentric contraction phase was 6.0±4.6%, and there was no significant difference between the three jump conditions. However, in CMJ and SQRJ, AI tended to be significantly greater in eccentric contraction phase compared with concentric one (CMJ; CC5.6±3.3% VS ECC 8.8±5.8%, SQRJ;CC6.4±6.3% VS ECC12.7±7.6%, P<0.05).
CONCLUSION: Assessment of asymmetry for muscle force outputs in both leg during stretch-shortening cycle movements might be useful as one of the effective alpine skiing training.

ESTIMATION OF HAND PROPULSIVE FORCES AT FOUR SWIMMING TECHNIQUES USING PRESSURE MEASUREMENT AND UNDERWATER MOTION CAPTURE

TSUNOKAWA, T., KAJI, T., MANKYU, H., OGITA, F.

NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Pressure measurement and underwater motion capture analysis has recently developed and is being applied to swimming research. Via simultaneous analysis using these techniques, fluid forces acting on the swimmer's body can now be analysed. Therefore, through pressure measurement and underwater motion capture analysis, this study aimed to estimate hand propulsive forces during four swimming techniques.
METHODS: Four male college swimmers participated in this study. Participants swam a 25 m at four swimming techniques with maximal effort. During trials, pressure measurement and underwater motion capture analysis were performed simultaneously. Using method reported in previous study (Tsunokawa et al., 2018), pressure measurement was used to estimate the pressure forces acting on both hands and the underwater motion capture analysis was used to analyse the direction of the pressure force. Six waterproof pressure sensors and five reflective markers were attached to landmark points on each hand. We estimated resultant pressure forces by multiplying the projected areas and the pressure differences between the palm and dorsal side of each hand. Acting directions of resultant pressure forces were analysed using a normal vector perpendicular to each hand, calculated from coordinates obtained using underwater motion capture analysis. In the present study, pressure forces acting on the swimming direction (y-axis) were defined as propulsive forces. Additionally, we calculated mean swimming velocity from coordinates of the midpoint of both hip during a stroke cycle.
RESULTS: As a result, hand propulsive forces and its fluctuations were estimated with no problem in any swimming techniques for all participants. Mean propulsive forces showed 58.2 ± 17.7 N for butterfly, 41.6 ± 11.1 N for backstroke, 40.0 ± 15.3 N for breaststroke, and 57.0 ± 8.8 N for front-crawl. Characteristics of each participants for each swimming technique could be evaluated from the fluctuation of hand propulsive forces. Propulsive forces showed multiple peaks during one stroke cycle along with the hand movement.
CONCLUSION: Swimmers who showed higher propulsive forces did not necessarily achieve higher swimming velocity. Similarly it did not necessarily show higher propulsive forces in faster swimming technique. Such results may be related to the fact that swimming velocities are related to active drag forces as well as propulsive forces. It was confirmed that pressure measurement and underwater motion capture analysis are useful for estimation of hand propulsive forces in four swimming techniques. Further research on hydrodynamics of swimming using this method can be expected.

THE INFLUENCE OF SKI WIDTH ON PERCEPTUAL CHARACTERISTICS DURING TRAINING IN YOUNG ALPINE SKIERS

SEIFERT, J.G.1, NUNNIKHOVEN, H.1, SNYDER, C.1, KIPP, R.W.2, DECKER, M.3

1: MONTANA STATE UNIVERSITY, BOZEMAN, MT USA, 2: SQUAW VALLEY, CA USA, 3: ROCKY MOUNTAIN CONSORTIUM FOR SPORTS RESEARCH, EDWARDS, CO USA

INTRODUCTION: Wide skis (WS) have become popular on all types of terrain and are the most popular ski sold in the USA (SIA, 2017). However, there are differences in ski technique between WS and narrow skis (NS) (Seifert et al., 2018). Psychological attributes play a role in sport performance. Martin & Gill (1991) reported that confidence in an activity is a predictor of performance. Performance in young athletes, especially, can be affected by levels of self-confidence and aggressiveness. Perceptions of performance and effort are factors that can add, or detract, from learning a movement. What is not known is how ski width affect performance and perceptual responses in young developing ski racers. The purpose of this study was to assess perceptions and performance in young ski racers after skiing WS and NS in a race type course.
METHODS: This study was IRB approved and informed consent was collected. Five males (mean (+/-SD) age: 12.9 (0.7) y old) and eight females (12.8 (0.5) y old) participated. Skiers used their own NS and WS (NS: 64 mm, WS: 98 mm underfoot ski widths). Data was collected on a groomed run with an intermediate pitch. Courses with poles set at 10m diagonal by 4m offset and 18m diagonal by 6m offset, both with 13 turns, were used. The course set distances were chosen to not bias either ski. A 10 pt Likert scale to assess confidence, aggressiveness, and racing line was completed at the end of each course. The scale ran from 1 (not at all) to 10 (most favorable). A 9-channel motion sensor measured edge angle and turn time. A Kruskal-Wallis nonparametric test was used to analyze data.
RESULTS: Confidence was greater for NS than WS on both courses [p<0.001; 10m: 7.8 (2.2) vs. 4.5 (1.8) and 18m: 8.0 (2.3) vs. 6.0 (1.9)], aggressiveness was greater for NS than WS [p=0.01; 10m: 6.0 (1.9) vs. 4.1 (1.4) and 18 m: 6.7 (1.6) vs. 5.5 (1.9)], perceived racing line was greater with NS than WS [p<0.001; 10 m: 6.3 (2.4) vs. 3.9 (2.3) and 18 m: 8.1 (0.9) vs. 5.8 (2.2)]. NS resulted in faster turn times than WS [p=0.04; 1.29 (0.22) vs. 1.34 (0.25) sec], edge angle was greater for NS than WS [p=0.05; 51 (4) vs. 47 (14) degrees].
CONCLUSION: Although it makes sense that WS would ski differently than NS, differences could also be representative of a feedback mechanism of motor activity patterns. This difference may alter the learning of a skill. The feeling of task completion with competence has been shown to increase motor learning of sport skills. Feeling confident, being aggressive, and skiing on line can make a positive impact on the timing and tactics of a training run, perhaps by decreasing inhibition and creating more effective movements. Young racers and coaches need to be aware of the implications of skiing WS while the athlete is still developing.

ASSESSMENT OF THE RELATIONSHIP BETWEEN ATHLETES PHYSICAL ABILITY AND PHYSICAL CONDITION

YOON, J.1, FUJII, K.2,3, TANIGAWA, S.1, YOSHIDA, T.1, FUJII, Y.2, TATEOKA, K.2, OKURA, T.1

1: UNIVERSITY OF TSUKUBA, 2: UNIVERSITY OF TSUKUBA, 3: IBARAKI PREFECTURAL UNIVERSITY OF HEALTH SCIENCES

INTRODUCTION: In order for the athlete to demonstrate the best performance in the game, physical condition management up to the game is important.
The athlete's best performance can be best demonstrated by self-monitoring of physical condition on a daily basis. However, there are very few convenient and objective methods to evaluate everyday physical condition changes. Recently, it has been reported that the physical function has been evaluated the ground reaction force at the time of rising from a chair using a motor function evaluation device (1). Peak reaction force per body weight (F / w) and rate of force development (Δ 90 ms) per body weight (RFD 9 / w), which the results of motor function evaluation, are known strong relation with physical ability. It is hypothesized that these factors may depend on athletes daily physical condition.
In this study, we examine the relationship with subjective physical condition using a motor function evaluation device (BM-220, TANITA) and examine whether this evaluation can grasp the physical ability or physical condition defect.
METHODS: Fifteen female basketball players (19.7 ± 1.4 years old) of the university were studied. For motor function evaluation, F / w and RFD 9 / w were used. The condition (degree of fatigue, pain, feeling) of participants was examined using Visual analogue scale. Each measurement was performed for 36 days before practice.
RESULTS: The relationship between the motor function and the subjective physical condition was examined by using linear mixed models. Each condition was set as a dependent variable and F / w and RFD 9 / w were added as independent variables. As a result, a significant association was found between the condition and F / w and RFD 9 / w (p=0.001~0.03).
CONCLUSION: Since there was a significant association between the physical condition and the motor function, it was suggested that the motor function could easily evaluate the state of physical ability and physical condition. Therefore, it may be possible to demonstrate the full performance at the game by routinely checking physical condition changes based on this method.

FOOT STRIKE PATTERNS AND SPRINT PERFORMANCE AMONG INFANTS

GOTO, Y.1, NAKATA, H.2, KANOSUE, K.1

1: WASEDA UNIVERSITY, 2: NARA WOMEN'S UNIVERSITY

INTRODUCTION: Foot strike pattern is one of factors that determine step length and step frequency. Foot strike patterns are classified into three types (forefoot strike: FF, midfoot strike: MF, rearfoot strike: RF). In research on adult runner, foot contact times are longer in RF runners than in FF and MF runners. In addition, the elementary school students aged 10 to 11 have similar characteristics (Miyamoto et al., 2018), and the foot contact time was negatively correlated with the maximum running velocity (Nobuoka et al., 2015). The purpose of this study was to clarify the relationship between foot strike patterns and sprint performance among infants.
METHODS: The participants were 135 boys and 147 girls ranged in 3 to 6 years old. They were asked to run 25 m at maximal sprinting. Their foot strike pattern, foot contact time, and aerial time over the distance from 9 m to 13 m were analyzed from videos recorded by a high-speed video camera sampling at 300 fps. Their maximum running velocity, step frequency, and step length were analyzed from videos recorded by a video camera sampling at 60 fps. One-way analysis of variance and multiple comparison (Tukey-HSD) were used for statistical analysis. The correlation analysis was determined to clarify the relationships among spatiotemporal components.
RESULTS: The proportion of the RF runner was the largest among the participants, and the proportion decreased in the order of the MF and FF runners in both boys and girls. In boys, the foot contact time was significantly shorter in the MF runner than in the RF runner. In girls, foot contact time, and aerial time were significantly shorter in the MF and FF runners than in the RF runner. On the other hand, there were no significant differences between the residuals of the maximum running velocity for foot strike patterns in both boys and girls. There were significant correlations between maximum running velocity and step length, foot contact time, and aerial time.
CONCLUSION: Difference in foot strike pattern among young children was related to their sprint velocity. These data suggested the significant relationship between foot strike patterns and sprint performance among infants, and confirmed results of the previous studies focusing on elementary school children. In the future, longitudinal studies are needed to clarify the development of foot strike pattern and running performance with increasing age.

AGE-DIFFERENCES IN TACTICAL BALL-GAME ABILITIES IN JAPANESE ELEMENTARY SCHOOL CHILDREN

OKUDA, T.1, AMBE, H.1, NAKASE, Y.2, BONO, S.3, MORITA, N.1

1.HOKKAIDO UNIV. EDUCATION IWAMIZAWA; 2.TOKYO SEITOKU UNIV. ; 3.HIROSHIMA BUNKA GAKUEN UNIV.

INTRODUCTION: In ball-games, it is important to enhance tactical ball-game abilities to handle more effectively various situations. Although previous studies have shown specific tactical skills in each ball-game sport, it is not clearly shown basic and general tactical ball-game abilities in elementary school children. In addition, only a few studies reported the creativity of tactical abilities in elementary school

children (e.g., Memmert & Roth, 2007). Thus, the purpose of this study was to determine the age-difference of tactical ball-game behaviors including creativity in 3rd and 5th grades Japanese elementary school children.
METHODS: Third and fifth-grade elementary school children participated (n = 33, 52% girls), and performed 3 types of tactical ball-game ability tests. The tests were 4-on-2 (1min, 2 sets), 3-on-3 (1 min, 2 sets), and 6-on-6 (3 min, 1 set). The ball-game tests were recorded by a digital video camera and then were assessed by certified ball-game coaches. The 4-on-2 test was performed to assess tactical creativity (diversity) by numbers of types of pass. The 3-on-3 test was used to evaluate tactical behaviors of on-the-ball and off-the-ball movements in experimental situations. By the 6-on-6 test, we assessed tactical off-the-ball behaviors of support and cut in practical situations (Kröger & Roth, 2005). Analyzing data were collected by Likert scale items in the 3-on-3 and 6-on-6 tests.
RESULTS: In the 4-on-2 test, numbers of pass types were significantly greater in 5th graders than in 3rd graders ($t = 2.11$, $p = 0.04$). However, there was no significant difference in scores of tactical behaviors between 3rd and 5th graders in the 3-on-3 test (on-the-ball, $t = -0.43$, $p = 0.67$; off-the-ball, $t = 0.47$, $p = 0.64$), and in the 6-on-6 test (support, $t = -0.11$, $p = 0.91$; cut, $t = -0.65$, $p = 0.52$). Numbers of pass types were correlated with support ($r = 0.67$, $p < 0.001$) and cut ($r = 0.55$, $p = 0.001$) behaviors in 3rd and 5th grade children.
CONCLUSION: These results suggest that tactical creativity, but not other tactical ball-game behaviors, could increase age-dependently. Our results also suggest that there is a difference in the development of tactical abilities between tactical creativity and other tactical ball-game behaviors.

FACTORS IMPACTING LEVELS OF TELEVISION VIEWING TIME AND PHYSICAL ACTIVITY GUIDELINES AMONG JAPANESE YOUNG CHILDREN

HYUNSHIK, K.

SENDAI UNIVERSITY

24rd annual ECSS Congress Praque/Czech Republic, 3-6 July 2019
FACTORS IMPACTING LEVELS OF TELEVISION VIEWING TIME AND PHYSICAL ACTIVITY GUIDELINES AMONG JAPANESE YOUNG CHILDREN
Kim, H, Ma, J., Hozawa T.
Faculty of Sports Science, Sendai University
INTRODUCTION: Decreased physical activity levels among young children have been reported to be related to increased obesity risk and decreased physical strength and motor ability. It has also been reported that sedentary behavior such as watching television and playing video games have a negative influence on children's health. This study investigated correlations with individual, family, and social/environmental factors affecting television viewing time and physical activity level guidelines among Japanese young children.
METHODS: We investigated the daily recommended television viewing time and physical activity levels among 1062 young children aged 3 to 6 years. Based on a survey with the parents, the independent variables were individual, family, and social/environmental factors of young children. Factors affecting recommended physical activity levels and television viewing time were analyzed using logistic regression analysis.
RESULTS: Our results showed that significant correlations were confirmed for the individual factor of sleeping time (OR, 4.39; 95% CI, 2.23 to 8.65), the family factor of parental television viewing time (OR, 4.81; 95% CI, 3.01 to 7.78), benefits of exercise (OR, 2.71; 95% CI, 1.37 to 5.31) and television in the bedroom (OR, 1.69; 95% CI, 1.15 to 2.72), and the social/environmental factors of transportation (OR, 1.45; 95% CI, 1.05 to 2.01) and play place (OR, 6.23; 95% CI, 3.80 to 9.20).
CONCLUSION: This study results suggest that to reduce children's sedentary behavior, television should not be placed in the bedroom, children should only view television with their parents, and television viewing rules and time restrictions should be determined together with the young children. In order for the healthy development of Japanese young children rather than spending too much time watching digital media, they should spend more time playing outdoors and moving their bodies with their friends.

THE EFFECT OF CRAWLING DURING CHILDHOOD ON CARDIOVASCULAR AND ANTHROPOMETRIC PARAMETERS IN APPARENTLY HEALTHY CHILDREN

CAZORLA-GONZÁLEZ, J., GARCÍA-RETORTILLO, S., CADELLANS-ARRONIZ, A., MUÑOZ-CASTRO, G., SERRANO-FERRER, J., FONT-LLADÓ, R., PRATS-PUIG, A.

UNIVERSITY OF GIRONA

INTRODUCTION: The development of the child in the first years of life is essential to the acquisition of motor skills such as crawling. It is known that those children who show a poorer motor development will be more likely to health problems, such as obesity and associated pathologies. However, the impact of the absence of crawling on the first year of life on cardiovascular and anthropometric parameters is unknown. The purpose of our study was to assess the difference between children who did crawl and those who did not crawl during childhood on cardiovascular (systolic blood pressure) and anthropometric parameters (fat mass, waist and BMI SDS) in apparently healthy children.
METHODS: Systolic blood pressure (SBP, Dinamp Pro 100), fat mass (TANITA), crawling during childhood (self-administrated questioner), waist (perimeter tape) and BMI SDS were assessed in a cohort of apparently healthy children (n=48, 26 girls and 22 boys) with a mean age 7.44 ± 0.33 included in the Physical Education, Health and Children (PEHC) Study. Differences on crawling (n=27) and no crawling (n=21) with cardiovascular and anthropometric variables were assessed by Mann Whitney U-test following multiple regression analysis to adjust for confounding variables.

RESULTS: In bivariate models, SBP (p=0.02) and waist (p=0.05) were higher in children who did not crawl. In multivariable analysis crawl was an independent predictor of SBP (p=0.01) and waist (p=0.007) after controlling for age and sex. However, when correcting by waist, age and sex, crawl didn't correlate with SBP (p=0.19).
CONCLUSION: These results suggest an effect of crawling on cardiovascular risk parameters but not on anthropometric parameter. Thus, the child's motor development should be monitored, because being an absence of crawling during the first year of life could have a negative impact on children cardiovascular health.

STRUCTURED ACTIVE PLAY PROGRAM FOR PRESCHOOLERS, STRENGTHENS BALANCE ABILITY

SATO, K.1, KIDOKORO, T.1, MIYATA, H.2, SUZUKI, K.3, NOI, S.4, MIYAKE, R.4

1>INTERNATIONAL CHRISTIAN UNIVERSITY, 2> TOKYO UNIVERSITY OF SOCIAL WELFARE, 3> JUNTENDO UNIVERSITY, 4> NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: Physical activity has been decreased in a redeny society. Although children are recommended to engage 60 min of MVPA, majority children don't achieve the recommendation (Hallal, Lancet, 2012). Therefore, in this research, we measured body balance ability using a force platform system during preschoolers, and examined the change of the balance ability throughout a structured active play intervention intended to improve comprehensive physical fitness.
METHODS: The participants in this study were 41 children, an exercise group of 19 subjects (10 boys, 9 girls, 5.5 years old, 103.3 cm tall, weighing 16.7 kg), and an exercise-free control group of 22 subjects (13 boys, 9 girls, 4.7 years, height 107.9 cm, Weight 18.2 kg)). We designed originally a structured active play program for improving physical fitness of preschoolers. We performed 30-minute sessions 3 times a week for 1 month at a kindergarten, and body balance test was conducted before and after that the intervention. As for the measurement method, markers were affixed to a wall 1 m from the floor so that one point could be seen, and subjects were required to stand upright for 10 seconds, both with their eyes open and closed. The measuring instrument was 1m from the wall. In the measurement, the total trajectory length and area can be expressed, the effect is seen if the distance is shortened, and the area is decreased. If the stable standing posture of 10 seconds could not be maintained, the measurement was repeated again. In the analysis, two way ANOVA(group ×time) was used to examine the effects of the structured active play program on the balance ability.
RESULTS: There was an interaction effect in the total eye trajectory length (F (1.37) =31.43, P=0.001). The total eye trajectory length was improved in the exercise group, while there was no change in the control group. There was an interaction effect in the closed eye trajectory length (F (1.35) =29.83, P=0.001). The closed eye trajectory length was improved in the exercise group, while there was no change in the control group. There was an interaction effect in the closed eye outer peripheral area (F (1.35) =4.31, P=0.045). The closed eye outer peripheral area was improved in the exercise group, while there was no change in the control group.
CONCLUSION: A structured active play program intended to improve comprehensive physical fitness caused preschoolers to improve body balance ability.

IMPACT OF LONGITUDINAL CHANGES IN MENSTRUAL PATTERN AND BODY COMPOSITION ON BONE MINERAL ACCRUAL IN JAPANESE COMPETITIVE GIRL RUNNERS

KINOSHITA, N., UCHIYAMA, E.

HOSEI UNIVERSITY

INTRODUCTION: Low bone mineral density (BMD) is frequently observed in adolescent runners with menstrual disorders. Thinness of runners is another reason for low BMD. However, the most of the findings were derived from cross-sectional researches. The aim of this study was to examine effect of longitudinal changes in menstrual pattern and body composition on bone mineral accrual in female adolescent runners.
METHODS: Consecutive 29 Japanese girl runners (15y/o, 159cm, and 46.1kg) in competitive high school teams were evaluated over 2 years. DXA was performed to measure lean mass (LM), fat mass (FM), BMD of total body less head, and z-score at 2 time points, 16 ± 6 months apart. Menstrual cycle was investigated by questionnaire with personal interview. The runners were categorized according to frequency of the cycle in the last 12 months at each time point; eumenorrheic (EU, 10-13 cycles) and menstruation disturbed (MD, <10 cycles). Furthermore, they were divided into 2 groups on the basis of changes in the categories from the 1st to 2nd time points; abnormal (ANL: MD or EU to MD, n=23) and normal (NL: MD or EU to EU, n=6). The effects of the time point and the group on BMD were analyzed by 2-way repeated measures ANOVA. T-tests were performed to compare variables between 2 groups. Bivariate correlation analysis was used to examine relationships between 2 variables. Written informed consent was obtained from the runners and their parents. P<0.05 was considered as statistically significant.
RESULTS: MD runners increased from 55 (1st) to 79% (2nd time point). BMD was correlated with LM at both time points (r=0.49 and 0.52, respectively) and increased significantly during the follow-up without z-score change (1.005 to 1.019g/cm^2 and 0.10 to 0.08, respectively). The increase in BMD was significantly correlated with LM gain (r=0.50), whereas it was not the case in FM. Two-way repeated measures ANOVA showed that the time had a significant effect on BMD with a significant interaction with the group, indicating BMD changed differently by group of menstrual pattern change; ANL acquired less BMD than NL (1.006 to 1.015 and 1.001 to 1.034g/cm^2, respectively). As for z-score, there was a significant interaction without significant main effects; z-score decreased in ANL and increased in NL (0.10 to 0.02 and 0.07 to 0.28, respectively) along the follow-up period. FM equally decreased in both groups (9.8 to 7.5 vs. 8.1 to 6.8kg, p=0.49, respectively), whereas the increase in LM was significantly larger in NL than ANL (35.9 to 38.4 vs. 35.1 to 35.9kg, respectively).
CONCLUSION: Runners who sustain or newly develop menstrual disorders have a risk of less BMD accrual along with smaller LM gain than those who kept or recovered to eumenorrhea in adolescence. The association of substantial LM gain with both BMD increase and normal/normalized menstrual cycle suggests that sufficient energy intake to develop LM by intensive exercise is important to prevent impaired bone mineral accrual and menstrual disorders.

COMPARISONS OF IN-SCHOOL AND OUT-OF-SCHOOL PHYSICAL ACTIVITY AMONG CHINESE JUNIOR MIDDLE SCHOOL ADOLESCENTS

ZHU, Z., SUN, C., ZHAO, S., CAO, Z.B.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: The health benefits of physical activity (PA) for children and adolescents has been presented by evidence (Janssen & Leblanc, 2010). Despite this, the overall PA level in children and adolescents remains low globally (Aubert et al., 2018). In the same vein, a large-population school-based survey highlighted that approximately 70% of school-aged children and adolescents did not meet the recommended guidelines of 60 minutes of moderate-to-vigorous PA (MVPA) daily in Chinese context (Fan & Cao, 2017). However, researches which examine adolescents' physical activity during school and outside of school remains relatively uncharted territory. Hence, the objective of this study was to compare in-school and out-of-school PAs among Chinese junior middle school adolescents.
METHODS: A cross-sectional study was conducted among 360 (8th grade) adolescents recruited from 3 junior middle schools in Shanghai, China. PA was measured in 5 consecutive school days by accelerometers. Minutes per hour (min/h) of MVPA and total PA (TPA) were calculated using established cut points. Adolescents' in-school and out-of-school MVPA and TPA were compared using paired t test. Independent t test was used to examine the gender differences in MVPA and TPA across the two study settings.
RESULTS: In total, 230 participants (boys: 44.8%, mean age: 13.7±0.4 years, weight:54.7±12.0 kg, height:163.0±7.0 cm, body mass index: 20.5±4.0 kg/m2) provided valid accelerometer data (defined as ≥ 2 days, ≥10 h/day) and were included in this study. Results showed a lower level of in-school MVPA compared to out-of-school MVPA (2.6 min/h vs 3.1 min/h, P<0.001). There was no difference between in-school TPA and out-of-school TPA (11.9 min/h vs 11.7 min/h, P=0.330). Boys showed a higher level of MVPA (in-school: 3.2 min/h vs 2.1 min/h, P<0.001; out-of-school: 3.7 min/h vs 2.6 min/h, P<0.001) and TPA (in-school: 13.6 min/h vs 10.5 min/h, P<0.001; out-of-school: 13.1 min/h vs 10.6 min/h, P<0.001) across the two study settings compared to girls.
CONCLUSION: Chinese junior middle school adolescents spent more time engaging in in-school MVPA compared to out-of-school MVPA, but not TPA. Boys showed a higher level PA compared to their counterpart girls. Findings suggest that PA promotion strategies should focus on developing within schools, especially among girls.

LONGITUDINAL CHANGES OF MUSCULOSKELETAL FINDINGS IN ELEMENTARY AND JUNIOR HIGH SCHOOL STUDENTS: A 2-YEAR PROSPECTIVE SURVEY OF MUSCULOSKELETAL EXAMINATION RESULTS

KASAI, T.1, KAMADA, H.2,3, TOMARU, Y.2, YAMAZAKI, M.2,3, MIYAKAWA, S.4, SHIRAKI, H.4

UNIVERSITY OF TSUKUBA

INTRODUCTION: In Japan, musculoskeletal examinations were first required by the School Health and Safety Law on April 1, 2016. The reports by Bone and Joint Decade Japan for some prefectures have shown data since 2005. On the other hand, almost all previous research studies and reports only had a cross-sectional study design. For this reason, the time with the most frequently reports on musculoskeletal findings is unclear. Similarly, a longitudinal analysis is important for research in children to determine individual growth and development. Thus, evaluation of the appropriate timing for obtaining musculoskeletal findings is important. We have performed musculoskeletal examination since 2008 in T-city, Ibaraki. Moreover, we created the "Health Notebook" for following-up children. Therefore, the purpose of this study was to investigate the characteristics of the appearance of musculoskeletal findings in elementary and junior high school children by using 2-year prospective longitudinal data from a long-term survey.
METHODS: The subjects were 1239 children aged 6–15 years who were in their first to eighth grade in the public elementary and junior high schools of Ibaraki prefecture, Japan. Their data from 2017 to 2018 were included in the analysis. We distributed questionnaires to the parents before screening. Furthermore, orthopedic surgeons performed direct musculoskeletal examination on all the subjects. In a cross-sectional analysis of the 2017 data, we calculated the frequency of musculoskeletal findings of all first- to eighth-grade children. Furthermore, in a longitudinal analysis, the patients who previously had no findings but eventually had findings were defined as the appearance group. In addition, the frequency of appearance of findings in each grade level was calculated. Statistical analysis was performed using the McNemar test. For comparison of the frequency of appearance of findings between the boys and the girls, the chi-square test was used.
RESULTS: The data of 1209 children (97.6%) were complete. No significant difference was found in the proportions of boys and girls in each grade level. In the cross-sectional analysis of the 2017 data, the following had particularly high frequencies in all grade levels: "limitation of standing forward flexion," "flat foot," and "rib hump." In addition to the results of the longitudinal analysis, the appearance of "limitation of standing forward flexion" was most frequent in the fifth and sixth grade for both the boys and the girls. Furthermore, the frequency of appearance of "limitation of standing forward flexion" was higher in the boys than in the girls in the third to fourth grade and fourth to fifth grade.
CONCLUSION: The results of the 2-year prospective longitudinal analysis of musculoskeletal examination results suggest that the appearance frequency rates of some screening items were high.

PREVALENCE OF BACK PAIN IN CHILDREN AND ADOLESCENTS IN RURAL AND URBAN AREAS IN NORTH RHINE-WESTPHALIA (GERMANY)

FRON, K., DE MARÉES, M., PLATEN, P.

FACULTY OF SPORT SCIENCE, RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Unspecific back pain (BP) in children and adolescents can have many reasons, resulting in high treatment costs and impaired quality of life [1]. More than 50% of German adolescents reported BP at least once in their life [2]. There are only a few studies in Germany dealing with BP in young age groups. This study analyses current prevalence rates of back pain in children and adolescents in rural and urban areas in North Rhine-Westphalia and investigates effects of age, gender and physical activity (PA).

METHODS: A questionnaire survey was conducted at 3 high schools in North Rhine-Westphalia regarding lifetime prevalence (LT-P), 3-month prevalence (3M-P) and 7-day prevalence (7D-P) of BP. Furthermore, PA (time spent for moderate activity and sport per week) and inactivity (time spent for homework and watching TV or playing videogames) were determined with modified questions of the International Physical Activity Questionnaire (IPAQ). The high schools were located in 3 different regions with numbers of inhabitants ranging from 14.100 to 55.700 and 364.700, in order to analyze urban and rural surroundings.
RESULTS: The study involved children and adolescents aged 10-17 years (n=730, 53% male, age: 13.6±2.1 years, height: 166.6±12.2 cm; weight: 53.8±13.9 kg). BP prevalence was 84.7%, 78.2%, and 21.8% for LT-P, 3M-P, and 7D-P, respectively. BP prevalence differed between age groups and sexes (LT-P: 10/11 yrs; 77.2%, 12/13 yrs: 85.5%, 14/15 yrs: 85.2%, 16/17 yrs: 89.3%; male: 80.9%, female: 88.9%; 3M-P: 10/11: 69.6%, 12/13 yrs: 78.8%, 14/15 yrs: 79.0%, 16/17 yrs: 82.1%, male: 74.9%, female: 81.9%; 7T-P: 10/11 yrs: 20.0%, 12/13 yrs: 17.7, 14/15 yrs: 19.9%, 16/17 yrs: 30.8%, male: 17.8%, female: 26.2%). There were no differences between rural and urban surroundings ($p>0.05$). Children who were more engaged in PA per week were less likely to be affected by BP (PA and BP: 4.7±1.8 hrs; PA and no BP: 5.1±1.7 hrs; $p\leq0.05$).
CONCLUSION: The prevalence rates revealed a high occurrence of BP in children and adolescents in North Rhine-Westphalia. This might be due to a general physical deconditioning in children. Age-specific differences in back pain might be due to alterations in PA patterns, pain perception and pain processing, to growth processes, and/or psychosocial factors in the somewhat older age groups [3,4]. Gender differences might be due to different PA patterns, maturity and puberty phases and different psychosocial factors between girls and boys. There were no differences between urban and rural surroundings regarding BP in children, which might be explained by similar lifestyles and infrastructures. Further studies should develop and evaluate preventive training programs in this age group.

A STUDY ON KNEE JOINT CONCENTRIC PEAK TORQUE AND STRENGTH ASYMMETRIES IN MEN'S PROFESSIONAL UNDER-23 VOLLEYBALL TEAM

NIKOLOV, H.R., KAPRALOV, S., PENCHEVA, N.
SOUTH-WEST UNIVERSITY

INTRODUCTION: Knee joint torque measurement enables assessment of the sport performance and injury risk for lower extremities (Schons et al., 2018). The aim of this study was: - to measure the peak concentric torque of knee extensors and flexors in male professional under-23 (U-23) volleyball players; and – to calculate, the hamstrings: quadriceps (H/Q) ratio and the limb asymmetry index (LAI).
METHODS: Eleven volleyball players (19.7±2.0 yr., 194.0±6.4 cm height, 80.9±6.2 kg body mass), were evaluated for peak torque (PT) of knee extensors and flexors with isokinetic dynamometer (Biodex 4 Pro) at the velocities (o/s): 60, 180 and 300. The LAI was calculated as the percentage difference between the knee extensors'PT or flexor'PT of the dominant limb (the one, which presented the greatest PT) versus the non-dominant (Lockie et al., 2012). The H/Q ratio was calculated as the PT of the flexors divided by the PT of the extensors, within the same limb. The data are reported as mean, SD and confidence interval (CI). One way ANOVA and Pearson coefficient determined torque differences and strength imbalances.
RESULTS: The values of PT of the dominant leg at 60, 180 and 300 o/sec of the knee extensors (269 ± 43, 166±33 and 125±27 Nm, respectively), did not differed ($p<0.05$) from those of the non-dominant and were consistent with data of elite U-23 volleyball players (Magalhães et al., 2004; Schons et al., 2018). However the flexors'PT values at the three velocities of both legs were 30-40% lower. The low values (mean, CI) of LAI of the extensors (7.7, CI 4.9-10.4; 5.8, CI 3.4-8.1; and 4.7, CI 2.1-7.3, at 60, 180 and 300 o/sec respectively) and the higher in flexors (11.4, CI 5.7-17.0; 13.3, CI 7.2-19.4; and 16.2, CI 10.4-22.0) show poor contralateral deficit in extensors, but pronounced asymmetry in flexors, especially at velocity 300 o/sec (greater than 15 % difference, $p<0.001$). No correlation was found between LAI tested at different velocities for quadriceps or hamstrings. Decreased values (mean, CI) of H/Q ratios at 60, 180 and 300 o/sec (49, CI 42-55; 60, CI 52-67; and 65, CI 57-73, for dominant and similar for non-dominant) can be considered as a substantial knee imbalance.
CONCLUSION: In the present study on male professional under-23 volleyball players it was established a more pronounced strength asymmetry between the knee flexors as well as a bilateral imbalance between the flexors and the extensors, within the same limb. The results suggest the need to create a targeted strength-training and injury prevention program with emphasis on the knee flexors of both legs, as well as the possibility for systemic assessment with isokinetic dynamometry.

THE RELATIONSHIP BETWEEN THE RANGE OF THE VELOCITY OF BATTED BALLS WHICH WERE PITCHED INTO VARIOUS COURSES AT THE TIME OF BATTING PRACTICE AND THE RESULTS OF GAMES

SATO, N., SUZUKI, C., MURAKAMI, K., FUJII, M., MAEDA, A.
NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Standard deviations in the position of bat during the swing in the unskilled players were lager than those at impact in previous research(1). However, little research has been done on the velocity of batted balls. Therefore, focusing on the velocity of batted balls, this study aims to clarify the relationship between the range of the velocity of batted balls which were pitched into various courses at the time of batting practice and the results of games and gain new knowledge as to coaching batting.
METHODS: Eighteen male college baseball players participated in this study as subjects. Each subject batted a ball pitched approximately 11 meters away from the subject 60 times. The laboratory equipment used "Rapsodo Baseball" to measure hitting ball velocity. The meas-

ured hitting ball velocity divided 25 course. The each course velocity calculated average and standard deviation. The game records is batting average, On-base percentage, slugging percentage in fall season game records in 2018. To calculate a coefficient of correlation of Peason using product made in statistics software SPSSver25(IBM company) to watch the relations of each parameter.
RESULTS: The WBV is not related to batting average, On-base percentage, slugging percentage. The WSD is moderately related to batting average (r=-.49,p<.05). The width of WSD is moderately related to On-base percentage (r=-.55,p<.05). The width of WSD is not related to slugging percentage.
CONCLUSION: The result of the experiment shows that having a skill to hit balls thrown in various courses in the same way can lead to good results of games. Maeda (2001) argues that even experts change their bat swing depending on the course of a pitched ball. Therefore, it is concluded that batters need to acquire various batting forms so that they can hit balls pitched in various courses in the same way.

PERFORMANCE DURING EXCLUSIONS IN FEMALE HANDBALL: RESULTS FROM THE 2017 PANAMERICAN CHAMPIONSHIP

TREJO, A.1, CAMACHO-CARDENOSA, M.2, CAMACHO-CARDENOSA, A.2, BRAZO-SAYAVERA, J.3

1 UNIVERSIDAD DE LA REPÚBLICA-ISEF; IUACJ. URUGUAY. 2 FACULTY OF SPORT SCIENCES. UNIVERSITY OF EXTREMADURA. SPAIN. 3 UNIVERSIDAD DE LA REPÚBLICA-ISEF. URUGUAY

INTRODUCTION: Coaches and analyst try to identify the variables in which winners and losers make the difference during a match. The scientific approach has provided a new perspective in sports such handball, incorporating critical events of the game, such as exclusions (Prieto, Gómez & Sampaio, 2015a).
The aim of the present study was to know in which period of the game winners and losers had differences in their performances based on the condition of numerical inequality as a consequence of exclusions.
METHODS: Sample consisted in 29 matches from the 2017 Panamerican Female Championship played by 10 national teams. A total of 211 exclusions occurred during those matches. Observational methodology procedures were followed to register the actions. The research team reviewed the videos and collected the data using the software Lince 1.1. Chi square test was applied to identify associations between the variables.
RESULTS: Results showed that 849 actions of numerical inequality took place, 466 in conditions of superiority and 383 in conditions of inferiority. Statistical significant association ($p<0.01$) was found between teams´ performance and period of time in both numerical situations (superiority and inferiority). Teams performance indicators during periods of time 2, 5 and 6 presented statistical significant associations ($p<0.05$) in winners and losers. Winners converted more goals, have fewer turnovers and goalkeeper saves than losers. No significant statistical associations ($p>0.05$) were found in any particular period of time during inferiority. Turnovers, goalkeeper saves and goals appeared in a statistical significant way ($p<0.05$). Winners scored more goals and have less throws saved by the rival goalkeepers than losers in both superiority and inferiority, coinciding with previous studies were teams take advantage of the numerical superiority during exclusions scoring more than rivals (Prieto, Gómez & Sampaio, 2015b). Losers presented more turnovers than winners, especially while being in inferiority.
CONCLUSION: Conclusions may state that during the second half of the game and, especially in the last part of the game (periods 5 and 6), winners present statistical significant performance indicators at both superiority and inferiority numerical situations.

INFLUENCE OF HALF TIME SCORE, MATCH LOCATION AND SCORING FIRST ON MATCH OUTCOME IN ROLLER HOCKEY

ARBOIX-ALIÓ, J.1, AGUILERA-CASTELLS, J.1, BUSCÀ, B.1, SÁNCHEZ-LOPEZ, M.J.2, GARCÍA-EROLES, L.3

1: FPCEE BLANQUERNA RAMON LLULL UNIVERSITY , 2: MEDICAL LIBRARY, HOSPITAL UNIVERSITARI SAGRAT COR , 3: HOSPITAL GERMANS TRIAS

INTRODUCTION: Performance analysis appears to be widely accepted by players, coaches and sports scientists as useful feedback in the coaching process in order to achieve better results (Liu et al., 2016). Although there have been several investigations on the different variables and performance indicators in some team sports such as basketball, handball or soccer (Garcia-Rubio et al., 2015; Prieto et al., 2015), there are few data regarding this topic about the sport of roller hockey. The aim of this study was to identify the effects of match variables in roller hockey, which are match location (ML), scoring first (SF), winning at halftime (WH) and wining at halftime for more than one goal (WHG). Second aim was to compare these match variables to know which is the most influential in the final outcome.
METHODS: The sample was composed by 240 matches of the First Spanish league (OkLiga) in the 2017-2018 season. The dependent variable was match outcome, this variable was established according the goal difference between confronting teams. Four independent variables were studied in order to identify the influence on match outcome: a) WH, b) ML, c) SF and d) WHG. Univariate analysis for each variable in relation to final outcome was performed by means the $\chi 2$ test with Yate's correction for categorical variables. Statistical significance was set at $p < 0.05$. Variables were subjected to multivariate analysis with a logistic regression procedure. Odds ratio and 95% confidence intervals were calculated from the beta coefficients and standard errors.
RESULTS: Results from the logistic regression showed that the entire match variable studied have a positive impact in the final match outcome. WHG was the strongest predictive variable with an OR value of 10.191. The second was WH (OR = 3.593) followed by SF (OR = 2.289) and ML (OR = 2.085).
CONCLUSION: These results reinforce the great importance of reaching at halftime with the partial score in favor, being the fact of winning at halftime for more than one goal an almost decisive predictor to win the match. In this way, initial events like scoring the first goal or the halftime result will condition the future develop of the match.
The analysis of the match variables it can provide valuable information to help coaches with the design of the lineups. Additionally, these findings could help staff teams to prepare training sessions based on the specificity of a particular stage of the competition or simulate

different scenarios. These hypothetical situations could be interesting to know each players response in front of these situations, being able teams to train how to play under pressure situations.

PERFORMANCE ANALYSIS OF THE SHOTS AND GOALS IN AFC FUTSAL CHAMPIONSHIP 2018

CHEN, Y.C., LIU, Y.T.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Shooting skill has been the most studied topic in the performance analysis in Futsal because the outcome of the game is solely determined by the number of goals. Futsal is a relatively new sport comparing to Football where Futsal was originated from. Research on the shooting performance of Futsal has been focused on the top-level teams such as those participated in FIFA Futsal World Cup and UEFA Futsal Cup. The purpose of the study was to examine the characteristics of the shooting performances in Asian Football Confederation (AFC) Futsal Championship 2018.
METHODS: There were 2152 shos analyzed from 32 games of the AFC Futsal championship 2018. Shooting time, shooting zone, position of ball contact at shot, and the shooting result were recorded with the Simi Scout notation analysis system. The Cohen's Kappa for the intra- and inter- observer reliability ranged from 0.83 to 1.00 for two observers. The Chi-squared tests of fitness and Chi-squared tests of independence were performed on the number of shots and the number of goals to examine the distribution of the shooting time and shooting zone, as well as the association among shooting time, shooting zone, position of ball contact, and the shooting result.
RESULTS: There were significantly greater number of shots and goals made from the zone of the center under 10m area whereas no significant difference was found over the 8 time periods when the shots and goals were made. In addition, there were more shots made when the ball was shot from the instep and the inside edge of the foot. However, only the ball was shot from the inside edge of the foot had significantly high association with goal.
CONCLUSION: In Futsal, the goalkeeper usually joins the offense system during the last period of game to gain momentum for shots and opportunity of goals. The finding that the number of shots and goals did not increase at the last game period indicates that there is room for improvement for attacking skills in Asian Futsal teams. In addition, although significantly greater number of goals were made from the zone closest to the goal which is consistent with the data from high level games such as Futsal World Cup (Göral, 2018), a more advanced instep shooting technique that has been observed widely in the UEFA and FIFA games (Lapresa et al., 2013; Abdel-Hakim, 2014) did not play a significant part of goal shots in the Asian teams. Performance analyses of Futsal games of all levels provide useful information for coaches and athletes. Research on Futsal game performances not only provide knowledge of the game but may also help systematically developing the training program and improve the game performances.

COMPARISON OF FIELD PERFORMANCE METRICS BETWEEN COLLEGIATE DIVISION II WOMENS FOOTBALL AND FIFA WOMEN'S WORLD CUP FOOTBALL

ANDERSEN, J.C., GRELLE, B., WADHI, T., FINLAY, S., DE SOUZA, E.
THE UNIVERSITY OF TAMPA

INTRODUCTION: There is limited published data available on performance metrics of Collegiate Division II (D2F) women's football players. In comparison, FIFA provides distance and velocity metrics for each team participating in the world cup, which could be used as a benchmark for the distance and velocity metrics in D2F. Specifically, we were interested in understanding the distance and velocity metrics of D2F, in comparison to FIFA. Therefore, the purpose of this study was to profile selected performance metrics of D2F obtained during one competitive season and compare these to similar data of FIFA.
METHODS: Fifteen D2F matches during the Fall 2018 competition season were monitored using global positioning systems and inertial movement units (Catapult Sports Innovations). During the 2015 Women's World Cup, fifty-six FIFA matches were monitored using the Prozone System (Prozone Sports). Both systems allowed the calculation of distance and velocity during each match for each participating player. For D2F, the average match total distance (TD), in meters (m) was obtained using Open Field software. For FIFA, TD, also in meters, was obtained from the 2015 FIFA technical analysis report. Velocity data was obtained in a similar manner. To compare the velocity demands between D2F and FIFA, velocity bands were categorized as follows: low speed distance (LSD) 0-12km/h, high speed distance (HSD) >12km/h, and sprint distance (SpD) >20km/h. D2F and FIFA absolute distances (m) and relative distance (% of TD) data are presented as mean±standard deviation. In addition, D2F and FIFA 95% within confidence intervals (CI) were calculated.
RESULTS: The average match TD for D2F was 7931±1743m while for FIFA was 10701.5±361m (TD: CI =7048.92 to 8813.07m and CI =10607 to 10796m, respectively). With respect to velocity band average distances, for LSD D2F was 6004±1389m while FIFA was 7551.8±328.4m (CI: 5301.06 to 6706.93m and CI: 7465.8 to 7637.8m, respectively); for HSD D2F was 1927±48m while FIFA was 3299.7±256.9m (CI: 1902.70 to 1951.29m and CI: 3232.4 to 3366.9m, respectively); and for SpD D2F was 284±87m while FIFA was 468.3±33.6m (CI: 239.9 to 328.02m and CI: 459 to 477.1m, respectively). Relative to TD, D2F LSD was 75.6±3.2% while FIFA was 70.7±4.8% of TD, D2F HSD was 24.3±3.2% of TD while FIFA was 30.8±1.7%, and D2F SpD was 3.6±0.9% of TD while FIFA was 4.4±0.3%.
CONCLUSION: Our results demonstrated that D2F accumulated 26% less TD per match in comparison to FIFA. Likewise, LSD, HSD, and SpD absolute distances were 21%, 42%, and 39% less in D2F compared to FIFA, respectively. Relative to TD, D2F accumulated 6.5% and 0.8% less HSD and SpD than FIFA, respectively. However, D2F accumulated 4.9% more LSD than FIFA. From our findings, we could hypothesize that increasing the amount of HSD relative to TD would produce improvements in D2F field performance. However, future studies should investigate if improving HSD would be translated in better performance in D2F athletes.

MODELING SOCCER PLAYERS' TACTICAL EFFICIENCY LEVELS.

BAGATIN, R.1, BARREIRA, D.1, FERNANDES, T.1, RIBEIRO, J.1, BACH-PADILHA, M.1, ABARGHOUEINEJAD, M.1, GUIMARÃES, E.1, FERNANDES, R.1, BAXTER-JONES, A.D.G.2, MAIA, J.1

1CIFI2D, FACULTY OF SPORTS, UNIVERSITY OF PORTO; 2COLLEGE OF KINESIOLOGY, UNIVERSITY OF SASKATCHEWAN

INTRODUCTION: It is well-known that young soccer players´ technical, tactical and physical skills are building blocks for their success in competition [1]. Coaches and sport scientists usually assess such skills mainly using small-sided games (SSG) and test batteries (drills). This study aimed to verify the differences between tactical efficiency of high level (HTE) and low level (LTE) groups, and to identify the effect sizes (odds ratios, OR) of technical, tactical and physical skills in predicting young soccer players´ tactical efficiency levels.
METHODS: Seventy-eight young male soccer players were recruited from the In search of excellence in sport- a mixed-longitudinal study in young athletes (INEX) project. All players were from six clubs of the Oporto Soccer Association (north of Portugal), and were divided in two groups: HTE (n=39, mean age 13.7±0.13yrs) and LTE (n=39, mean age 13.7±0.12yrs). The FUT-SAT [2] was used to evaluate tactical efficiency during a GK+4vs4+GK SSG, and included: Penetration, Offensive Coverage, Delay and Defensive Coverage Hit Percentage. Technical skills were compared [3], as well agility using the T-test in SPSS software, as were multivariate logistic regressions; alpha = 5%.
RESULTS: Descriptive stats were: Penetration (HTE 89.27±21.77% versus LTE 59.44±34.33%), Delay (HTE 60.37±24.95% versus LTE 40.46±22.89%), Defensive Coverage Hit Percentage (HTE 83.07±28.40% versus LTE 62.57±43.92%), and agility (HTE 9.99±0.73 versus; LTE 10.00±1.89). HTE players were more accurate than LTE players in Penetration [t(75)=4.201; p<0.001], delay [t(83)=3.699; p<0.001], but not in Defensive Coverage Hit Percentage [t(29.344)=2.006; p=0.054] nor agility [t(84)= -.054; p=0.95].
The logistic model was statistically significant (X2=44.00; p=0.001, Pseudo-R2=0.76), and correctly classified 90.7% of players in both groups. Players with higher Penetration (OR=1.08; 95%CI=1.02-1.13), Delay (OR=1.10; 95%CI=1.02-1.18), Defensive Coverage Hit Percentage (OR=1.03; 95%CI=1.00-1.06) and better agility (OR=0.16; 95%CI=0.31-0.90) were more likely to belong to HTE group.
CONCLUSION: Players who control and manage accurately offensive and defensive actions closer to the ball were more likely to be classified as HTE. Furthermore, indicators of technical effectiveness assessed in decontextualized game settings did not seem to predict tactical effectiveness levels of young soccer players in the game situation. Therefore, coaches and researchers should assess technical and tactical skills within the game context. Additionally, SSG seem to be a useful strategy to develop young players´ tactical efficiency.

MATCH OUTCOME AND TECHNICAL-TACTICAL PERFORMANCE OF THE PRESENT ASIAN SOCCER-EVIDENCE FROM 2019 AFC ASIAN CUP

GONG, B.N.1,2, LI, C.M.1, DU, L.D.1,3, CUI, Y.X.1, LIU, H.Y.1, GÓMEZ, M.A.2

1: BEIJING SPORT UNIVERSITY, BEIJING, CHINA. 2: TECHNICAL UNIVERSITY OF MADRID, MADRID, SPAIN. 3: CHINESE FOOTBALL ASSOCIATION

INTRODUCTION: Benefited from different interests-orientation in globalization and international relations, Asian football has grown rapidly in the past decade in terms of national teams and individual players (Connell, 2018). The athletics competitiveness and FIFA ranking of many Asian countries is changing profoundly in recent years. Although there has been an increasing interest in analyzing match performance of Asian football teams, more research is needed to deepen the understanding of technical-tactical demands in Asian football matches and key performance indicators to match success. Therefore, the aim of our research was to assess the performance of selected technical-tactical indicators in relation to match outcome within matches of the 2019 Asian Cup.
METHODS: Data of all 24 teams competing in 2019 Asian Football Confederation—Asian Cup were provided by Data Stadium Inc. and AMISCO Tracking system. Of all 51 matches, 45 matches were included for the analysis because the data of two matches were missing and another four matches were ended in extra time plays. A total of 25 match performance indicators were considered and were grouped into: shooting-performance indicators, passing-performance indicators and defending-performance indicators. Matches were divided into three groups based on the final goal-line: win, lose and draw. A one-way ANOVA was used to determine the differences in match performance among three match outcomes. Subsequently, a discriminant analysis was run on the significant indicators from previous analysis in order to determine key performance indicators that contributed most to the differentiation of match outcomes. The significance level was set at $p<0.05$.
RESULTS: The results showed that there were significant differences between match outcomes in shots, shots on target, shots and shots on target in penalty area, average possession%, total passes, pass success%, total passes into middle third area, pass success into attacking third%, passes from middle third, pass success from middle third%, passes from attacking third and pass success from attacking third% ($p<0.05$) with moderate to large effect sizes (partial $\eta 2$: 0.07-0.41). There is no difference in defense performance. The winning teams outperformed losing teams in all previous-noted indicators, but when contrasting winning and drawing teams, the only significant differences between them were shooting performance indicators, pass success into attacking third% and pass success from attacking third%. The discriminant analysis identified ten indicators that were the major contributors to the differentiation of three match outcomes, excluding total passes, pass success from middle third% and passes from attacking third.
CONCLUSION: Goal attempts, ball possession and pass success have constituted the victory for the winning teams in Asian Cup. More specifically, shots in penalty area, successful passes into and from attacking third were the key to that performance. The findings indicated that Asian teams are building their success based on ball possession and accurate pass in the attacking area. Knowledge gained from the study would be helpful for coaches and players to reconsider their training planning and match tactics.

THE EFFECT OF GENERAL FATIGUE ON THE CAPABILITY TO MAINTAIN BODY BALANCE

MAZUR-RÓŻYCKA, J., LACH, P.

CENTRAL INSTITUTE FOR LABOUR PROTECTION - NATIONAL RESEARCH INSTITUTE

INTRODUCTION: The aim of the study was to determine the effect of general muscular fatigue on the functioning of the single-leg and both-leg body balance in healthy young men.
METHODS: Fourty men aged 24.5 ± 3.9 years participated in the study. The tests were performed during two visits to the laboratory. The first visit of the studied persons was to determine the maximum minute oxygen uptake (VO2max) during which the maximum heart rate of the subjects (HRmax) was recorded during the exercise test. The second visit was started with measurements of balance. Next, the general fatigue of the organism was caused during running on the treadmill, increasing the speed of running the treadmill every 3 minutes. During the exercise, the tests were stopped at the test heart rate of 40% (40% HRmax), 60% (60% HRmax) and 85% (85% HRmax) of the difference between the maximum and resting heart rate. Immediately after the tested heart rate was obtained, measurements of balance parameters were made. The non-parametric Friedman ANOVA test was used to determine changes caused by local and general effort.
RESULTS: A statistically significant difference was observed for all analyzed parameters ofsingle-legbody balance. For the total, anterior-posterior and medial-lateral stability index values, a significant difference was observed after general effort to 85% of the difference between the maximum and at rest. The body balance parameters obtained during the both-leg test did not change under the influence of general fatigue.
CONCLUSION: The negative effect of general fatigue on postural control was observed only for body balance tests performed on a single-leg. This result may indicate that single-leg tests may be more sensitive than both-leg tests and will be a better indicator of the impact of different types of effort on body balance parameters.

SLEEP PATTERNS OF ELITE SHOOTERS BEFORE AND DURING COMPETITION

LU, J.J., AN, Y., CHEN, Y.Q., SHI, J.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Good athletic performance in shooting is due to a high level of concentration, while good sleep is critical for improving attention span and concentration. Although shooting is a sport with long career,individual sport athletes had increased likelihood of poor sleep as they aged. Acturally many elite athletes report worse sleep in the nights prior to important competitions.The aim of this study was to determine whether such sleep is poorer than that before a usual training day and for individuals, how can we find out the sleep problems in time and help athletes get a good nights sleep before and during competition.
METHODS: Twenty elite shooters'(10 male, 10 female, age 26.4±5.1y) sleep patterns were assessed using commercially available accelerometers (ActiGraph GT3X), which were worn on the non-dominant wrist and analysed using the manufacturer's software (ActiLife v6.13.3, Algorithm: Cole-Kripke). All subjects sleep activity datas including sleep efficiency,total sleep time,total minutes,wake after sleep onset(WASO)and awakening frequency were recorded for fifteen nights, including a six-night baseline training phase(Baseline), seven nights before competition(Pre-match),two or three nights during competition(Match-day) and two nights after competition(Post-match).
RESULTS: Average of total sleep time in Pre-match (mean±SD; 7.5±1.2h) and Match-day (7.7±0.9h)were 7% and 5% less than that at Baseline (8.1±1.3h; P = 0.007 and P = 0.025) respectively.Sleep efficiency in the first night of competition(79.8±9.3, P = 0.001) was the lowest throughout the course of the experiment ,where the average of sleep efficiency in Pre-match (82.3±6.1)was significantly lower compared with Baseline (88.1±3.6, P=0.021). WASO and awakening frequency in Pre-match and Match-day were higher than that at Baseline but there was no significant difference statistically. Athletes reported poor sleep two days after the competition but we just found that most athletes went to bed later in Post-match than Baseline. We also found female athletes had higher rates of sleep problems than male athletes, especially during competition.
CONCLUSION: The competition condition changed the sleep patterns when compared with the usual training condition. Athletes, especially the female athletes had more sleep problems but each individual changes in sleep pattern was different. However, the risk of sleep problem did not increase with age as we imagine (probably Older athletes have more experience with how to adjust their status during a match, and less tension).In the future, we need to pay more attention on the correlation between sleep pattern changes and performance. This will help coaches and athletes to develop a greater understanding of how sleep changes during different phases of competition and enable them to plan training programmes to ensure the best performance in the competition.

RESPIRATORY TRAINING MODIFIES THE BREATHING PATTERN TOWARD A MORE EFFICIENT ONE DURING MAXIMAL INCREMENTAL EXERCISE.

BALLERIO, F., SORINO, N., MERLO, C., FRANCHI, M., PIZZOLATO, M., PRATALI, L., COGO, A.

UNIVERSITÀ DI FERRARA-CENTRO STUDI BIOMEDICI APPLICATI ALLO SPORT

INTRODUCTION: The optimal breathing pattern is characterized by a predominant increase in tidal volume (TV) compared to respiratory rate (RR). The managing of breathing pattern (i.e. the ratio between TV and RR), during physical exercise, is a key point for the efficiency of ventilation in term of gas exchange. In healthy subjects, exercise training and specific respiratory muscle training with isocapnic hyperpnea, improve the breathing pattern toward a more efficient one at rest and during endurance exercise.
AIM:
to evaluate the effect of a specific 8 weeks respiratory training (RT) on breathing pattern measured during an incremental exercise test.
METHODS: 18 subjects, recreational sport practitioners (13 M, 5 F), age 22-61 yrs, underwent: spirometry, maximal ventilatory ventilation (MVV) and cardiopulmonary exercise test (CPET) on a treadmill (Bruce protocol). These measures were performed at baseline and 8 weeks after a RT, programmed, taught and supervised by apnea instructors. RT= 30 minutes/day; quadratic ventilation featured by inspiratory and expiratory apnea of the same duration. The length of apnea started from 4 sec and arrived to 15 sec in the last trainings.

In addition, they performed 3 sets of 5 minutes of forced ventilation with maximal inspiration and expiration. The protocol didn't include any physical training program and the subjects were free to exercise according to their commitments and preferences.
RESULTS: all subjects completed the experimental protocol. T-Test analysis for paired samples was performed to analyze differences between pre (T0) and post (T1) measures. Spirometry: FVC (5.13 L vs 5.46 L p=0.04); no significant difference of MVV was found (p 0.08). Maximal Ventilation didn't change (123L/min vs 120L/min) but TV was higher at T1, from baseline to anaerobic threshold ($p<0.05$). In the following steps, this difference disappeared. CPET: VO2mL/kg/min at T1 showed a trend towards a reduction at each stage even if the difference was significant only at maximal intensity (p=0.002).
CONCLUSION: 8 weeks of specific RT can modify the breathing pattern spontaneously adopted by the subjects during exercise, toward a more efficient one. This finding was just significant until anaerobic threshold, which can mean that in the last stages of incremental exercise the ventilatory drive becomes predominant and subjects loose the benefits of a more efficient breathing pattern. The reduction of VO2 at the higher intensities might be due to a more efficient performance of respiratory muscles after the training.

INFLUENCES OF LONG-TERM SPORTS EXPERIENCE ON THE CORTICAL INHIBITION DURING DUAL-TASK

FUKUMOTO, H.1, NISHIHIRA, Y.2, SAKEMOTO, N.3, KUROIWA, K.4, SHIMODA, M.1

1: TOKYO UNIVERSITY OF AGRICULTURE AND TECHNOLOGY, 2: UNIVERSITY OF TSUKUBA, 3: SEIWA UNIVERSITY, 4: TOKOHA UNIVERSITY

INTRODUCTION: We previously reported the influence of long-term sports experience on corticospinal tract excitability during dual-task performance (ECSS, 2017). It was suggested that corticospinal tract excitability in an athlete group is significantly higher than that in a non-athlete group regardless of the task and plastic change induced by long-term sports experience at a level higher than the spinal cord including primary motor cortex (M1). It has also been reported that long-term sports experience influences cortical inhibition, i.e., the influence of cortical inhibition is involved in the high-performance level acquired through long-term sports experience (Pearce AJ et al., 2000; Rosenkranz K et al., 2007). However, the influence of long-term sports experience on cortical inhibition during dual-task performance is unclear. Therefore, the aim of this study was to examine the influence of long-term sports experience on cortical inhibition during dual-task, based on cortical silent period (CSP) duration, and motor evoked potential (MEP) induced by transcranial magnetic stimulation (TMS).
METHODS: An experiment was conducted, involving 12 athletes and 12 non-athletes to implement tasks under the following 2 conditions: 1) retention of power gripping force with 30% MVC for 15 sec (ST), and 2) simultaneous calculation task as a dual-task (DT). In each task, TMS was applied to the left M1, and the CSP and MEP were recorded from the first dorsal interosseous (FDI), the flexor carpi radialis (FCR) and the extensor carpi radialis (ECR) of the right hand. The background EMG area (bEMG) in 100 ms before TMS was calculated.
RESULTS: The MEP amplitude of the FDI in the athlete group was higher than that in the non-athlete group ($p < 0.05$). On comparison of the CSP durations under the ST and DT conditions, the CSP duration was longer in all muscles in the athlete than the non-athlete group ($p < 0.01$). No significant difference was found in the bEMG between the 2 groups.
CONCLUSION: There was no difference in excitability of spinal cord motor neurons between the 2 groups, suggesting that long-term sports experience caused plastic change at the upper spinal cord, including M1. The MEP amplitude was the in the athlete than non-athlete group under the ST and DT conditions, suggesting that cortical inhibition also became more active in association with it and resulted in the final adjustment of muscle exertion. On the other hand, the CSP duration shortened in the non-athlete group compared with that in the athlete group, suggesting that the final muscle exertion was maintained by attenuating cortical inhibition. These findings suggest that cortical inhibition during voluntary movement becomes more active through long-term sports experience, changing the balance between excitement and inhibition.

DEVELOPMENT OF STROKE RATE IN ROWING FROM 2013 TO 2018

ALTMANN, K.

INSTITUTE OF APPLIED TRAINING SCIENCE

INTRODUCTION: The purpose of this study was to check whether the stroke rate (SR) in rowing has increased within world-class athletes in the last two seasons (2017 & 2018) in comparison to the last Olympic cycle (2013 to 2016). The boat speed in rowing is the product of the SR and distance per stroke. The higher the SR at the same stroke length, power and conditions, the higher the boat speed. However, the relation between boat speed and SR is not proportional. Hence, a higher boat speed can only be achieved to a certain level by increasing the SR (Kleshnev, 2016). Nevertheless, the stroke frequency is essential for the rowing performance as it is less influenced by external conditions than the boat speed or the propulsion per stroke.
METHODS: SR and boat speeds are automatically recorded by Swiss Timing (Corgémont, Switzerland) at least every 50 meters. Thus, it is possible to calculate the average values of the SR for the entire two-kilometer race track and for selected sections. Global Positioning System (GPS) data were evaluated at almost all World Rowing Cups and World Rowing Championships from 2013 to 2018 for the A-finalists of all Olympic boat classes. The data were analyzed using an independent samples t-test.
RESULTS: In all boat classes, the SR has increased in the A-Finals from the last Olympic cycle 2013 to 2016 (N = 412) to the first two years of the current Olympic cycle (N=418; $t(828) = -10.3$, $p < .001$, $d = 0.72$). Differences between the boat classes in the increase are however evident. In the women's single, we have the largest percentage change (6.38 %) in SR (32.7 to 34.8; $t(132) = -8.112$, $p < .001$, $d = 1.57$), while in the women's pair the stroke frequency only increases by about 1.35 % (36.2. to 36.7; $t(120) = -2.479$, $p < .001$, $d = 0.45$). With a first closer look to the data of the men's eight and the women's single, we see that the SR has increased more than the boat speed in percentage terms. In the comparison of the medal winners with the places 4, 5 and 6, no differences could be observed regarding the SR. In the middle part of the race, there is a slightly higher frequency increase than at the first and the last 500 meters.
CONCLUSION: The SR in rowing has increased from the last to the current Olympic cycle, but you have to look at each boat individually. The consequences include that the demands on motor skills and technique are increasing due to higher pulling speeds and higher speeds at the reversal points. A focus of aerobic training and strength training in the first months of the training year usually leads to an increase in the stroke width, but often also to a reduction in the stroke frequency. Speed aspects at the end of each rowing session can help athletes maintain a higher SR. Of course, when increasing the SR, care must be taken to ensure that an optimum stroke amplitude and propulsion are guaranteed.

CENTRAL OBESITY AND BIOLOGICAL MATURITY AS DETERMINANTS OF THE CENTRE OF PRESSURE PATH LENGTH

FONT-LLADÓ, R., CADELLANS-ARRONIZ, A., CAZORLA-GONZÁLEZ, J., GACTO-SÁNCHEZ, M., PRATS-PUIG, A.

UNIVERSITAT DE GIRONA

INTRODUCTION: Increased skeletal muscle injury risk has been associated with sensorimotor function for postural control (static and dynamic). Postural control acquisition in children is closely related to biological maturity, while in adults the center of pressure path length depends on obesity parameters, mainly central obesity. However, there are no studies regarding the association between the center of pressure path length and obesity parameters in children.
Our goal was to assess whether obesity parameters are related to the centre of pressure path length in children independently of biological maturity.
METHODS: The center of pressure path length on dominant leg (Wii fit), biological maturity (Mirward formula) and anthropometrical parameters (waist and height) were assessed in a cohort of 171 apparently healthy children (81 girls and 90 boys) with a mean age of 7.45 ± 0.33 included in the Physical Education, Health and Children (PEHC) Study. Associations between the centre of pressure path length and anthropometric variables were assessed by Pearson correlations following multiple regression analysis to adjust for confounding variables.
RESULTS: In all children higher values for the centre of pressure path length in the dominant leg were associated with higher biological maturity ($r=0.345$; $p<0.0001$) and waist ($r=0.253$; $p=0.002$). However, the association with waist remain significant only in girls ($r=0.694$; $p<0.0001$). In multiple regression analyses in all children; waist ($\beta= 0.239$; $p= 0.011$), biological maturity ($\beta= 0.734$; $p=0.000$) and height ($\beta= -0.237$; $p= 0.012$) were independently related to the centre of pressure path length at dominant leg explaining 18.5% of its variability. Finally, the abovementioned association were only significant in girls (waist ($\beta= 0.324$; $p=0.018$), biological maturity ($\beta= 0.052$; $p=0.012$) and height ($\beta= -0.415$; $p= 0.011$)) explaining 26.9 % of its variability.
CONCLUSION: These results showed an independent effect of both central obesity and biological maturity on the centre of pressure path length in dominant leg in apparently healthy children. We suggest that not only biological maturity but also obesity parameters should be taken into account, at least in girls, while training postural control skills.

EFFECT OF FOOT TYPES ON THE WEIGHT-BEARING RESPONSE OF THE FOOT MORPHOLOGY USING PMRI

MARUYAMA, M., OKAMOTO, Y., SHIRAKI, H.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Human foot structures are associated with some problems of lower extremity (1). Especially, flatfoot induces some damages to multiple joints. Therefore, the assessment of the morphology of the foot is very important in the clinical work-up and management of symptomatic foot disorders. Although, navicular bone height and radiographic measure are conventional methods for measurement of foot morphology (2), these methods have technical limitations that these cannot grasp the three-dimensional (3D) foot morphology. Recently, positional MRI (pMRI) has been developed, which provide three 3D foot morphology, and deformation upon loading. The purpose of this study is to clarify the effects of weight-bearing in different types of foot.
METHODS: 23 healthy men (age: 24.04±2.47 years) were categorized into two groups depending on their morphological types, namely normal (15 foot) and low (8 foot) by Arch-height-index. MRI scans of 23 feet were performed under 2 different conditions; non-loading (NL) and full weight-bearing (FW). We analyzed these MRI images using a measurement tool of the DICOM viewer. Height and the angle of the foot arch bones were evaluated three dimensionally. Unpaired sample t tests were used to examine significant differences in NL between two groups. A 2-way ANOVA with repeated measures was used to analyze height and angle of the foot arch bones. When a significant interaction was observed, the simple main effects of group or time were determined.
RESULTS: The height of MLA foot arch bones in lower group were lower than normal group, and the angle of foot arch bones were different. The height of talus, navicular, cuboid, and 1st head of metatarsal tended to interact between the 2 groups (talus: $F = 6.55$, $P < 0.05$; navicular: $F = 8.86$, $P < 0.01$; cuboid: $F = 6.52$, $P < 0.01$; 1st head of metatarsal: $F = 5.86$, $P < 0.05$). The angle of navicular, intermediate cuneiform tended to interact between the 2 groups (navicular: $F = 8.13$, $P < 0.05$; intermediate cuneiform: $F = 4.47$, $P < 0.05$).
CONCLUSION: We found that the movement of talus, navicular, cuboid, and 1st head of metatarsal upon loading were difference between Normal and Low, and the foot arch bone alignment were different in NL. Our data suggest that the difference of foot arch bone alignment might affect the deformation pattern.

CARDIOVASCULAR EFFECTS OF LOAD CARRIAGE IN SOLDIERS; A PILOT STUDY

LARSSON, J., ENGBERG, A., TURNSTEDT, M., DENCKER, M., BREMANDER, A., OLSSON, M.C.

FACULTY OF MEDICINE, LUND UNIVERSITY. RYDBERG LABORATORY OF APPLIED SCIENCE, HALMSTAD UNIVERSITY

INTRODUCTION: Previous studies have shown that risk of physical fatigue increases if prolonged average work intensity exceeds 50% of oxygen uptake (VO2). In order to avoid persistent fatigue in a work setting, it is important to conduct suitable work capacity analyses. In physically demanding jobs where wearing protective gear and/or external load is mandatory, monitoring of cardiovascular demands through heart rate (HR) is one way to track the workers' relative effort. There are limited studies examining effects of load carrying on cardiovascular capacity where it appears that VO2peak differ when soldiers and firefighters are tested with work-related equipment/clothing compared to light clothing. The aim of this pilot study was to investigate effects of load (combat gear) on HR, VO2 and muscle oxygen saturation (SmO2) compared to no load in soldiers during a graded treadmill protocol.
METHODS: Eight volunteer army soldiers (1 woman, 7 men) performed a graded treadmill test until exhaustion. All soldiers performed the test twice, once with light clothes and no load (NL) and once with added load, their personal combat gear (CG), with at least 48 h between sessions. The treadmill protocol stages included supine and standing positions, followed by marching speeds of 5.4 km/h and 8 km/h at 0 incline (all 5 min) immediately followed by a set marching speed of 8 km/h with a starting incline of 2 % increasing the incline 2 % every third minute until voluntary exhaustion. Measurements of HR, VO2 and SmO2 were collected continuously and the last 30 s of each stage were averaged and used for statistical analyses (paired t-tests).

RESULTS: The mean added load for all soldiers with CG was 16.8 ± 1.1 kg. All soldiers completed at least 6 stages (range 6-11 stages) with both NL and CG, where time to exhaustion with NL was longer (19.1 ± 3.2 min) compared to CG (9.1 ± 2.9 min; p <0.01). Submaximal HR and VO2 were both significantly higher with CG compared to NL (at absolute intensities) at all marching speeds all soldiers completed (5.4 km/h 0 % grade - 8 km/h 4% grade; all p<0.05). For SmO2, marching with CG compared to NL resulted in increased muscle oxygen utilization, at submaximal stages 8 km/h 0% -4% grade (all p<0.05). For values at maximal effort the CG had a significantly lower VO2peak (3.7 ± 0.5 L/min) compared to NL (4.1 ± 0.6 L/min, p <0.01), whereas there was no difference in HRpeak or the lowest value of SmO2 between CG (193.1 ± 7.2 bpm; 42.4 ± 30.3%) and NL (195.4 ± 8.9 bpm; 47.0 ± 29.2%).
CONCLUSION: This pilot study suggests that assessment of aerobic capacity in soldiers should be conducted with combat gear to help determine their actual work capacity during combat and other load carrying tasks. These results suggest that if soldiers' work performance is determined without added load it overestimates their aerobic capacity (VO2peak) in tasks wearing combat gear, which might lead to added fatigability and deleterious effect on performance.

EVALUATION OF A GROUP BASED 8-WEEK OUTDOOR FITNESSTRAINING ON PHYSI-OLOGICAL PERFORMANCE IN RECREATIONAL ATHLETES

HENDKER, A., EILS, E.

HUMAN PERFORMANCE & TRAINING IN SPORTS

INTRODUCTION: Regular activity is indispensable for health. Countless prove was given for the influence of physical activity and health (Bourchard et al., 2015). Alarmingly, it remains that much of the population are still unable to achieve the minimum recommended level of physical activity for health improvements (WHO, 2018). As such, many training concepts have been created to avoid potential barriers to exercise, e.g. lack of time. One such time efficient method is outdoor circuit training (otherwise known as bootcamp training). Here, whole body movements simultaneously recruit various muscle groups under supervision of a personal trainer to ensure correct execution. However, the physiological effects of such training on different health promoting variables in recreational athletes are currently not well known. Therefore, the aim of this study was to evaluate the physiological responses on an 8-week outdoor circuit training in recreational athletes.
METHODS: Forty-three (30 f, 13 m; 33±7 y, 175±9 cm; 72±12 kg) participants volunteered for the study. Subjects were unexperienced to such a training and completed a battery of physical performance tests (a bootcamp specific functional fitness test, a treadmill based stepwise incremental test and a core stability test (McGill, 2007)) pre and post an 8-week outdoor circuit training intervention. While this intervention, they performed a guided one hour functional HIIT outdoor circuit training in small groups twice a week. Trainings where whole body exercises with specified levels of difficulty. A two way repeated measures ANOVA was calculated to evaluate the difference in test outcomes (α-level=5%).
RESULTS: Results show a significant increase in specific functional and strength exercises for outdoor circuit training. On average, participants perform significant higher repetitions in the posttest e.g. squat (pre: M=27.8±5.5; post: M=35.2±5.9) F(1, 42)= 385.6, p<.001, peta2= .90. The isometric core stability increased in all directions, e.g. back extension (pre: M=78.3±30.3; post: M=111.7±41.0) F(1, 42)= 100.7, p<.001, peta2= .71. In the stepwise incremental test, participants ran longer after intervention (2236m±607; 2498m±751, respec-tively) F(1, 38)= 36.40, p<.001, peta2= .49 whereas no changes could be found in lactate accumulation at one given speed (pre: M=6.7±2.6; post: M=6.4±2.5) F(1, 6)= 3.03, p=.132, peta2=.336. Maximum heart rate at the end of the test was higher in pre (M=185.1±9.6) than in posttest (M=182.7±9.2) F(1, 38)= 6.296, p=.016, peta2= .14.
CONCLUSION: Over all, this time efficient training helped to improve physical fitness in recreational athletes. Furthermore, an 8-week outdoor circuit training improves not only training specific functional exercises but also core-stability and endurance tasks. No changes in lactate accumulation could be explained by longer running distances or a higher lactate toler-ance.

NEUROMUSCULAR RESPONSES DURING A SUSTAINED, ISOMETRIC LEG EXTENSION MUSCLE ACTION AT A CONSTANT PERCEPTION OF EFFORT

KELLER, J., HOUSH, T., HILL, E., SMITH, C., SCHMIDT, R., JOHNSON, G.

UNIVERSITY OF NEBRASKA - LINCOLN

INTRODUCTION: Ratings of perceived exertion (RPE) are becoming increasing common for prescribing resistance training loads. Little is known, however, regarding the motor unit activation strategies utilized during resistance training anchored to RPE. Therefore, the purpose of the present study was to examine the fatigue-related patterns of responses for electromyography (EMG), mechanomyography (MMG), and force during a sustained, submaximal isometric leg extension muscle action anchored at RPE=5.
METHODS: Ten men (22.9 ± 2.0 yr) performed two, maximal voluntary isometric contractions (MVIC) prior to and following an isometric leg extension muscle action that was sustained at RPE=5 for a maximal time-limit of 5 min or until RPE=5 could not be maintained (actual time-limit). EMG amplitude (AMP), EMG mean power frequency (MPF), MMG AMP, MMG MPF, and force values were determined every 5% of the actual or maximal time-limit. Polynomial regression analyses were used to examine the neuromuscular parameters and force versus time relationships, and a t-test was used to examine MVIC force values.
RESULTS: The pretest MVIC (62.4 ± 14.3 kg) was significantly (p<0.001; d=1.07) greater than posttest (47.9 ± 12.8 kg) MVIC. The actual time-limit was 202.0 ± 95.5 s (range: 96.4 to 300.0 s). The percent decline in force production during the sustained isometric muscle action was 47.5 ± 19.6%, and there was a significant negative, quadratic force versus time relationship (p<0.001; R= -0.980). There was a significant negative, quadratic EMG AMP versus time relationship (p<0.001; R= -0.789), but no significant (p>0.05) relationships for EMG MPF, MMG AMP, or MMG MPF versus time.
CONCLUSION: The current findings indicated that it was necessary to reduce force and EMG AMP to maintain RPE=5. Therefore, we hypothesize that the maintenance of RPE=5 was initially accomplished by an anticipatory feedforward mechanism and then continuous integrations of afferent feedback, which resulted in reductions of EMG AMP and force production, possibly due to reductions in neural drive, to attenuate the impact of metabolic byproducts on perceived exertion.

EFFECTS OF THE DIRECTION OF CROSS TAPING OF THE MIDDLE SCALENE MUSCLE ON MUSCLE TONE AND STIFFNESS

CHOI, H.S., LEE, J.H.

DONG-EUI UNIVERSITY

INTRODUCTION: Cross taping is widely used to treat various musculoskeletal diseases worldwide. The cross tape has been reported to be applied in the direction that produces a positive response (stronger digit flexion) in modified O-ring test after applying four rows at an angle of 45° to the right or left of the direction of the muscle fibre. However, no studies have investigated the changes in muscle tone after applying the cross tape in the direction determined on the basis of the modified O-ring test. Therefore, this study aimed to examine whether muscle tone and stiffness differ according to the direction of the cross-tape application in the middle scalene muscle.
METHODS: Six adults (two men and four women) who provided informed consent were enrolled in this study. First, the modified O-ring test was performed to determine the direction of the cross-tape application. The tone and stiffness of the middle scalene muscle on the side with limited neck rotation were measured using MyotonePRO before and after applying the cross tape in the direction determined on the basis of the modified O-ring test for 5 minutes. The immediate changes in the tone and stiffness of the middle scalene muscle were compared using Wilcoxon signed-rank test.
RESULTS: The middle scalene muscle tone and stiffness significantly decreased when the cross tape was applied in the direction determined on the basis of the modified O-ring test ($p < 0.05$).
CONCLUSION: On the basis of our results, we suggest that the cross tape should be applied in the direction that generates a positive response in the modified O-ring test such that the four rows are at a 45° angle to the right or left of the direction of the muscle fibre.

EFFECT OF KINESIO TAPING® ON VERTICAL JUMP PERFORMANCE IN JUNIOR TENNIS PLAYERS

ULUSOY, B., HARPUT, G., OZUNLU PEKYAVAS, N., CAM, I., BALTACI, G.

HACETTEPE UNIVERSITY GRADUATE SCHOOL OF HEALTH SCIENCES

INTRODUCTION: Tennis has a wide appeal; positive health benefits and increases well-being. Vertical jump is a general approach used to evaluate jump height and muscular strength.(1) Kinesio taping® is an elastic therapeutic tape used for improve joint function by enhancing sensory mechanisms, altered muscle function by the effects of the tape on weakened muscles (2-4). The aim of this study was to examine the effects of kinesiotaping application on vertical jump performance in junior tennis players.
METHODS: Sixty-six junior tennis players (40 boys, 26 girls; age mean: 10.81 ± 1.46 yrs; height 149.1 ± 10.6 cm; body mass 39.25 ± 8.24 kg; BMI: 17.9 ± 1.97 kg/m2; active time in their sport 4.15 ± 1.86 y) participated in this study. A vertical jump test was performed before and after the application of kinesiotape on bilateral quadriceps and gastrocnemius muscles. The maximum height and flight time data was collected using a portable optical timing system (Optojump Next; Microgate, Bolzano, Italy) during a counter movement jump. Mean maximum jump height and flight time were calculated from three trials. Student t test was used for statistical analysis.
RESULTS: There were significant difference in maximum jump height and flight time between untaped and kinesiotape conditions ($p<0.05$). Kinesiotape was found to increase maximum jump height (Untaped: 21.16 ± 5.37 cm, Kinesiotape: 22.64 ± 4.26cm, $p=0.01$) and to decrease flight time (Untaped: 0.39 ± 0.1 s, Kinesiotape: 0.42 ± 0.04 s, $p=0.002$).
CONCLUSION: The findings of the present study demonstrated that kinesiotaping application on quadriceps and gastrocnemius muscles can enhance jump performance in junior tennis players. Therefore, kinesiotape may be an option in tennis training programs to improve jump abilities in those players.

THE EFFECTS OF SELF-MYOFASCIAL RELEASE AND STATIC AUTO-STRETCHING EXERCISES IN THE RANGE OF MOTION AND STRENGTH OF TRUCK EXTENSORS

FONTA, M.1, MANDALIDIS, D.2,1

TECHONOLOGICAL EDUCATIONAL INSTITUTE OF WESTERN GREECE

INTRODUCTION: Previous studies have shown that a single bout of self-myofascial release increases the joints' range of motion, especially in the lower limbs, without affecting the strength of the surrounding musculature (MacDonald et al 2013). Static stretching, on the other hand, although traditionally has been used for joints' range of motion enhancement it may influence muscle strength particularly if it is executed before sport performance (McHugh and Nesse 2008). The purpose of the present study was to evaluate the effectiveness of self-myofascial release using a foam roll, in the range of motion of trunk movements and the strength of the trunk extensors compared to auto-stretching exercises.
METHODS: Twenty-five individuals, 14 males and 11 females, aged between 23 and 39 years, participated in the study. The study was carried out using the cross over experimental design method with the participants randomly performed a seven minutes program of self-myofascial release and static auto-stretching exercises with one-week interval between interventions. The bilateral range of motion of trunk's side flexion and rotation as well as the sit-and-reach along with the maximum and endurance strength of the trunk extensors were assessed before and after interventions.
RESULTS: Statistical analysis of the data revealed a significant increase in trunk side flexion and rotation as well as in sit-and-reach using either self-myofascial release or static auto-stretching exercises ($p<0.001$). However, trunk extensors maximum strength and endurance showed a significant increase following self-myofascial release ($p<0.001$). In contrast both maximum strength and endurance were significantly decreased after performing static auto-stretching exercises
CONCLUSION: The results of the present study revealed that both self-myofascial release using a foam roller and static auto-stretching exercises significantly improved the range of motion of trunk's movements with the first intervention contributing to the production of greater strength and endurance of trunk extensors as opposed to the latter.

FOAM ROLLING AND INDICES OF AUTONOMIC RECOVERY FOLLOWING EXERCISE-INDUCED MUSCLE DAMAGE

DAMICO, A., MCCARTHY, K., LEFTIN, J., MOLLOY, M., HEIM, H., BURKE, C., GILLIS, J.

SALEM STATE UNIVERSITY

INTRODUCTION: With the increased popularity of foam rolling (FR) as a recovery tool, it is important to explore possible mechanisms of action. The purpose of this study was to examine the impact of FR on recovery of select autonomic parameters following exercise-induced muscle damage.
METHODS: In a between-group design, 40 participants performed 40x15m sprints, inducing muscle damage. Immediately following sprinting and in the four days following, heart rate variability and pulse wave velocity were recorded, in addition to perceived muscle soreness, vertical jumping ability (VJ), and agility. Nineteen subjects (mean±sd; age 23.1±5.0 yrs; BMI 25.6±3.3 kg.m-2) foam rolled prior to testing each day (FR), while 21 (mean±sd; age 24.2±3.4 yrs; BMI 26.3±4.0 kg.m-2) served as a non-foam rolling control (CON). Measurements recorded during the five days of recovery from the repeated sprint protocol were compared to those obtained during three baseline days of familiarization the prior week. The area under the curve (AUC) was calculated by summing all five scores, then these data were compared by condition using a two-tailed Mann-Whitney U test (alpha level = 0.05).
RESULTS: Neither heart rate variability, pulse wave velocity, agility, nor vertical jumping performance differed significantly between groups ($p>0.05$). Perceived muscle soreness was significantly diminished in the foam rolling condition ($p<0.05$). Mean Monday to Friday values for perceived muscle soreness in CON were 16.52, 30.24, 24.48, 17.19, and 11.10, respectively. Mean Monday to Friday values in FR were 12.63, 24.63, 21.79, 15.05, and 10.16, respectively.
CONCLUSION: FR may be useful for reducing soreness following damaging exercise, but under the conditions of the present experiment, the effect does not appear to be mediated by the autonomic nervous system.

EFFECTS OF TISSUE FLOSSING ON GASTROCNEMIUS MUSCLE EXERTION AND FLEXIBILITY

KANEDA, H.1, TAKAHIRA, N.2, TSUDA, K.1, TOZAKI, K.1, SAKAI, K.1, KUDO, S.1, TAKAHASHI, Y.1, FUKUSHIMA, K.3, KENMOKU, T.3

1: KITASATO UNIVERSITY GRADUATE SCHOOL, 2: KITASATO UNIVERSITY, 3: KITASATO UNIVERSITY HOSPITAL

INTRODUCTION: Tissue flossing is a simple method of fascia release that improves muscle flexibility and pain by decreasing the viscoelasticity of the fascia. It is widely performed among athletes and for rehabilitation because of its empirically known effectiveness on muscle pain and function. However, evidence regarding the quantitative improvement in muscle exertion and flexibility by flossing is lacking. This study aimed to examine the effects of flossing on gastrocnemius muscle exertion and flexibility in comparison with that of static stretching (SS), which is generally performed for injury prevention before and after exercise.
METHODS: This study adopted a 2 (time) × 3 (intervention) design for within-subject factors. Measurements were made in 20 healthy young males (age, 22.5 ± 1.0 years) on two days at least one week apart. All measurements and interventions were performed on the gastrocnemius muscle in the non-dominant leg (the one not involved in kicking the ball). The experimental intervention was FLOSSING, where passive mobilization and active ankle movement were performed with the lower leg wrapped tightly using a floss band (Sanctband COMPRE Floss™ Blueberry; 2 in × 3.5 m). The control intervention was SS for 5 min. The subjects rested in the supine position for 6 min (REST). Outcomes were measured before (PRE) and after (POST) each intervention in the order of dorsiflexion ROM, myotendinous junction (MTJ) displacement, maximal isometric voluntary plantar flexion contractions (MVC), rate of force development (RFD), and muscle activity. The pre-post changes in the outcomes for each intervention were assessed using a paired t-test. The pre-post changes among the 3 interventions were compared using a paired t-test with Bonferroni's correction.
RESULTS: FLOSSING significantly increased the ROM [mean: PRE, 7.9; POST, 10.5 (°); 95% confidence interval (CI) of difference: 1.6 to 3.7], MTJ displacement [1.7; 2.0 (cm); 0.1 to 0.5], and RFD 0–50 [3.8; 4.6 (Nm/kg/s); 0.2 to 1.3]. SS significantly increased the ROM [6.9; 9.6 (°); 1.6 to 3.8] and MTJ displacement [1.8; 2.0 (cm); 0.0 to 0.4], and significantly decreased the MVC [1.3; 1.2 (Nm/kg); −0.1 to −0.0], RFD 0–150 [3.8; 3.2 (Nm/kg/s); −1.0 to −0.1], RFD 0–200 [3.3; 2.8 (Nm/kg/s); −0.8 to −0.0], and muscle activity [1.1; 0.9 (V); −0.4 to −0.0]. FLOSSING showed significantly higher increases than SS in RFD 0–50 [95% CI of difference: 0.0 to 2.3], RFD 0–100 [0.0 to 2.0], and muscle activity [0.0 to 0.6].
CONCLUSION: Flossing improved both flexibility and muscle exertion unlike SS. Therefore, flossing before exercise may contribute to preventing injury and increasing performance.

EFFECTS OF MASSAGE AND COLD-WATER IMMERSION AFTER AN EXHAUSTIVE RUNNING SESSION ON PHYSIOLOGICAL AND PSYCHOLOGICAL PARAMETERS IN RUNNERS

DUÑABEITIA, I., GIL, J., ESAIN, I., GIL, S.M., IRAZUSTA, J., BIDAURRAZAGA-LETONA, I.

UPV/EHU

INTRODUCTION: The efficacy of cold-water immersion (CWI) and massage for physiological and psychological recovery in runners has shown conflicting results. Therefore, the objective of this study was to analyze the effects of CWI and massage performed after an exhaustive running session on running economy (RE), blood lactate and perceived recovery status (PRS)1 in runners.
METHODS: The sample included 32 well-trained male runners. Each participant attended the laboratory on two occasions. The first session was performed to obtain baseline measurements 24-h after a standardized exhaustive running session and included a treadmill speed test at three speeds (12, 14 and 16 km/h). Immediately after each speed, capillary blood samples were obtained for the determination of blood lactate concentration. RE was determined as the relationship between steady-state VO2 and running velocity (mlO2/kg/km). One hour after the speed treadmill test, subjects received either CWI (10-min, 10°±0.5°C) or massage (40-min). The PRS scale was administered immediately after the recovery interventions (0-min) and at 30-min, 2-h, 24-h and 48-h. Runners responded separately about the cardiopulmonary PRS (PRSres) and the muscular PRS (PRSmus). Twenty-four hours after the recovery intervention runners repeated the treadmill speed test.
RESULTS: No significant changes were observed in lactate at any of the velocities in both groups. However, RE significantly decreased in the massage group at 12 km/h and 14 km/h ($p<0.05$). No significant time x group interaction was observed in both variables.
No differences were found in PRSres between the different moments in both groups. In contrast, in PRSmus the CWI group results were significantly lower 30-min after the intervention when compared to 0-min ($p<0.05$). Similarly, the PRSmus values in the massage group were significantly lower at 24-h and 48-h when compared to 30-min and 2-h ($p<0.05$).
No significant time x group effect was observed in PRSres. However, a significant group effect was observed for PRSmus ($p<0.01$; $\mu 2=0.260$). Moreover, statistically significant post-hoc differences between the groups were observed at 30-min and 2-h ($p<0.05$).

CONCLUSION: Results of this study suggest that massage is a more effective recovery modality for enhancing RE. However, CWI showed a trend to be an advanced recovery method toward alleviating the symptoms of muscular perceived recovery status immediately after the intervention. Therefore, athletes should be aware that the choice of the recovery methods can influence differently physiological and psychological recovery.

IS VIBRATION ROLLING AS A WARM-UP EXERCISE MORE EFFECTIVE TO IMPROVE ON FLEXIBILITY, JOINT PROPRIOCEPTION, MUSCLE STRENGTH, AND DYNAMIC BALANCE COMPARED TO NON-VIBRATION ROLLING AND STATIC STRETCHING

LYU, B.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Warm-up is an essential component for optimizing performance before exercise. Myofascial release is one type of warm up method. Foam roller is a new tool for self myofascial release; it can increase joint range of motion (ROM). However, foam roller appears to have no beneficial effects on muscle strength (1). Vibration therapy is one type of warm up methods (2).It can improve flexibility, balance, countermovement jump peak power and height. Recently, vibrating foam rollers has been designed which combined with SMR and a local vibration technique (3). However, a few literatures on the use of vibration foam rolling are currently being investigated, particularly in warm up exercises. Accordingly, this study aimed to investigate the immediate effects of vibration rolling (VR), non-vibration rolling (NVR), and static stretching during warm-up on the athletic performance in young adults.
METHODS: This design was a crossover study. Thirty male college students were received three interventions: VR, NVR, and static stretching. Participants underwent pretests (flexibility tests, isokinetic strength, knee joint proprioception tests, and Y balance test) and then performed 6 minutes (3x30 sec quadriceps/hamstring, both legs) of VR, NVR, or static stretching(randomized) on quadriceps and hamstring muscles. Posttest measures were performed in the same order as the pretest measures immediately after the intervention.48 hours of rest was between each test.
RESULTS: Time effect (compared with the pre intervention): VR induced the range of motion of knee flexion and extension significantly increased by 2.5% and 6%, respectively, and isokinetic peak torque and dynamic balance for muscle strength and dynamic balance increased by 33%–35% and 1.5%, respectively. Group Effect (compared with three interventions): Most outcomes between VR and NVR were comparable; however, the participants had a significantly higher knee joint reposition error after NVR than after VR, indicating that NVR would have a disturbing knee joint proprioception effect. In particular, compared with static stretching, VR significantly increased the quadriceps muscle strength by 2-fold and dynamic balance by 1.8-fold.
CONCLUSION: We recommend including VR as a part of the warm-up regimen in male adults. This investigation provides new insights into future research on this technology. Athletic professionals may take this information into account for designing more efficient and effective pre performance routines.

EFFECTS OF ELASTIC TAPING ON DRIVING DISTANCE AND ACCURACY IN PROFESSIONAL GOLFERS

KIM, J.W., LEE, J.

DONG-EUI UNIVERSITY

INTRODUCTION: Driving distance is a decisive factor in the outcome of a golf game. Many methods such as stretching, muscle strengthening, and elastic taping are used to enhance golfers' swing performance. Recently, elastic taping has been found to improve athletes' performance, prevent injuries, and promote recovery from muscle fatigue. However, few research data are available with regard to the effects of elastic taping on the internal oblique and external oblique abdominal muscles, which play a crucial role in professional golfers' downswing. Therefore, this study aimed to investigate the effects of elastic taping on the distance and accuracy of drive shots in professional golfers by applying it in the internal and external oblique abdominal muscles.
METHODS: A cross-over design was adopted, and eight professional golfers aged ≥20 years without neurological and musculoskeletal injuries were included as subjects in this study. Downswing was analysed using GOLFZON Driving Range before and after randomly applying an elastic tape on the internal and external oblique abdominal muscles at 1-week intervals. The immediate changes in driving distance and accuracy were compared using Wilcoxon signed-rank test.
RESULTS: Applying elastic taping on the internal and external oblique abdominal muscles led to significant changes in the distance and accuracy of the drive shots by the professional golfers ($p < 0.05$).
CONCLUSION: This study found that elastic taping of the internal and external oblique abdominal muscles, which are important in downswing, enhanced the distance and accuracy of the drive shots by professional golfers. Thus, elastic taping of the internal and external oblique abdominal muscles during downswing is expected to be an effective training intervention for professional golfers to enhance their driving distance and accuracy.

EFFECTS OF KINESIOLOGY TAPING OF THE SHOULDER ON DYNAMIC BALANCE IN BASEBALL ATHLETES WITH MUSCLE FATIGUE

IMRAK, C., JUNGHOON, L.

DONG-EUI UNIVERSITY

INTRODUCTION: The shoulder, which has the widest range of motion in the human body, is vulnerable to injuries during overhead sports that involve repeated and excessive movements, especially baseball. Various interventions are used to treat shoulder injuries, and recent findings suggest that kinesiology taping of the skin improves pain, strengthens muscles, and facilitates joint movement. This study aimed to investigate the effects of kinesiology taping of the shoulder on dynamic balance in baseball athletes with muscle fatigue.
METHODS: Six baseball athletes provided informed consent to participate in this study. The peak torques of the shoulder's internal and external rotations were measured using a Biodex isokinetic dynamometer, and muscle fatigue was artificially induced. When the peak torque value decreased by >50% in three consecutive measurements, the shoulder's dynamic balance was measured three times using

Y-balance test. Then, kinesiology tape was applied to the deltoid and supraspinatus muscles before dynamic balance was re-measured. The immediate changes in dynamic balance were compared using Wilcoxon signed-rank test.
RESULTS: Applying kinesiology tape after inducing muscle fatigue in the shoulder significantly increased the shoulder dynamic balance in the baseball athletes.
CONCLUSION: Kinesiology taping was reported to improve fatigued muscle movement and increase muscle strength by stimulating the tactile sensation of the skin and activating the γ motor neuron in the muscle spindle. It has also been found to affect joint position sense. Therefore, kinesiology taping is speculated to increase the dynamic balance of fatigued shoulders by contributing to the elasticity of skeletal muscles, muscle actions, and joint position sense.

EFFECTS OF A 4-WEEKS PROPRIOCEPTIVE TRAINING BY USING PEDALO ON BALANCE DURING WIND-UP AND STRIDE POSTURES IN PROFESSIONAL BASEBALL ATHLETES.

KANG, H.S., LEE, J.H.

DONG-EUI UNIVERSITY

INTRODUCTION: In baseball, the pitching mechanism consists of wind-up, stride, cocking, release, and follow-through. Among these components, balance is critical during wind-up and stride, as the force is delivered from the legs to the upper body. A pitcher accumulates potential and elastic energy during wind-up and converts the potential energy to kinetic energy through gravity during stride. Thus, this study aimed to investigate the effects of wind-up and stride training by using pedalo equipment on balance in professional baseball pitchers.
METHODS: Twelve professional baseball pitchers were divided into intervention (n=6) and control groups (n = 6). The intervention group underwent training using a pedalo stabilizer by taking wind-up (30sec/five repetitions) and stride postures (30sec/five repetitions) on the stabilizer three times a week for 4 weeks. The control group underwent single-leg stance and stride posture training on a flat surface for the same duration as the intervention group. Balance was assessed by measuring changes in the area (mm2) and distance (cm) of the centre of pressure (COP) during wind-up with eyes closed and stride with eyes opened on a single leg.
RESULTS: The intervention group showed a significant reduction in changes in the distance and area of the COP during wind-up with eyes opened and stride with eyes closed after 4 weeks of training ($p < 0.05$).
CONCLUSION: Sekendiz et al. (2) reported that training in an unstable support surface enhances balance by effectively stimulating proprioceptive, tactile, and vestibular senses and inducing weight shift. Six weeks of proprioceptive training using the pedalo led to significant changes in muscle response, joint position sense, and posture in patients with ankle instability (3). Thus, we suggest wind-up and stride posture training using the pedalo, which offers an unstable surface, to enhance balance ability of baseball athletes.

EFFECT OF CARBOHYDRATE INGESTION AFTER MUSCLE GLYCOGEN DEPLETION ON HIGH-INTENSITY ENDURANCE PERFORMANCE

TSUKAMOTO, M.1, TOGO, M.2, SATO, M.3, HATTA, S.3, TANAKA, H.4, KIMOTO, R.5, AKIZUKI, A.6, YAMAGUCHI, T.3, KAMBAYAHI, I.4

1:TOKAI UNIVERSITY, 2:RITSUMEIKAN UNIVERSITY, 3:RAKUNO GAKUEN UNIVERSITY, 4:HOKKAIDO UNIVERSITY OF EDUCATION, 5: FUJI WOMEN'S UNIVERSITY, 6: HEALTH SCIENCES UNIVERSITY OF HOKKAIDO

INTRODUCTION: When muscle glycogen is depleted after exercise, the body must recover as much muscle glycogen as possible during the recovery period in order to maintain the level of performance during a second session of high-intensity exercise (1). However, there is little information whether carbohydrate ingestion contributes to high-intensity endurance performance. The purpose of this study was to compare high-intensity endurance performance in two conditions: a condition drinking a carbohydrate-electrolyte beverage containing sugar (CHO) and another condition drinking water (W). We also compared glucose (Glu), lactate (Lac), insulin (Ins) concentrations in blood and autonomic nerves system (ANS) activity after drinking in the recovery period of the two conditions.
METHODS: Eight trained male volunteers (age 20.1±1.6 yr, height 175.3±5.0 cm, weight 68.7±7.3 kg) participated in an incremental exhaustive exercise to determine maximal oxygen uptake (VO2max) and maximal work load (Wmax). A week later, the subjects did a high-intensity intermittent exercise and a moderate aerobic exercise (40%Wmax) to deplete muscle glycogen (2). Immediately after exercise, the subjects consumed a 500 ml carbohydrate-electrolyte beverage containing sugar (1.2g/kg weight) (3) in CHO or a 500 ml of water in W. This study had a randomized crossover design. After the 2 hours resting period, the subjects took part in a performance test at the intensity of 75Wmax (equivalent to 90%VO2max) until exhaustion. We determined Glu, Lac, Ins and ANS activity seven times, before (Pre) and immediately after (Mid) glycogen depletion exercise, 30min, 45min, 60min and 120min after drinking CHO or W, and after the performance test (Post). The area under the curve (AUC) from Mid to 120min in each index was used to compare two conditions.
RESULTS: Endurance time (637.1±82.7sec) of performance test in CHO was significantly shorter ($p<0.05$) that that of W (726.0±84.0sec). On the other hand, AUC of Glu, Lac and Ins during the recovery period in CHO were significantly higher ($p<0.01$) that those of W, respectively. The level of ANS activity on CHO tended to be lower than that on W.
CONCLUSION: Although it is believed that carbohydrate ingestion is effective for muscle glycogen repletion, our results did not show that it contributed to maintain the performance of the high-intensity endurance exercise. The results in the rise of Ins and the decline of ANS activity during the recovery suggest that these changes may have a negative influence on human body.

THE INFLUENCE OF DIFFERENT AMOUNT OF CARBOHYDRATE DIET INGESTION AFTER EXHAUSTION EXERCISE ON POSTPRANDIAL LIPEMIA

YANG, T.J., CHANG, C.K., CHIU, C.H.

NATIONAL TAIWAN NORMAL UNIVERSITY, NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: Muscle substrate concentrations may play some roles on postprandial lipemia the next day (1). It has been suggested that the insufficient of IMTG recovery after exercise can decrease the benefit of exercise on postprandial lipemia (2). Therefore, the objective of this study was to investigate the effects of ingesting meals with the same calorie intake but different nutritional contents after exercise on postprandial lipemia after a meal the next day.
METHODS: Eight healthy male participants (22 ± 1.3 yrs) completed two two-day trials in a random order. Participants underwent 90 minutes bicycle exercise at 66% VO2max for 14 min followed by high-intensity intervals at 85% VO2max for 4 times. After intervention, participants were asked to ingest three low-carbohydrate (LC) or high-carbohydrate (HC) diet. After fasting for at least 12 hr, participants ingested a high fat meal and rest for 4 hours.
RESULTS: There is no significantly different between LC and HC in postprandial TG concentrations (P >.05). The plasma glucose concentration of total area under the curve(AUC) (LC: 20.73 ± 1.33 mmol/l*4 hr vs. HC: 19.28 ± 1.57 mmol/l*4 hr; p = 0.007), NEFA AUC (LC: 3.14 ± 0.63 mmol/l*4 hr vs. HC: 2.68 ± 0.56 mmol/l*4 hr; p = 0.021) and glycerol AUC (LC: 203.81 ± 41.19 mmol/l*4 hr vs. HC: 154.28 ± 31.97 mmol/l*4 hr; p = 0.001) were significantly higher in LC trial than the HC trial.
CONCLUSION: This data suggested that high-carbohydrate diet after endurance exercise may not influence postprandial TG concentrations but may influence glucose metabolism.

THE IMPACT OF PRE-EXERCISE CARBOHYDRATES SUPPLEMENTATION WITH HIGH-CONCENTRATIONS DRINKS ON ENERGY METABOLISM AND EXERCISE INTENSITY IN FEMALE COLLEGIATE ATHLETES

KIMOTO, R.1, SOMA, A.2, AKIZUKI, A.3, TSUKAMOTO, M.4, TOGO, M.5, YAMAGUCHI, T.6, KAMBAYASHI, I.2

1: FUJI WOMEN'S UNIVERSITY, 2: HOKKAIDO UNIVERSITY OF EDUCATION, 3: HEALTH SCIENCES UNIVERSITY OF HOKKAIDO, 4: TOKAI UNIVERSITY, 5: RITSUMEIKAN UNIVERSITY, 6: RAKUNO GAKUEN UNIVERSITY

INTRODUCTION: Generally, intake of carbohydrates before exercise appears to be beneficial to performance (1). Meanwhile, it has been pointed out that intake of high concentrations of carbohydrates causes lowering of blood glucose level during exercise that may impair performance (2). However, previous studies have mainly been conducted among males, data on female collegiate athletes are lacking. This study aimed to investigate whether intake of high concentration of carbohydrates before moderate aerobic exercise could affect female collegiate athletes in terms of energy metabolism and exercise intensity.
METHODS: This study had a randomized crossover design. Ten trained female athletes (age: 19.3±1.6yrs, VO2peak: 45.5±5.4ml/kg/min) had been asked to fast for 12h, and then they drank a 500ml beverage containing 150g of glucose (CHO) or an equal amount of placebo water (PW) 30min before the exercise. The exercise load was set to achieve 50% of VO2peak (75.8±11.3w) each subject previously determined. Blood samples were collected 30min before the exercise, at 0min, 15min, 30min, 45min, 60min during the exercise and 15min after the exercise to analyse blood glucose level. During the exercise, cardio-respiratory data and heart rate (HR) were measured, and respiratory exchange ratio (RER) and CHO oxidation (3) were also calculated from VO2 and VCO2. In addition, rate of perceived exertion (RPE) was recorded every 6 min.
RESULTS: The blood glucose level in CHO condition dropped at 15min of the exercise after the rapid increase. Furthermore, it was significantly higher in CHO than in PW at all points except at 15min during the exercise ($p<0.01$). The mean of RER and CHO oxidation were significantly higher in CHO (0.91±0.03, 1090.5±131.4mg/min) than in PW (0.86±0.04, 818.1±135.3mg/min) ($p<0.01$). The mean of HR and %VO2peak were significantly higher in CHO (139.4±11.3bpm, 49.9±4.5%) than in PW (127.5±10.9bpm, 48.2±4.7%) ($p<0.01$ and $p<0.05$, respectively). RPE from 24min to 36min of the exercise was significantly higher in CHO than in PW ($p<0.01$).
CONCLUSION: In CHO condition, there was a spike and a rapid fall in blood glucose level, and carbohydrate was used as the main energy substrate during the exercise compared to PW condition. The results of HR, %VO2peak and RPE were higher in CHO condition than that of PW condition although the same load was used, suggest that pre-exercise carbohydrates supplementation in female collegiate athletes increased the physical and mental stress.

ACUTE EFFECT OF NUTRITION INTAKE BEFORE OR AFTER RESISTANCE EXERCISE ON MUSCLE BREAKDOWN IN THE MORNING IN HEALTHY YOUNG MEN

KUME, W., KATAYAMA, K., HASHIMOTO, T.

RITSUMEIKAN UNIVERSITY

INTRODUCTION: Previous study found that muscle hypertrophic effect (MHE) of resistance exercise (RE) in the morning was less than evening due to hormone balance of testosterone and cortisol, which is related to muscle synthesis (MS) and muscle breakdown (MB), respectively 1). Also, RE-induced MB could be elevated due to malnutrition in the morning 2), and breakfast skippers has less muscle mass 3). On the other hand, Bird et al. (2006) found that nutrient intake during RE suppressed MB, and such acute response might reflect promoted MHE to chronic RE training 4). These findings suggest the importance of nutrient state for MHE in the morning. Another concern is the timing of nutrient intake. Tipton et al. (2001) reported that the response of net MS to nutrient intake before RE is greater than that after RE 5). On the other hand, Fujita et al. (2009) mentioned that nutrient intake before RE does not enhance MS after RE compared with RE without nutrients 6). However, it is still unclear whether which is the better timing of nutrient intake before or after RE for augmented MHE 5) 6).
The aim of this study was to examine the effect of timing of nutrient intake before or after RE on MB in the morning.
METHODS: There healthy young men (22.7±0.9 years) performed three trials: 1) nutrient intake before RE (Pre), 2) nutrient intake after RE (Post), and 3) RE without nutrient intake (No). They performed 5 types of multiple RE at 70%RM intensity from 8:30 to 9:30 in all conditions. The time of nutrient intake in the Pre was at 7:00, while in the Post was at 9:30. Soybean granola 100g, Greek yogurt 100g, whey protein 32g, milk 200ml and a bunch of banana (total energy, 868kcal; protein, 55.4g [25.6%]; fat, 24.8g [25.7%]; carbohydrate, 105.6g [48.7%])

were provided. Blood samples were collected at 7:00, 8:30, 9:30, 10:30, 13:00 and 15:00, and insulin, 3-methylhistidine (3-MH), a MB marker, testosterone and cortisol concentration were measured.
RESULTS: The area under the curve (AUC) for insulin after RE was significantly higher in Post than that in No ($P < 0.05$). The time-course changes of 3-MH after RE tended to be lower in Post than those in No ($P = 0.11$). Also, the concentration of 3-MH in Pre was significantly higher at 13:00 than that at 7:00($P < 0.01$). There was a tendency of negative correlation between 3-MH and insulin after RE ($r = -0.3$, $P = 0.07$).
CONCLUSION: These results suggest that nutrient intake after RE may be more effective in suppression of MB than that before RE in the morning.

THE EFFECTS OF COWS MILK, GOATS MILK, WHEY PROTEIN AND AN ENERGY-MATCHED CARBOHYDRATE DRINK ON RECOVERY FROM REPEATED SPRINTING AND JUMPING IN TEAM SPORT ATHLETES

CURRISTIN, M., FITZPATRICK, P., RANKIN, P.
INSTITUTE OF TECHNOLOGY CARLOW

INTRODUCTION: Effective recovery following intense exercise is integral for any athlete to ensure subsequent performance is not comprised. The aim of this investigation was to determine the effects of cows milk, goats milk and whey protein on recovery from a sprinting and jumping protocol.
METHODS: Thirty-two team sport athletes participated in an independent group investigation. Participants were randomly but equally assigned to a goats milk group (GOAT), a cows milk group (COW), a whey protein group (WHEY) or an energy-matched carbohydrate group (CHO), with 750ml of the allocated fluid consumed following a sprinting and jumping protocol. Assessment of muscle damage (creatine kinase (CK), soreness and tiredness (visual analogue scale (VAS)), perceived recovery - daily analysis of life demands for athlete's (DALDA) questionnaire), palatability (Likert Scale) and muscle function (peak torque (PkTq), rate of force development (RFD), 20m sprint, countermovement jump (CMJ), reactive strength index (RSI)), took place pre- and 24h, 48h, and 72h post-exercise.
RESULTS: Compared to CHO, GOAT had a beneficial effect on CMJ B-24h (2 v -8%; likely, small) and B-48h (-1 v -6%; possible, trivial). COW had a beneficial effect B-24h (-4 v -8%; possible, trivial) and WHEY comparisons were unclear. GOAT v COW showed a benefit for GOAT at B-24h (2 v -4%; possible, small) but other comparisons were trivial. GOAT v WHEY showed a benefit for GOAT at B-48h (-1 v -6%; possible, trivial). COW v WHEY comparisons revealed COW benefits B-24h (4 v -6%, possible, trivial) and B-48h (-3 v -6%; possible, trivial). Peak torque revealed trivial or unclear outcomes, though a benefit for GOAT was seen at B-48h for peak torque (60○/s) extension (-4 v -8%; possible, trivial) and B-48h for peak torque (180○/s) extension (-3 v -11%; possible, small). WHEY comparisons showed beneficial effects across all time frames. A benefit for COW was found for 5m B-24h (1 v 1%; possible, trivial), B-48h (2 v 0.4%; possible, small) and B-72h (1 v 0.4%; possible, small). Similarly, for 10m, B-24h (1 v 0.4%; possible, trivial). GOAT, COW and WHEY had a positive effect on soreness and tiredness B-24h, B-48h, B-72h compared to CHO. Less severe CK increases in GOAT compared to COW had a likely large beneficial effect B-24h and a likely moderate beneficial effect B-48h and B-72h. CK levels in CHO compared to WHEY had a likely moderate harmful effect from B-24h, a possibly moderate harmful effect B-48h and a possibly small harmful effect B-72h.
CONCLUSION: Consumption of 750 mL of cows milk, goats milk and whey protein following repeated sprinting and jumping can limit decrements in muscle function, increases in serum proteins and increases in muscle soreness and tiredness and daily stresses, thus, enhancing recovery. These beverages may augment recovery and thus, have a positive effect on performance during subsequent training and games. However, considerable variation in the results was observed and thus, further investigation is warranted.

THE EFFECTS OF CYSTINE AND GLUTAMINE SUPPLEMENTATION ON GASTROINTESTINAL PERMEABILITY AND SUBJECTIVE FATIGUE IN REPONSE TO CYCLING EXERCISE IN YOUNG MEN

MIYASHITA, M.1, YADA, K.1, MA, S.1, ONO, M.2, TOYODA, T.2, SUZUKI, K.1
1: WASEDA UNIVERSITY, 2: AJINOMOTO CO., INC.

INTRODUCTION: An acute bout of intense exercise has been shown to increase gastrointestinal permeability, attenuating barrier function which leads to an initial proinflammatory cascade, and eventually causing gastrointestinal distress and impaired performance (1). Recently, our preliminary study found that the oral ingestion of the mixture of cystine and glutamine alleviates the intestinal barrier disruption by intense exercise in mice. In addition, the previous study reported that orally administered glutathione, which is derivative of cystine, attenuates exercise-induced fatigue feeling by enhancing fat utilisation (2). Therefore, the aim of the present study was to examine the effects of oral cystine and glutamine supplementation on gastrointestinal permeability and subjective fatigue in response to intense exercise in young men.
METHODS: Thirteen recreationally active men completed two trials in a random order: 1) placebo and 2) cystine plus glutamine supplementation. Subjects were given either placebo or cystine plus glutamine supplementation three times a day for 7 days, separated by a three-week washout period. In each trial, subjects performed cycling at 70% of maximal oxygen uptake for 1 h on days 6 and 7. Gastrointestinal permeability was assessed using ratio of lactulose to mannitol (L:M) in urine. Circulating concentrations of intestinal fatty acid binding protein (I-FABP) and metabolites were measured at pre-exercise, immediately post-exercise, 30 min post-exercise, and 1 and 2 h post-exercise. Heart rate and ratings of perceived exertion (RPE) were assessed during cycling.
RESULTS: Intestinal damage markers, L:M and I-FABP, were not changed by cycling exercise in both trials. RPE elevation during exercise recorded on day 6 was lowered in the cystine plus glutamine supplementation trial than the placebo trial. Serum free fatty acids concentrations on day 6 was lowered in the cystine plus glutamine supplementation trial than the placebo trial. There were no differences in serum glycerol concentrations measured on days 6 and 7 between placebo and cystine plus glutamine supplementation trials.
CONCLUSION: The present study demonstrates that although gastrointestinal damage was not observed in our exercise protocol oral cystine plus glutamine supplementation attenuates subjective feelings of fatigue during 1 h of cycling. In addition, blood metabolites findings may indicate that energy utilisation from fat is enhanced during cycling and this possibly reduces subjective feelings of fatigue.

INTAKE OF BRANCHED-CHAIN AMINO ACIDS IN COMBINATION WITH ENDURANCE EXERCISE – NO EFFECT ON MRNA EXPRESSION OF PROTEINS REGULATING MITOCHONDRIAL BIOGENESIS

EDMAN, S., HORWATH, O., BLOMSTRAND, E.
THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

INTRODUCTION: One of the most well-known adaptations to endurance exercise is the elevation of mitochondrial content in skeletal muscle. Mitochondrial biogenesis is recognized to be mediated by the master regulator peroxisome proliferator-activated receptor gamma coactivator-1-alpha (PGC-1alpha). Consequently, mRNA expression of PGC-1alpha is highly responsive to endurance exercise stimuli (1). Moreover, in experimental animals, branched-chain amino acid (BCAA) supplementation was reported to potentiate PGC-1alpha mRNA expression (2). Recently, different isoforms of PGC-1alpha were discovered and suggested to mediate diverse training adaptions ranging from mitochondrial biogenesis to skeletal muscle hypertrophy (3). Here, we examine the effect of BCAA intake on mRNA expression of the PGC-1alpha isoforms following endurance exercise in man.
METHODS: Ten recreationally active subjects, 7 males and 3 females, performed two sessions of one-legged knee extension exercise. In randomized order, the subjects ingested an aqueous solution with BCAA (130 mg/kg) or flavoured water (placebo) during exercise and recovery. Muscle biopsies were taken from the vastus lateralis before, 90 and 180 min after exercise in both the exercising and the resting leg. Blood samples were collected throughout exercise and recovery. Muscle biopsies were freeze dried and mRNA levels of PGC-1alpha1, PGC-1alpha4 and the mitochondrial transcription factor (TFAM) were analysed using qRT-PCR. HPLC was used to determine plasma free amino acid concentrations.
RESULTS: As expected, the plasma concentration of BCAA rose following intake of these amino acids (approximately 2-fold, $P<0.05$ vs placebo). Exercise led to an increase in TFAM, PGC-1alpha1 and PGC-1alpha4 mRNA at 180 min post exercise ($P<0.05$ vs baseline), the increases were 11%, 2.5-fold and 10-fold, respectively. In addition, PGC-1alpha4 was elevated 5-fold 90 min into recovery ($P<0.05$ vs baseline) and PGC-1alpha1 showed a similar trend ($P=0.051$). However unexpectedly, intake of BCAA had no effect on mRNA expression of these proteins. Minor or no effects of exercise were seen in the resting leg.
CONCLUSION: Both PGC-1alpha1 and PGC-1alpha4 were highly responsive to endurance exercise in recreationally active subjects. However, intake of BCAA did not affect the mRNA expression of proteins involved in the regulation of mitochondrial biogenesis neither in the exercising nor in the resting leg.

AMOUNT, SOURCE AND PATTERN OF DIETARY PROTEIN INTAKE ACROSS THE ADULT LIFESPAN: A CROSS-SECTIONAL STUDY.

SMEUNINX, B., CAROLYN, A.C., BREEN, L.
UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Sub-optimal dietary protein consumption may partially underlie the age-related loss of muscle mass and function (sarcopenia). Specifically, dose, timing, source and distribution of dietary protein across the day might influence muscle anabolism in individuals from across the lifespan.
METHODS: The present study aimed to assess daily and meal-specific protein intake, protein source and protein intake pattern in 40 young (23.8 ± 4.3 yrs), 40 middle-aged (51.6 ± 4.1 yrs) and 40 old (77.4 ± 7.4 yrs) individuals using 3-day weighed food diaries.
RESULTS: Old individuals consumed on average 83.4 ± 24.6 g of daily protein, which was significantly lower compared with young but not middle-aged individuals who consumed, respectively, 105.1 ± 43.0 g and 97.0 ± 31.1 g of daily protein ($P = 0.013$). No significant difference in daily protein intake was found with middle-aged individuals. Dietary protein intake pattern was uneven across meals for all groups ($P < 0.001$ for all). Sources of protein consumption were similar between groups except at lunch where old individuals ingested lower quality proteins compared with middle aged and young individuals.
CONCLUSION: Although total daily protein intake was sufficient in the majority of participants, per-meal protein intake and protein distribution contend the current knowledge regarding optimal protein intakes. Increasing protein intake, especially at breakfast and lunch, could mitigate age-related muscle loss.

CP-PM23 Endurance methods: Recovery

DIFFERENCE IN VENTILATION AND CYCLING ECONOMY IN TWO SITTING POSITIONS ON A BIKE.

KVIDALAND, H., KRISTOFFERSEN, M.B., GUNDERSEN, H., BOVIM, L.P., RØKSUND, O.D.
WESTERN NORWAY UNIVERSITY OG APPLIED SCIENCE

INTRODUCTION: In road-cycling sitting position is important regarding aerodynamics and cycling economy. The aim of this study was to compare the effect of two different sitting positions on ventilation and economy of effort, when air resistance is not taken into account.
METHODS: Twenty-four trained cyclists (age 36±9) participated in a randomized counterbalanced cross-sectional study with a within subject design. The tests were conducted on two days with a minimum of 48 hours in-between. Before test day one, the participants were randomized either to cycle with hands on the handlebar (UP) or in the drops (DP). At test day two, participants were cycling in the opposite sitting position. Spirometry (Vyntus Pneumo, Carefusion, Germany) were identically tested each test day before entering the bike. Maximal voluntary ventilation test (MVV), incremental cycling lactate profil test (90 RPM) and a maximum oxygen consumption test (VO2max-test) were identically performed both days in randomized sitting position. Oxygen consumption and minute ventilation was

measured using Vyntus CPX (Carefusion, Germany), heart rate using Polar 450 (Polar, Finland) and lactate using Lactate scout+ (SensLab GmbH, Leipzig Germany). All tests were performed on the cyclists' own bikes, using a Tacx Neo Smart trainer (Tacx, Netherland).
RESULTS: Compared with hands on the handlebar, hands in the drops shows significantly higher minute ventilation (L/min) (98±26 vs 104±23, p=.001), breath per minute (35±6, vs 37±6, p=.007), lactate levels (mmol/L) (4.7±0.9 vs 5.4±1.0), p<.001) and heart rate (bpm) (162±10 vs 164±11, p=.039). No significant difference in mean VO2max (mL/kg/min) (54±5.9 vs 53±4.9, P=.096) was found. However, 42% (10 out of 24 cyclists) managed to bike one extra interval (at higher watt) during the VO2max-test having the hands in the handlebar position. Spirometry and MVV showed no significant differences between positions.
CONCLUSION: An upright position with the hands on the handlebar position is more favorable than a more forward position with hand in the drop, for road cycling, when it comes to ventilation and economy of effort.

INDIVIDUAL PHYSICAL WORKING CAPACITY – A NEW METHOD TO DETERMINE PERFORMANCE FROM SUB-MAXIMAL INCREMENTAL EXERCISE

MÜLLER, A., BIRNBAUMER, P.H., TSCHAKERT, G., TRAUNMÜLLER, C., HOFMANN, P.

UNIVERSITY OF GRAZ

INTRODUCTION: The classical Physical Working Capacity (PWC) is dependent on age and therefore an age-corrected individual PWC (PWCi) has been prescribed earlier (1). Our study validated PWCi against threshold values from standard incremental ergometer exercise. We hypothesized that PWCi is not significantly different from standard threshold values.
METHODS: Results from incremental ergometer exercise of 97 (4 female) subjects (age: 41.5±8.8 yrs; weight: 85±13.4: BMI: 26.1±3.4; VO2max: 41.1±8.7 ml/kg-1.min-1) were analyzed with respect to PWCi. Ventilatory Threshold (VT2), Lactate Turn Point (LTP2) and Heart Rate Turn Point (HRTP) were determined. PWCi was calculated as the power output at 90% of age-predicted maximal HR (HRmax=210-age) by linear interpolation. VT2 was determined as the second increase in ventilation accompanied by an increase in VE/VO2 and VE/VCO2. LTP2 was determined as the second increase in lactate concentration. HRTP was defined as the deflection of HR. Errors of estimation were calculated. Comparisons were made by Wilcoxon rank test, as LTP2 was not normally distributed.
RESULTS: Maximal HR (184.7±10.3 b.min-1) and age predicted HRmax (168.5±6.8 b.min-1) were significantly different (r=0.323, p<0.0006). Calculated HR at PWCi (151.7±6.1 b.min-1) and HR at LTP2 (156.1±11.5 b.min-1), were significantly related (r=0.293, p<0.003) but significantly different (p<0.0003). Power output at VT2 (172.4±40.0 W) and HRTP (174.5±40.6 W) were not significantly different from LTP2 (172.2±39.4 W) and they were significantly correlated (VT: r=0.989, p<0.0001; HRTP: r=0.991, p<0.0001). PWCi calculated from age predicted HRmax (163.6±44.8 W) was significantly related to PLT2 (r=0.786, p<0.0001) but significantly different by 8.7±28.1 W (median difference). Error of measurement for PWCi determination was 4.6±16.8%.
CONCLUSION: Although HRmax as well as threshold HR were significantly different PWCi allowed to calculate submaximal performance with an acceptable error below 5%. PWCi was highly related to standard threshold values but slightly underestimated performance in an age heterogeneous group of untrained subjects but it may be applied in age heterogeneous groups to estimate performance from a submaximal incremental exercise.

PREDICTING AEROBIC ENDURANCE PERFORMANCE – SAVE TIME AND BLOOD!

JOHANSEN, J., SUNDE, A., HELGERUD, J., STØREN, Ø.

UNIVERSITY OF SOUTHEASTERN NORWAY, BØ, NORWAY; NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, TRONDHEIM, NORWAY

INTRODUCTION: Maximal oxygen uptake (VO2max), oxygen cost of movement (C) and lactate threshold (LT) are the main determinants of aerobic endurance performance. A formula of these three factors can calculate power at LT in cycling in a precise manner (1). The formula presupposes no or minor adaptations in LT percentage of VO2max with training (2). The purposes of the present study was to assess 1) if the same formula used in cycling could calculate velocity at LT (LTV) in cross country skiing when double poling (DP), and 2) how accurate this formula could predict cross-country skiing DP performance among well-trained cross-country skiers.
METHODS: 18 well trained cross-country skiers (12 males and 6 females) with an average VO2peak in DP of 56.9 ± 9.4 ml·kg·min-1, and an outdoor 5.6 km DP roller skiing time trail performance of 851.6 ± 100.6 sec, participated in the present study. All participants were tested for blood lactate concentration ([La-]b) and VO2 during an incremental step test of four min DP at different set velocities to determine LT and LTV. A VO2peak test in DP and an outdoor DP roller-skiing time-trail was also conducted. LTV was first defined as the DP velocity representing warm up [La-]b +2.3 mmol·L-1. Then LTV was calculated by the following formula: LTV = LT %VO2peak · (VO2peak / CDP at LT).
RESULTS: The calculated LTV expressed a perfect correlation to blood sample measured LTV (R=1.00, p < 0.001, SEE = 0.1%). Calculated LTV also showed a very strong correlation to 5.6 km DP performance (R = -0.94, p < 0,001, SEE = 2.0%). This correlation was superior to VO2peak, CDP and the product of the two factors (R = -0.86, R=0.31 and R=-0.83 respectively).
CONCLUSION: The results of the present study supports the need of only one LT assessment with blood samples in order to conduct subsequent LTV assessments in DP. Later LTV assessments thus only require measurements of VO2peak and CDP. This saves time and blood sampling when testing well-trained and elite cross-country skiers. By use of VO2peak, CDP and LT %VO2peak, cross country DP skiing performance could be predicted with high accuracy (SEE = 2.0%). Thus, this formula is a useful tool for trainers when evaluating their cross-country skiers.

PHYSIOLOGICAL DETERMINANTS OF ELITE MOUNTAIN BIKE CROSS-COUNTRY MARATHON PERFORMANCE

CARMO, E.C., ABAD, C.C.C., PRADO, D.L., INOUÉ, A., MACHADO, T., LOTURCO, I., TRICOLI, V.

SENAC UNIVERSITY CENTER; UNIVERSITY OF SÃO PAULO; NUCLEUS OF HIGH PERFORMANCE IN SPORTS - NARSP; BRAZILIAN NAVY

INTRODUCTION: Most of the studies on mountain bike (MTB) have focused the Olympic cross-country (XCO) format and few are known about cross-country marathon (XCM). These few studies have shown strongest correlation between performance and maximal oxygen consumption (VO2max) and peak power output (PPO) in a 4h race (1) or with PO at lactate threshold in an 8-day multi-stage race (2).

However, more studies are necessary to advance in knowledge about the topic. Therefore, the purpose of this study was to verify the relationship between laboratory assed physiological variables with performance in XCM-MTB.
METHODS: Brazilian elite athletes (n = 9; 28 ± 7 years, 173 ± 7cm height, 64.4 ± 6 kg), including national and Pan-American championships performed the followed tests: Tensiomyography (TMG) of vastus lateralis (VL), rectus femoris (RF) and biceps femoris (BF) muscles; squat jump; counter movement jump; drop jump from 30 cm box (DJ30); drop jump from 45 cm box (DJ45); jump squat (JS) and half squat (HS) to assess the optimal load (OPL) and mean of propulsive power outputs (MPP) and isometric HS to verify the maximal voluntary isometric strength (MVIS); a submaximal cycling test at 150w; a maximal progressive aerobic test (MAT) and a Wingate test (WT). The cycling tests were performed on a mountain bike coupled to Cyclus2 ergometer (RBM elektronik-automation GmbH, Leipzig, Germany). The analyzed MTB-XCM race was the fourth stage of Mountain Bike International Cup with the course of 64km in total length and total ascent of 1573m. Pearson correlation coefficient was used to verify the level of association between variables and interpreted as <0.1, trivial; 0.1-0.3, small; 0.3-0.5, moderate; 0.5-0.7, strong, 0.7-0.9, very strong; > 0.9, nearly perfect. A multiple linear regression with the stepwise procedure was used to verify the level of determination between variables.
RESULTS: The race performance (total time) was significantly ($p < 0.01$) and strongly correlated with peak cadence and anaerobic capacity in WT; velocity of contraction of RF and BF muscles in TMG; high in DJ30, MMP at 40% and 60% of body mass in JS and MIVS. It was observed very strong correlations with cycling economy at submaximal test; PO at first ventilator threshold (VT) in MAT; peak power and average power in WT. Nearly perfect correlations were observed to PO at second VT (POVT2) and PPO in MAT. The highest significant predictive model indicated by step-wise analysis was MTB-XCM race time = VT2 + OPL in HS and MPP in HS ($r2 = 0.96$; $p = 0.04$).
CONCLUSION: The physiological variables assessed in laboratory tests were associated with performance in XCM-MTB. Only POVT2 explained 87% of performance variance, which was increase to 96% when OPL and MPP in HS were added to the model.

EFFECTS OF COLD WATER IMMERSION RECOVERY STRATEGY ON PHYSIOLOGICAL INDEXES AFTER HIGH-INTENSITY INTERMITTENT EXERCISE

YANG, Y.1, CHEN, S.C.2, YANG, W.T.3, KUO, J.T.H.3, CHIEN, K.Y.3

1GRADUATE INSTITUTE OF ATHLETICS/COACHING SCIENCE, NTSU 2DEPARTMENT OF RECREATIONAL SPORTS MANAGEMENT, YDU 3 GRADUATE INSTITUTE OF SPORTS SCIENCE, NTSU

INTRODUCTION: High-intensity interval training is considered to be one of the most effective methods of improving cardiopulmonary function and metabolic function (Buchheit & Laursen, 2013). It has been loved by many fitness enthusiasts. However, the high-intensity training load makes it easier for trainers to cause symptoms such as muscle fiber soreness, muscle fiber damage or individual fatigue after exercise (Esfarjani & Laursen, 2007). Cold Water Immersion (CWI) is thought to accelerate the recovery of physiological and motor skills after exercise (Wilcock, Cronin, & Hing, 2006). But, it is also a cold environment recovery strategy - Whole Body Cryotherapy (WBC). Studies have shown a significant increase in blood pressure after use (Lubkowska & Szygula, 2010). According to the research team, only one is about the effect of cold water immersion on blood pressure. However, for the cold water immersion recovery conditions commonly used after exercise, immersion for 10-15 minutes at 10 °C -15 °C, there is no research on the effect of cold water immersion recovery strategy on blood pressure after exercise. Therefore, this study compared the differences in response to body mass indicators such as blood pressure, heart rate, lactic acid, and ear temperature after using high-intensity intermittent exercise with cold water immersion recovery strategy and static recovery, and compared the differences in subjective indicators rating of perceived exertion(RPE).
METHODS: We recruited 20 males (21.5±1.6 years). Using a randomized crossover design, each participant performed a maximum exercise performance test on the bicycle to measure the heart rate, then six cycles of high-intensity intermittent exercise (1 minute 120% heart rate reserve (HRR) and 4 minutes 40%HRR) were performed in a random sequence, and the recovery period was either cold water immersion or static recovery. Blood pressure, heart rate, the rating of perceived exertion (RPE), lactate and ear temperature were performed before exercise, at the end of the exercise, and at the 6th, 20th, and 35th minute of the two test scenarios.
RESULTS: Systolic and diastolic blood pressure were significantly higher than SR at 6th and 20th minute of CWI recovery, and significantly higher than quiet state at 6th minute; the heart rate was significantly lower than SR at the 20th minute and 35th minute of CWI recovery; and RPE was significantly lower than SR at 6th and 20th minute of CWI recovery; there was no significant difference in lactate between the two recovery strategies; the ear temperature was not significant difference when it was quiet, the end of exercise, and the 6th and 35th minute of recovery, but at the 20th minute of recovery, CWI was significantly higher than SR.
CONCLUSION: Cold water immersion after high-intensity intermittent exercise reduced the extent of blood pressure decreases. For the fatigue-related heart rate and RPE indicators, the cold water immersion is better than static recovery. In addition, cold water immersion causes the ear temperature to rise during recovery, and the length of the immersion time is the main cause of this result.

AN ANALYSIS OF GAME MOVEMENT DEMANDS OF INTERPROVINCIAL WOMEN'S RUGBY UNION

CALLANAN, D., RANKIN, P., FITZPATRICK, P.

INSTITUTE OF TECHNOLOGY CARLOW

INTRODUCTION: The growth in women's Rugby Union (RU) has led to an increase in its professionalism, competitiveness and intensity. This warrants the need to identify the physiological demands to ensure practitioners can develop accurate planning and periodisation of training sessions (Lynn Virr et al., 2014; Ziv and Lidor, 2016). Despite the growth of female participation rates in RU, there is a dearth in the research examining women RU players, especially in regards to positional groups.
METHODS: One hundred and twenty-eight Interprovincial women Rugby Union players (n = 128) from two teams playing in the Interprovincial series were analysed across two seasons (December 2017, August/September 2018). To be included in the analysis, participants must have completed • 60 minutes in a match during the Interprovincial series (Cunningham et al., 2016). This resulted in a total of 161 individual data files collected (n = 161) (forwards = 85; FR = 33, SR = 22, BR = 30 and backs = 76; HB = 23, MF = 20 and B3 = 33). Game movement demands were recorded using a 10 Hz global position series integrated (PLAYERTEK•, Dundalk, Ireland). The locomotor variables that were analysed include the following: total distance (TD) (m), relative distance (RD) (m.min-1), max velocity (m.s-1) and sprint distance (SD) (>5.5 m/s) (m).
RESULTS: It was reported that MF covered the greatest average TD (6144 ± 516 m) across the series, with MF and HB covering a significantly greater distance than both FR and SR ($p < 0.01$). The B3 recorded the average highest max velocity (7.2 ± 0.36 m.s-1), with analysis reporting a significant difference between B3 and FR, SR, BR and HB ($p < 0.01$). MF reported a greater average max velocity than FR and

SR ($p < 0.01$). HB recorded the greatest RD (73.2 ± 8.01 m.min-1), with HB and MF reporting significantly higher intensities than FR and SR ($p < 0.01$). In SD, B3 covered the greatest average distance (353 ± 175 m), with MF and B3 covering a greater distance than FR and SR, with B3 also covering a greater distance than the BR ($p < 0.01$).
CONCLUSION: These results highlight the various differences in game movement demands between sub positional groups. This information is pivotal for both coaches and sport science practitioners. The ability to quantify the games movement demands can allow conditioning staff to periodise individual training sessions to elicit the required physiological adaptations. It may provide additional information on the demands on the game for specific positional groups which may have an impact on the subsequent recovery process. Future research should examine contextual factors in conjunction with the game movement demands.

DOES HIGH-INTENSITY PRE-LOAD HAVE AN EFFECT ON LACTATE ELIMINATION RATE AFTER CROSS-COUNTRY SKIING SPRINT PERFORMANCE?

VALIULIN, D.1, PURGE, P.1, HOFMANN, P.2, KIVIL, A.1, MUELLER, A.2, TSCHAKERT, G.2, BIRNBAUMER, P.2, MÄESTU, J.1, JÜRIMÄE, J.1

1> UNIVERSITY OF TARTU, TARTU, ESTONIA ; 2> UNIVERSITY OF GRAZ; GRAZ, AUSTRIA

INTRODUCTION: Lactate (La) production is an essential process of anaerobic work and body energy supply. The heart and oxidative muscle fibers remove and combust La as an extra energy source shuttled from areas of high glycogenolytic rate to areas of high cellular respiration (1). The purpose of this study was to investigate the buffer mechanism efficiency and lactate elimination rate starting from different baselines.
METHODS: 13 well-trained college level male cross-country skiers (age: 18.3 ± 2.9 yrs.; body height: 180.8 ± 4.6 cm; body mass: 70.8 ± 7.3 kg; body fat: 15.5 ± 3.5 %) performed two maximal 1000 m upper-body cross-country ski ergometer bouts with (MPThigh) and without (MPTlow) pre-load in a randomized order. Both bouts were preceded by low intensity 20 minute warm-up and 14 minutes recovery. Additionally to low intensity warm-up, 30 seconds of all-out leg cycle ergometer exercise pre-load was performed before MPThigh bouts to increase systemic La. La concentration was determined for both conditions at rest, after the warm-up, after the anaerobic-preload, and during recovery.
RESULTS: In MPTlow subjects completed the 1000m maximal bout in 225.1 ± 17.6 sec compared to MPThigh condition with 226.1±15.7 sec ($p>0.05$). La concentrations were not statistically different between two groups after low intensity warm-up. High-intensity pre-load elevated La to 8.2 ± 2.2 mmol.l-1 in MPThigh compared to 1.4 ± 0.3 mmol.l-1 in MPTlow ($p<0.05$). However, net La production during 1000 m maximal performance in MPThigh (6.5 ± 3.4 mmol.l-1) remained lower ($p<0.05$) than MPTlow Lanet (10.5±2.2 mmol.l-1).
CONCLUSION: La elimination tendency was statistically similar/homogeneous between groups ($p>0,05$) during recovery phase after maximal skiing performance. Despite significantly different maximal La values after 1000 m maximal cross-country skiing performance, the elimination curve remained identical between MPThigh and MPTlow groups. La elimination speed remain unchanged ($p<0.05$) with all buffer mechanisms working on maximal capacity with La levels above 9.6 ± 0.3 mmol.l-1 .
Although net La was significantly lower in MPThigh, performance was not significantly reduced, indicating that even with high pre-loads such as in repeated heats performance can be kept on a high level.

CORRELATION BETWEEN EARLOBE SURFACE TEMPERATURE AND INNER EAR TEMPERATURE IN A HOT ENVIRONMENT

SATO, K., RYOICHI, N.

TOHOKU UNIVERSITY

INTRODUCTION: Global warming has resulted in a significant increase in the risk of heat stroke of athletes. In order to prevent heat stroke accidents, the common strategies are to avoid working or competing in hot environments, to follow alerts regarding environmental temperature, to avoid dehydration, etc. Unfortunately, individual differences are rarely considered.
Considering the pathology of heat stroke, initiatives are needed to promptly implement an individualized method for monitoring increased body temperature, particularly brain temperature, due to a hot environment or heat production caused by exercise, and implement actions to suppress the increase in brain temperature.
However, brain temperature cannot be directly measured, and conventionally, tympanic temperature or inner ear temperature has been used as a substitute for brain temperature [1]. Currently available methods of the temperature measurement, however, may not be suitable for athletes in action. The present study was aimed to find an appropriate body surface area out of several target regions, the surface temperature of which corresponds to inner ear temperature representing brain temperature in order to design a suitable system that can be easily implemented during work or exercise.
METHODS: We recruited healthy young men and performed measurement in 22 subjects from whom consent could be obtained (mean age: 23.1 ± 5.6 years). The study protocol was approved by the institutional review board of the Tohoku University Graduate School of Medicine (2018-1-425).
In advance, an earhole-type clinical thermometer was inserted into the ear canal, and a thermistor for measurement of body temperature was attached to the ear lobe using a clip. At the same time, the surface temperature of the forehead, nasal tip, and cheek was measured using a thermal camera. The subjects were moved at a heated room, and after 5 minutes of rest, asked to cycle on an exercise bike at an exercise intensity of 60% as determined by heart rate reserve for 10 minutes.
RESULTS: Multivariate correlation with measurement data as an explanatory variable and earhole body temperature as a target variable was performed using a 5% significance level.
Ear-hole temperature and the earlobe surface temperature showed a stronger correlation ($r2 = 0.81$) as compared to the temperature recorded from other areas.
CONCLUSION: Monitoring the increase in brain temperature is important for predicting the risk of heat stroke. The surface temperature of the earlobe may well reflect brain temperature as shown by a high correlation with the inner ear temperature. The advantage of the earlobe was that it lacks sweat glands, and thus had not been influenced by sweat during exercise. Here, we report the possibility of using a sensor device on the earlobes as an alert device for heat stroke during work and exercise.

CP-PM24 Disease and physical activity

THE USEFULNESS OF ACTIVITY TRACKERS AND HEART RATE MONITORS IN LIFESTYLE MEDICINE – A CASE STUDY

DVORÁK, M.1,2, BABAI, L.2, TÓTH, M.1

1 UNIVERSITY OF PHYSICAL EDUCATION, BUDAPEST, 2 ÉLETMÓD ORVOSI KÖZPONT, BUDAPEST

INTRODUCTION: Exercise and physical activity programs form an important part of the therapy of metabolic and cardiovascular diseases (mainly diabetes, hypertension, dyslipidemia, obesity). Although the professional association (such as American Heart Association or diabetes associations) guidelines include general recommendations about exercise programs for each of these diseases about the intensity, duration, regularity of the trainings, in practice it is hard to follow the movement therapies of the patients.
Nowadays hundreds of smart watches, activity and fitness trackers are available, but their useful effects are not really familiar to doctors, physiotherapists and trainers in the field of lifestyle medicine.
METHODS: This case study followed the lifestyle program of a 65 years old, male patients. through 6 months. The patient had high blood pressure, dyslipidemia, type-2 diabetes, obesity (at start body weight 131kg, BMI 44) and serious arthrosis in both knees. Before the program there was a blood test, medical check-up, dietary's consulting (repeated monthly) and a submaximal fitness test (YMCA cycling test). The patient wore a heart rate and activity tracker (POLAR A300) every day and measured the heart rate of every training (678 sessions). A trainer twice a week worked with him, but most importantly, analysed and consulted the results of the trainings (with the help of POLAR flow application), made by the patient alone.
RESULTS: The patient's daily steps increased dramatically (from 9133 to 16087 steps) and training hours of the week changed from 13,3 hours to 22,6 hours, in which he spent in moderate physical activity 182 minutes a week at the baseline, and 469 a week in the last month (the recommendation of the WHO is 150 minutes).
Along with this increase in the intensity and duration of his physical activity, his body weight decreased by 23,1 kg, as well his blood pressure, blood sugar, HgA1c, cholesterol levels. As a result of these changes, his doctor lowered the amount of medication for high blood pressure, and totally take out the diabetes medication Meforal. The patient's fitness level significantly increased at the YMCA test.
CONCLUSION: The role of activity trackers and heart rate monitors are important in the therapy of patients with metabolic- and cardiovascular diseases. With them trainers not just optimize the heart rate during training, but are able to follow the whole exercise program (not just the leaded trainings) and can correct it in intensity, duration and regularity. In this control, the therapy is more useful and safer, and even patiens' health and fitness can increase rapidly.
This case study shows how these wearable fitness trackers can work in an effective way, but for better results we need further studies with more kind of patients in condition and diseases.

THE EFFECTS OF OMEGA-3 FATTY ACIDS SUPPLEMENTATION ON AIRWAY INFLAMMATION IN AMERICAN UNIVERSITY FOOTBALL ATHLETES

IMAI, T.1, TAKADA, Y.2, WATANABE, K.2

1. AICHI INSTITUTE OF TECHNOLOGY, 2. UNIVERSITY OF TSUKUBA

INTRODUCTION: Introduction: Athletes have a high risk of developing upper and lower airway dysfunction. They are chronically exposed to airway stressors such as air pollution, allergens, and cold and dry air during daily training. These stressors constantly contribute to airway damage and promote airway inflammation and respiratory disorders such as exercise-induced asthma. Omega-3 fatty acids (ω3) are commonly considered to be anti-inflammatory agents and exert protective effects in inflammatory diseases including asthma and allergies. We hypothesized that ω3 dietary supplementation would reduce the risk of airway inflammation in athletes. Purpose: To assess the effects of ω3 supplementation in American university football athletes over a 3-week period.
METHODS: A total of 25 (20±1.6 years) participated in this 4-week study. During the first week, the fraction of exhaled nitric oxide (FeNO) at baseline was measured. Subsequently, subjects were divided into 3 groups: airway inflammation and ω3 intake (AI+ω3) (54.7±26.7 ppb, n=10), non-airway inflammation＋ω3 intake (NAI+ω3) (13.9±4.1 ppb, n=5), and NAI+Non-ω3 (NN) (19.2±4.4 ppb, n=10). The level of the airway inflammation marker FeNO was used as an indicator of eosinophilic airway inflammation (FeNO >25 ppb). Athletes were given beverage type of ω3 supplement (600 mg eicosapentaenoic acid (EPA) and 260 mg docosahexaenoic acid (DHA)) once daily for 3 weeks, from week 2 to 4. The subjects were instructed to follow a normal lifestyle maintaining daily habits. The measurements were conducted at the same time of day for each subject to avoid the effects of fasting and circadian rhythm. The FeNO was measured using a portable NIOX Vero ®, Forced vital capacity (FVC), forced expiratory volume1 (FEV1), FEV1/FVC ratio, and peak expiratory flow (PEF) were determined using a spirometer. Blood samples were drawn from athletes and the differential leukocyte count and fatty acid fraction were determined.
RESULTS: For the ω3 intake groups, AI＋ω3 and NAI＋ω3, the serum EPA and EPA/AA ratio (58.2±23.4 μg/mL, 0.31±0.1, respectively) significantly increased after 4 weeks compared to values at 1 week (25.4±14.7 μg/mL, 0.13±0.1). DHA and arachidonic acid (AA) levels did not change significantly after 4 weeks and serum EPA, DHA, and AA levels did not change in the NN. The FeNO significantly decreased at weeks 3 and 4 compared to week 1 in the AI＋ω3 (45.4±24.2 ppb, $p<0.05$). However, the FeNO did not change in the NAI＋ω3 (13.6±5.2 ppb) and NN (19.4±4.9 ppb) compared to weeks 1 to 4. Blood eosinophilic counts did not change for the 3 groups, but monocytes significantly decreased at week 4 compared to levels at week 1 in the AI＋ω3. Indices of pulmonary function did not observe significantly interaction (time×group).
CONCLUSION: We propose that ω3 supplementation may prevent the development of airway inflammation and may play a role in the maintenance of their physical conditions.

THE INFLUENCE OF SHORT TERM STOP-REGULAR-EXERCISE ON CARDIOVASCULAR DISEASE RISK FACTORS IN MEN

WU, C., WANG, H., CHIU, C., HUANG, Y., WU, S., CHANG, C.

CHUNG HSING UNIVERSITY; NATIONAL TAIWAN UNIVERSITY OF SPORT; CHANGHUA CHRISTIAN HOSPITAL

INTRODUCTION: Regular exercise has been proposed to reduce the risk of cardiovascular diseases. One of the underlining mechanism is thought to be reduced plasma lipids profiles and inflammatory markers. However, very limited study investigated the influence of stop-regular-exercise (SRE) on the risk factors of cardiovascular diseases. Therefore, the current study was designed to examine the effect of short term SRE on plasma lipids profiles and inflammatory markers.
METHODS: Twelve healthy adults (age: 23.3 ±1.9yrs, Ht: 171. 7±7.8cm, Wt: 70. 7±13.3kg) participated in regular exercise at least 30min x 3 times/wk were recruited in this study. Subjects were asked to stop their regular exercise for 7 days. Maximal oxygen uptake (VO2max) and body composition were measured before and after 7 days SRE. Saliva samples and blood sample were obtained before, on day 3 and day 7 of SRE for Silva IgA, plasma lipids profiles and inflammatory markers analysis.
RESULTS: The results showed that VO2max was significantly decreased (45.8±6.4 ml/kg/min vs 44. 6±6.6 ml/kg/min, p=0.036) and plasma triglycerides (p=0.026) and body fat percentage (p=0.007) were significantly increased after 7 days SRE. There were no differences in saliva IgA concentrations and plasma cholesterol, HDL-c, IL-1B, IL-6, IL-8 and TNF-a concentrations before and after 7 days SRE (p>0.05).
CONCLUSION: The current data suggested that short term SRE might increase the risk factors of cardiovascular diseases via increased plasma triglycerides concentration and body fat percentage.

EXAMINING THE PHYSICAL ACTIVITY OF CHILDREN WITH DIABETES

BALATONI, I., SZÉPNÉ, H.V., AMBRUS, F., FELSZEGHY, E., BALLA, G., CSERNOCH, L.

UNIVERSITY OF DEBRECEN

INTRODUCTION: Childhood plays a decisive role in the development of our adult habits concerning exercise and sports. Becoming a healthy adult is hard to imagine without learning and developing a conscious, movement-centered lifestyle, one of the pillars of which is regular exercise in childhood. Children with type 1 diabetes (T1DM) form a special group in terms of sporting habits, as in this case parents' attitude to disease and sports is also crucial in the development of sporting habits. In our research we explored the sporting habits of children with T1DM living in the North Great Plain region of Hungary and the Transcarpathian region of Ukraine.
METHODS: Data collection was carried out in 2018 in the form of a questionnaire-based survey involving children with T1DM treated in the Department of Pediatrics of the Clinical Center of the University of Debrecen and their parents, Transcarpathian Hungarian children with T1DM and their parents, and non-T1DM children treated in the Department of Pediatrics of the Clinical Center of the University of Debrecen and their parents. The questionnaire was filled in voluntarily and the completed questionnaires were processed with the EvaSys software. In addition to demographic data, we asked questions about diabetes (development, family incidence, frequency of measurements, insulin treatment, HgbA1C, symptoms and their frequency), and about sporting habits (does the child do sports and if so what, how often, if not, why not, does he/she participate in school PE classes).
RESULTS: The questionnaire was completed by 140 children with T1DM or their parents, 151 non-T1DM children or their parents (serving as the control group), and 14 Transcarpathian children with T1DM or their parents. 57.5% of the children in the T1DM group and 66% of the children in the control group regularly do sports, whilst this ratio in the Transcarpathian group is 42.9%. The sport most often chosen was cycling (25%) and football (15.7%) in the T1DM group, dancing (17.2%) and football (16.6%) in the control group, while football (14.3%) and dancing (14.3%) in the Transcarpathian T1DM group. If the child is not doing sports, reasons behind this were mostly the lack of time both in the case of the T1DM and the control group (20.7% and 12.6% respectively), while in the Transcarpathian T1DM group the lack of facilities ranked first (35.7%). 3.6% of the respondents of the T1DM group and 14.3% of the Transcarpathian group feel that their health condition is a barrier in doing sports.
CONCLUSION: T1DM children and their parents should be made aware that regular exercise improves the health condition. Children need to be motivated to do more exercise; motivation is the shared interest and responsibility of the health care staff, the educators, and the parents.

CAN EXERCISE PRESERVE MOTOR AND NON-MOTOR FUNCTION IN PARKINSON'S? – LONGITUDINAL OBSERVATIONAL STUDY

MEADOWS, S., DAVISON, G., FULLERTON, C., FERRUSOLA-PASTRANA, A.

UNIVERSITY OF KENT

INTRODUCTION: Parkinson's is a chronic neurodegenerative disease, which usually leads to disability and disengagement with active lifestyles. There is good evidence that exercise is effective at improving and sustaining cognitive and/or physical function in people with Parkinson's (PwP). However, more studies are needed to investigate those outcomes concurrently and try to shed light on their underlying biological mechanisms. Furthermore, few studies have assessed long-term effects of exercise and the optimal dose for PwP remains unclear. In addition to the mostly studied single type exercises, a combined exercise session also involving cognitive aspects may be more beneficial. Therefore, a weekly community-based multi-modal exercise session for PwP was established to evaluate its effects on physical and cognitive function.
METHODS: 17 participants (15 male, 2 female: age 65 ± 8 years) attended a once-a-week multi-modal group exercise session (60 minutes) for over one-year. Health and functional assessments were completed at the start and repeated every three months for one year (i.e. total of 5 time points), including: six-minute walking test (6MWT), timed up and go (TUG), 1-minute sit-to-stands (STS) and bilateral grip strength (GS). Cognitive function was subsequently added and assessed with the Clock Drawing Test (CDT), Mini-Mental Parkinson's (MMP), the Trail Making Test A (TMT-A) and B (TMT-B); plus quality of life with the brief Older Peoples Quality of Life Questionnaire (OPQOL-Brief).
RESULTS: Scores for 6MWT, TUG and bilateral GS did not significantly change. The number of STS significantly increased during one year, specifically between baseline and after the first three months (from 21 to 24; P = 0.005). Scores for CDT, TMT-A, TMT-B and OPQOL-Brief

did not significantly change across four different assessments, equivalent to a year. MMP increased significantly between baseline and each assessment (from 26.12 to 29.29, 29.18 and 29.06; P < 0.001).
CONCLUSION: A once-a-week multi-modal group exercise programme for PwP showed an improvement in STS and MMP scores and no other significant changes (i.e. no decline) in health, cognition and physical function over one year. That functional and cognitive performance were slightly increased or maintained is a positive outcome given the progressive nature of Parkinson's.

STRENGTH AND FUNCTIONAL CAPACITY IN WOMEN WITH POLYCYSTIC OVARY SYNDROME

BAIOCCATO, V., QUINTO, G., ROVAI, S., FOCCARDI, G., NEUNHAEUSERER, D., GASPERETTI, A., BATTISTA, F., BULLO, V., GOBBO, S., MIONI, R., BERGAMIN, M., ERMOLAO, A.

UNIVERSITA DEGLI STUDI DI PADOVA DIPARTIMENTO DI MEDICINA

INTRODUCTION: Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women of reproductive age, with a prevalence in Europe of about 6.5%. It is known that women with PCOS have different hormonal pattern, with high variability through phenotypes. High levels of androgens may cause an increase in lean body mass. It is not yet clear whether patients with PCOS have greater muscle strength than women not suffering from this syndrome. Our aim was to investigate whether patients with PCOS have different lean mass, strength and aerobic capacity, respect to patients without the syndrome.
METHODS: This is an observational study where patients underwent the following evaluations:
- Functional tests, such as cardio-pulmonary exercise and handgrip test;
- Evaluation of body composition with DEXA;
- Blood analysis (testosterone, androstenedione).
Statistic evaluation was made with SPSS.
RESULTS: We evaluated 40 women (27 women with PCOS vs 13 women without PCOS). These two populations examined were comparable for BMI, age (18-46 years), total body composition and upper limbs Fat Free Mass (evaluated by DEXA). No differences were found in hormonal patterns too.
The most interesting results were the observation in PCOS group of a greater handgrip strength, when related to kg of lean mass in arms (p=0,001). Also aerobic capacity, expressed as VO2 max per Kg (p=0,01) and VO2 per Kg of lean mass (p=0,02), was higher in the PCOS population. Similarly, OUES and maximal exercise capacity (expressed as METs) suggested the presence of a better fitness in the PCOS group.
The analysis based on VO2 determinants (multivariate analysis) demonstrate that only having PCOS is an independent predictor of a better functional capacity (expressed as VO2max, VO2 max per Kg, VO2max per lean mass Kg and as OUES). Further, we demonstrated that VO2max per kg of lean mass is predicted by testosterone and lean mass too.
CONCLUSION: In conclusion, our data could suggest the presence of greater muscle strength, higher aerobic and functional capacity in women with PCOS, despite the presence of a similar lean mass quantity and hormonal levels.

PROSPECTIVE TRIAL ON NUTRITIONAL INTERVENTION IN EARLY-STAGE BREAST CANCER PATIENTS: ADHERENCE TO DIETARY GUIDELINES, BODY WEIGHT CHANGE AND PHYSICAL ACTIVITY LEVELS.

TRESTINI, I., AVANCINI, A., CARBOGNIN, L., FIORIO, E., TREGNAGO, D., BONAIUTO, C., PAROLIN, V., LANZA, M., PILOTTO, S., SCAMBIA, G., TORTORA, G., MILELLA, M., BRIA, E.

UNIVERSITY OF VERONA, AZIENDA OSPEDALIERA UNIVERSITARIA INTEGRATA, VERONA; FONDAZIONE POLICLINICO UNIVERSITARIO A. GEMELLI, I.R.C.C.S., UNIVERSITÂ CATTOLICA DEL SACRO CUORE, ROMA.

INTRODUCTION: Weight gain and overweight have been related to an increased risk of recurrence and mortality in patients (pts) affected by Early-stage Breast Cancer (EBC). Weight control and lifestyle (diet and PA) changes are recommended as an important part of survivorship care of EBC pts. The aims of this prospective study were to evaluate the adherence to dietary guidelines (ADG) and the effectiveness of nutritional intervention in terms of weight control and physical activity (PA) levels in pts with EBC undergoing treatment.
METHODS: We present the preliminary results of 39 pts with EBC undergoing adjuvant treatment. The eligible pts received a nutrition evidence-based 6 months-tailored educational intervention by a skilled dietitian. Anthropometric measures were assessed using standard methods and the ADG was estimated through the validated Med-Diet score (MDS) by Med-Diet 14 item questionnaire. PA level was calculated using the International Physical Activity Questionnaire short form (IPAQ). Descriptive statistics was adopted. Longitudinal mixed models were used to analyze change over time.
RESULTS: At baseline, 28% and 26% of pts were overweight and obese respectively and only 13% of pts reported a high ADG (median MDS ≥10). The majority of pts presented dietary patterns high in fat (mean fat intake: 35.8% from total energy intake) and low in dietary fiber (mean dietary fiber intake: 19.3 g/day). The PA level was low; according to IPAQ, only 23% of women resulted in moderate category and 77% of them were in low. Six months after the intervention, 74% of pts reported a high ADG, with improving body weight (p=0.008). Total energy expenditure (METs) significantly improved (p=0.01) from baseline; the increase regarded vigorous (p=0.002) and walking (p<0.001) activities. The percentage of pts that remained in low category declined to 46%, while 41% resulted in moderate and 13% in high category (p=0.006). High ADG was inversely significantly correlated with BMI (p<0.0001) and positively correlated with METs of walking (p=0.01).
CONCLUSION: A tailored nutritional intervention for EBC pts undergoing treatment has the potential to improve their ADG and the PA levels, in order to manage body weight control.

PHYSICAL ACTIVITY (PA) LEVEL, INTEREST AND PREFERENCES IN CANCER PATIENTS

AVANCINI, A.1, PALA, V.2, KROGH, V.2, SIERI, S.2, MARIANI, L.2, TREGNAGO, D.3, CAFARO, D.3, MILELLA, M.3, TRESTINI, I.3, LANZA, M.4, PILOTTO, S.3

UNIVERSITY OF VERONA

INTRODUCTION: Exercise (EX) after a cancer diagnosis improves physical function, quality of life, reduces fatigue and the risk of cancer recurrence and mortality.(1) Unfortunately, most cancer patients do not engage in PA.(2) The purpose of this study is to investigate the EX level and preferences in oncological patients.
METHODS: A questionnaire to assess EX preferences, physical activity (PA), demographic and health information was designed for use in cancer patients. A representative sample of patients from the Medical Oncology Unit of the Verona Hospital were asked to anonymously

complete the questionnaire. PA behavior in the previous week was assessed by leisure score index (LSI) using the validated Godin's Leisure Time Exercise Questionnaire (GLTEQ) (3). The EX preferences questions were drawn from Jones and Courneya questionnaire (4).
RESULTS: A total of 334 cancer patients participated (58% response rate). Physical activity level was low, only 9% of patients resulted sufficiently active according with LSI. A majority indicated that they were willing (77%) to participate in an exercise program designed for cancer patients. Breast cancer patients seemed to be more interested to EX compared to other cancer sites. Young age, short time from diagnosis, and high education level influenced the interest to EX.
Regarding EX counselling the oncologist was the preferred category (56%) followed by physiotherapist (27%). A face to face approach is the preferred way of information delivery (72%).
The patients chose to train in the morning (47%) or in the afternoon (30%). The preferred composition of EX group was with "other cancer patients" (25%) and the favorite places to exercise were outdoors (26%) or a fitness center for adapted physical activity (22%). Two (39%) and three (27%) times per week were the preferred EX frequencies. "Mild" was the preferred EX intensity (46%), followed by "moderate" (37%). Working out in groups was preferred by 39% of patients, whereas 26% choose an individually supervised home program.
CONCLUSION: Only a small percentage of cancer patients was found to be sufficiently active, but about 77% were willing to start EX programs. Designing a personalized EX program based o patient's preference may optimize adherence and outcomes in cancer patients.

EFFECT OF ENDURANCE VERSUS RESISTANCE TRAINING ON SYSTEMIC AND LOCAL MUSCLE INFLAMMATION AND OXIDATIVE STRESS IN COPD

RYRSØ, C.K., THANING, P., SIEBENMANN, C., LUNDBY, C., LANGE, P., PEDERSEN, B.K., HELLSTEN, Y., IEPSEN, U.W.
RIGSHOSPITALET, UNIVERSITY OF COPENHAGEN

INTRODUCTION: Limb muscle dysfunction is frequently observed in patients with chronic obstructive pulmonary disease (COPD) and might be associated with local and/or systemic inflammation and oxidative stress. Therefore, we investigated whether two major training modalities in COPD rehabilitation, endurance training (ET) and resistance training (RT), could alter markers of inflammation and oxidative stress.
METHODS: Skeletal muscle biopsies and venous blood samples were obtained from patients with moderate to severe COPD (n = 30; 63±2 years, FEV1 56±3 % of predicted value) before and after 8 weeks of RT (n = 15) or ET (n = 15). Healthy sedentary age-matched subjects were included as baseline controls (n = 8; 64±3 years, FEV1 110±3 % of predicted value). Inflammatory markers in muscle and plasma were determined by interleukins (IL), tumor necrosis factor alpha (TNF-alpha), and leukocyte concentration. Distribution of macrophages per muscle tissue area within the skeletal muscle was determined with immunohistochemical staining. Muscle oxidative stress were determined by NADPH oxidase (NOX) and superoxidase dismutase 2 (SOD2) protein expression analyzed by western blotting.
RESULTS: Before exercise training, COPD patients had a higher muscular NOX content and circulating IL-8, IL-18, CRP, and leukocyte levels but similar number of muscle-infiltrating macrophages compared with controls. Eight weeks of ET or RT increased muscle SOD2 content ($P<.05$) with no difference between groups. Plasma TNF-alpha increased ($P<.05$) after ET and tended ($P=.06$) to increase after RT, but had no effect on muscular NOX content, number of infiltrating macrophages, or systemic levels of other proinflammatory cytokines or leukocytes.
CONCLUSION: In patients with moderate to severe COPD we found elevated systemic inflammation, but no evidence of muscular inflammation. Eight weeks of either ET or RT did not alter the inflammatory status. However, both training modalities increased local muscle antioxidant content, which might improve muscle function and contribute to prevent local inflammation and oxidative stress.

RELATIONSHIP BETWEEN SKIN-GAS NITRIC OXIDE CONCENTRATION AND CAPILLARY VELOCITY FOLLOWING REPEATED SUBMAXIMAL HANDGRIP EXERCISE.

EGUCHI, Y., TOYA, Y., GOSHIMA, K., TAJIRI, N., TSUDA, T., ITOH, H.
NAGOYA INSTITUTE OF TECHNOLOGY

INTRODUCTION: It is well known that an increase in blood flow stimulates vascular endothelial cells and advances the production of nitric oxide (NO) (1,2). Itoh et al. (3) have demonstrated that the repetitive wrist flexion-extension exercise increases regional blood flow and skin-gas NO concentration of the exercising hand. The capillary which consists of basement membrane and endothelial cells accounts for more than 95% of blood vessels of the whole body, therefore, shear stress on capillary plays an important role in an increase of skin-gas concentration during exercise. However, no one has confirmed the effect of capillary endothelial shear stress on skin-gas concentration during exercise hyperemia following repeated exercise.The purpose of this study was to examine the relationship between skin-gas nitric oxide concentration and capillary velocity following repeated submaximal handgrip exercise.
METHODS: Seven healthy male students (22.0 ± 0.6 years; mean ± SD) performed repeated submaximal (20%MVC) handgrip exercise (dominant hand) for 2 min. The skin-gas samples were obtained from the exercised hand by covering with a polyethylene bag in which pure nitrogen gas (150mL) was introduced for a min, and collected in a sampling bag at rest and 0, 5, 10, 15 min recovery of the exercise. The skin-gas NO concentration was measured by a chemiluminescence analyzer (Pico-Device Co., Ltd., Japan). Capillary velocity was measured at the same time by a blood flow observation instrument (BSCAN-Z, Toku Corporation, Japan) and analyzed by a blood flow analysis software.

RESULTS: The repeated submaximal handgrip exercise significantly increased skin-gas NO concentration ($p<0.05$) and capillary velocity ($p<0.001$) after the exercise compared to the resting values. Furthermore, there was a significant positive correlation between skin-gas NO concentration and capillary velocity ($r=0.763$, $p<0.001$).
CONCLUSION: Increased NO concentrations in this study have suggest that NO production was facilitated with increased cyclic wall stress associated with increasing pulsatile blood flow during repeated exercise hyperemia. Especially, increased shear stress on capillary vessels might be much more effective for an increase in skin-gas NO concentration.

SHEAR STRESS ON CUTANEOUS CAPILLARY ENDOTHELIAL DURING WHOLE BODY EXERCISE.

TOYA, Y., EGUCHI, Y., GOSHIMA, K., TAJIRI, N., TSUDA, T., ITOH, H.
NAGOYA INSTITUTE OF TECHNOLOGY

INTRODUCTION: NO is the most important endothelium-derived relaxing factor, which plays a pivotal role in modulating smooth muscle tone in the human conductance and resistance vessels (1). Therefore, during the whole body exercise, an increase in blood flow stimulates vascular endothelial cells and advances the production of nitric oxide (NO) (2,3) in the whole body. On the other hand, more than 95% of blood vessels of the whole body are capillary vessels which consists of basement membrane and endothelial cells. Although shear stress on capillary plays an important role for cutaneous and muscle vasodailation during exercise, there is no data concerning the effect of capillary endothelial shear stress on skin-gas concentration during the whole body exercise. The present study aimed to confirm the effect of capillary shear stress on skin-gas NO concentration during the whole body exercise.
METHODS: Eleven healthy male students (22.1 ± 0.3 years; mean ± SD) performed submaximal (50% HRmax) cycle exercise for 20 min. The skin-gas samples were obtained from the dominant hand by covering with a polyethylene bag in which pure nitrogen gas (150mL) was introduced for 1 min, and collected in a sampling bag at rest and 0, 5, 10, 15 min recovery of the exercise. The skin-gas NO concentration was measured by a chemiluminescence analyzer (Pico-Device Co., Ltd., Japan). Capillary velocity was measured at the same time by a blood flow observation instrument (BSCAN-Z, Toku Corporation, Japan) and analyzed by a blood flow analysis software.
RESULTS: The whole body exercise in this study significantly increased skin-gas NO concentration ($p<0.05$) and capillary velocity ($p<0.05$) after the exercise compared to the resting values. Furthermore, there was a significant positive relationship between skin-gas NO concentration and capillary velocity ($r=0.649$, $p<0.001$).
CONCLUSION: A significant relationship between skin-gas NO concentration and cutaneous capillary velocity in this study suggests that an increase in shear stress on cutaneous capillary vessels might be much more effective for an increase in skin-gas NO concentration during the whole body exercise. Furthermore, sympathetic nervous activity, circulating hormones, exercised muscle-derived metabolites including reactive oxygen species might also affect the production of NO during the exercise.

VALIDITY AND RELIABILITY OF CONTINUOUS-WAVE NIRS VS FREQUENCY-DOMAIN NIRS TO MEASURE SKELETAL MUSCLE MICROVASCULAR HEMODYNAMIC AND OXYGEN-UPTAKE KINETICS TO EXERCISE IN NORMAL AND TYPE 2 DIABETICS MEN

ROWLANDS, D.S., LUCERO, A., GRAM, M., RAMAKERS, I., RYAN, T., ENRIQUEZ, O., FAULKNER, J., STONER, L.
MASSEY UNIVERSITY

INTRODUCTION: Near infrared spectroscopy (NIRS) provides potential for the non-invasive assessment of skeletal muscle hemodynamic and respiratory responses. These applications can be used to test interventions at rest and in exercise in healthy and some clinical populations, such as, Type 2 diabetes (T2D). Continuous wave (CW) NIRS offers advantages of price, portability, and technical ease of use over other NIRS technologies, making it appealing for exercise science applications; however, its validity and relative reliability against the first-principles based frequency-domain (FD) NIRS has not been established. Therefore, the purpose of the current study was to estimate the validity and between-day reliability of CW-NIRS measure of skeletal muscle blood flow and oxygenation against FD-NIRS in non-diabetic (ND) and T2D men at rest and during dynamic exercise.
METHODS: 10 healthy (ND, 25.0 y, SD 6.2) and 10 T2D [55.6 y (SD 5.6)] men volunteered for assessment of resting and exercise measures of skeletal muscle blood flow (mBF), oxygen consumption (mȮ2), total hemoglobin concentration (perfusion, [tHb]), tissue O2 saturation, and mȮ2 recovery rate constant (k) index of muscle oxidative capacity. Exercise data were collected during isotonic knee extension exercise at 5% and 15% of maximal voluntary contraction on 3 separate occasions within 10 days.
RESULTS: For both groups, patterns of change and mean values for mBF and m, Ȯ2 during exercise were not substantially different between devices (not shown) and were of moderate to high reproducibility (ICC: 0.72-0.98). Mean standardized typical errors were small and not clearly different between groups and technology: mBF CW-NIRS (ND 0.54, 90%CI 0.43-0.80; T2D 0.50, 0.39-0.73) and FD-NIRS (ND 0.41, 0.32-0.59; T2D 0.41, 0.31-0.59); mȮ2 CW-NIRS (ND 0.44, 90%CI 0.34-0.64; T2D 0.41, 0.32-0.60) and FD-NIRS (ND 0.26, 0.21-0.39; T2D 0.22, 0.17-0.32). However, in T2D, average (both intensities) mBF and mȮ2 were likely lower with CW-NIRS (mBF 4.5 ml/min/100ml, SD 3.0; mȮ2 1.1 ml/min/100g, 0.5) during exercise compared with FD-NIRS (7.0 ml/min/100ml SD 2.9; mȮ2 1.4 ml/min/100g 1.2). In contrast, [tHb] perfusion index and tissue saturation of O2 during combined exercise intensities were substantial (i.e. >0.2*SD). Perfusion ([tHb]) was overestimated with CW-NIRS in both groups vs FD-NIRS (uM, mean, SD: CW-NIRS ND 109, 20, T2D 99, 23; FD-NIRS ND 103, 40, T2D 82, 28). Reflecting the muscle pump, [tHb] range in FD-NIRS was lower in T2D than ND (mean, SD: T2D 11, 14; ND 7.5, 10) but not in CW-NIRS.
CONCLUSION: CW-NIRS demonstrated reproducible assessment of mBF and mȮ2 similar to FD-NIRS for non-invasive measures of skeletal muscle hemodynamic and oxidative health during exercise. However, CW-NIRS underestimated mBF and mȮ2 in T2D participants, while over-estimating perfusion index during exercise in both groups, likely reflecting limitations of constant scattering and contribution of skin blood flow to O2Hb between populations.

EFFECTS OF ELECTRICAL MUSCLE STIMULATION ON COGNITIVE PERFORMANCE AND CEREBRAL PERFUSION

TAKAGI, Y., SATO, K., KOIKE, Y., WATANABE, H., SUDO, M., FUJIBAYASHI, M., TSURUGANO, S., ANDO, S.
THE UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: Electrical muscle stimulation (EMS) is applied to elicit muscle activation without central motor command. Previous studies indicated that EMS increases glucose metabolism [1]. Nevertheless, it is unclear how EMS influences cognitive performance and cerebral perfusion. The purpose of this study was to clarify the effects of EMS on cognitive performance and cerebral perfusion.

METHODS: In study 1, participants performed Go/No-Go tasks before and after 20 min EMS or rest (Control) (n=18, 23.0±2.1yr.). Two types of EMS were applied; hypertrophy mode (20Hz) and aerobic mode (4Hz). We used reaction time (RT) and accuracy of the cognitive task to assess cognitive performance. In study 2, we measured the blood flow in the internal carotid artery (ICA) and vertebral artery (VA) before, during, and after EMS (aerobic mode) (n=9, 22.7±1.6yr.).
RESULTS: RT and accuracy of the Go/No-Go task were not altered in all conditions (EMS 20Hz pre: 344±26.4ms, post: 343±36.8ms; EMS 4Hz pre: 339±20.6ms, post: 337±27.9ms; Control pre: 348±42ms, post: 344±38.3ms, all Ps>0.38). ICA blood flow increased during EMS as compared with before EMS (pre: 311±63.5ml/min, during EMS: 356±78.3ml/min, +14.5 ± 10.4 %, P < 0.03). In contrast, VA blood flow did not change during EMS (pre: 119±44.2ml/min, during EMS: 124±42.6ml/min, P=1.00). In the Control condition, ICA and VA blood flow did not change (P=0.84 and P=0.62, respectively).
CONCLUSION: The absence of cognitive improvement suggests that physiological changes induced by muscle contraction was not sufficient to alter cognitive performance. Blood flow in ICA and VA increases during low to moderate exercise [2]. In contrast, in the present study, EMS increased blood flow only in the ICA, but not in VA. Vianna et al. has shown that EMS did not change anterior cerebral artery mean velocity (3). Hence, increase in anterior cerebral blood flow is primarily due to afferent inputs to sensorimotor areas from skeletal muscles where middle cerebral artery supplies blood. The present study appears to suggest that central motor command is critical for cognitive improvement and increases in VA blood flow during voluntary exercise.

INFLUENCE OF INCREMENTAL SHORT-MAXIMAL EXERCISE ON URINARY LIVER-TYPE FATTY ACID-BINDING PROTEIN

KUMAMOTO, S.1, KOSAKI, K.1, SUGAYA, T.2, TANAHASHI, K.1, KUMAGAI, H.3, MAEDA, S.1
1: UNIVERSITY OF TSUKUBA. 2: ST. MARIANNA UNIVERSITY SCHOOL OF MEDICINE. 3: JUNTENDO UNIVERSITY.

INTRODUCTION: An incremental short-maximal exercise is widely performed for evaluating individual aerobic fitness in a clinical setting. On the other hand, it has been known that exercise induces the redistribution of tissue blood flow, which greatly increases blood flow to the active muscles and decreases renal blood flow in an intensity-dependent manner (1). Thus, the short-maximal exercise may theoretically lead to accentuated renal hypoperfusion and renal damage progression. However, it remains obscure that the influence of incremental short-maximal exercise on renal perfusion. The purpose of this study was to determine in the influence of incremental short-maximal exercise on renal perfusion evaluated by urinary liver-type fatty acid binding protein (L-FABP) which is capable of reflecting the renal perfusion (2).
METHODS: A total of 116 adults (aged 24-83 years) without renal disease participated in this study. Using cycling bicycle ergometer, participants underwent the incremental short-maximal exercise consisting of 2 min at 20 W followed by a 10 W increase every 1 min. Exercise was finished under the following criteria; the participants reached 1) their age-predicted heart rate (i.e., 220-age), 2) Borg's scale > 19, 3) respiratory equivalent > 1.2, or 4) pedaling speed > 55 rpm. Spot urinary sampling was performed before and immediately after the exercise to evaluate the levels of urinary L-FABP, albumin, and creatinine. Urinary L-FABP and albumin levels are reported as ratios relative to urinary creatinine levels.
RESULTS: Urinary excretion of L-FABP and albumin levels significantly increased immediately after the incremental short-maximal exercise ($p = 0.008$ and $p < 0.001$). Urinary excretion of creatinine levels did not change significantly ($p = 0.730$). The relative changes in urinary L-FABP levels immediately after the exercise were significantly correlated with age ($r = -0.377$), peak oxygen consumption ($r = 0.380$), peak exercise load ($r = 0.452$), and the relative changes in urinary albumin levels ($r = 0.547$).
CONCLUSION: Our results revealed that the incremental short-maximal exercise immediately increased urinary L-FABP levels and suggested that it might lead to acute renal hypoperfusion in especially young adults.

THE RELATIONSHIP BETWEEN ARTERIAL STIFFNESS AND INCREASE IN BLOOD PRESSURE DURING EXERCISE IN MIDDLE-AGED OVERWEIGHT AND OBESE MEN.

TANAHASHI, K.1, KOSAKI, K.1, TAGAWA, K.2, MATSUI, M.2, KUMAMOTO, S.2, MYOENZONO, K.2, PARK, J.2, SATO, T.2, MAEDA, S.1
UNIVERSITY OF TSUKUBA

INTRODUCTION: Increased arterial stiffness is associated with higher risk of incident hypertension. Furthermore, it is well known that obesity is strongly associated with hypertension and increase in arterial stiffness. The blood pressure response to exercise reflects the future risk of developing hypertension and cardiovascular disease. However, the relationship between the arterial stiffness and the blood pressure response to exercise in overweight and obese men is unclear. Therefore, we investigated whether arterial stiffness is associated with blood pressure during exercise in middle-aged overweight and obese men.
METHODS: Forty-five middle-aged overweight and obese men (body mass index: BMI ≥ 25 kg/m2) participated in this study. Arterial stiffness was measured by brachial-ankle pulse wave velocity (baPWV). Brachial systolic blood pressure (SBP), diastolic blood pressure (DBP) and oxygen uptake (VO2) was measured during the incremental cycle ergometer exercise. We assessed blood pressures at the ventilatory threshold (VT) and peak exercise stages.
RESULTS: The average of age was 48±8 years, BMI was 27.9±2.2 kg/m2, and baPWV was 1441±184 cm/sec. The baPWV correlated significantly to SBP at VT ($r = 0.469$, $p < 0.05$) and peak ($r = 0.404$, $p < 0.05$) stages. In multiple regression model, SBP at VT stage had a significant association with baPWV after an adjustment with age, VO2VT and BMI ($p < 0.05$). In addition, SBP at peak stage had a significant association with baPWV after an adjustment with age, VO2peak and BMI ($p < 0.05$).
CONCLUSION: In middle-aged overweight and obese men, increased arterial stiffness, as reflected by baPWV, is accompanied by higher SBP at the VT and peak stage of exercise test. This finding suggests that increased arterial stiffness in overweight and obese individuals may leads to enhanced blood pressure response to exercise.

THE INFLUENCE OF VITAMIN D STATUS ON PULSE WAVE VELOCITY FOLLOWING ACUTE MAXIMAL EXERCISE IN ADULTS

CHEN, L.A.1, FANG, S.H.2, WANG, S.C.1, HE, C.S.1

1: NATIONAL CHUNG CHENG UNIVERSITY, 2: NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: It has been indicated that vitamin D deficiency increased the risk of cardiovascular disease in a general healthcare population (1). Vitamin D deficiency has been implicated as a risk factor for cardiovascular disease and overall mortality in the general population. Furthermore, the pulse wave velocity (PWV) has been identified as an independent risk predictor of major cardiovascular disease related events (2). However, the relationship between vitamin D levels and PWV is still unclear. The primary objective of this study was to determine the link between vitamin D levels and PWV by exploring the relationship between 25-hydroxyvitamin D (25(OH) D), an established marker of vitamin D status, and vascular function in healthy adults.
METHODS: Fifty male healthy adults from National Chung Cheng University participated in the study. Participants were divided in the 25(OH)D sufficient group (n=28, 25(OH)D > 50 nmol/L) and deficiency group (n=22, 25(OH)D <50 nmol/L). The acute maximal exercise was performed using an incremental cycling test to exhaustion (warm-up 2 min at 0 W, began cycling at 50 W and followed by a 30 W/2 min increase). And the PWV was obtained at rest and 2, 15, 30, 45, 60 minute after maximal exercise by Biopac MP150. Two way mixed design ANOVA was used to evaluate changes in PWV following maximal exercise between groups. Bivariate correlations between 25(OH)D levels and PWV were determined with Pearson product-moment analyses. The significant level is $\alpha = 0.05$.
RESULTS: Compared with 25(OH)D deficiency group, we found that 25(OH)D sufficient group had lower PWV in post-exercise 2 minute (4.74 ± 0.83 vs 5.29 ± 0.73 m/s, p<0.05), post-exercise 15 minute (4.54 ± 0.75 vs 5.13 ± 0.53 m/s, p<0.05) and post-exercise 30 minute (4.80 ± 0.55 vs 5.22 ± 0.85 m/s, p=0.11). Furthermore, the 25(OH)D significantly associated with PWV in post-exercise 2 minute (r = -0.37, p<0.05), post-exercise 15 minute (r = -0.41 , p<0.05) and post-exercise 30 minute(r = -0.29 , p<0.05).
CONCLUSION: Our study demonstrated that adults with sufficient 25(OH)D status had lower PWV following maximal exercise than 25(OH)D deficiency adults. Also there was an inverse correlation between 25(OH)D levels and PWV. Therefore, vitamin D may play an important role in vascular endothelial function.

ACUTE AND REPEATED EFFECTS OF WHOLE-BODY CRYOTHERAPY: INVESTIGATION OF A DOSE-RESPONSE EFFECT ON BLOOD CATECHOLAMINES AND HEART RATE VARIABILITY

THEUROT, D., DUPUY, O., DUGUE, B., LOUIS, J.

LABORATOIRE MOVE

INTRODUCTION: Whole-body cryotherapy (WBC) is commonly used for various purposes such as treatment of chronic pain and/or inflammatory pathologies, recovery after strenuous physical exercise or physical wellness (Bouzigon et al. 2016). In addition to a reduction in pain sensations and inflammation, the main physiological effect sought by using WBC is an increased parasympathetic activation (Douzi et al. 2018; Hausswirth et al. 2013). Parasympathetic activation is associated with a faster recovery following physical exercise and could improve sleep quality (Douzi et al. 2018). Knowing the effect of WBC on the autonomic nervous system, it is therefore warranted to investigate the optimal dose-response. The aim of this study was to determine the acute and repeated effects of three different cryotherapy temperatures on the sympathovagal balance. We hypothesized that a lower temperature would induce greater parasympathetic activation.
METHODS: 40 healthy males were randomly assigned in 4 different groups of WBC exposure (-110°C, -60°C, -10°C, room T°) and undertook 5 sessions of WBC in 5 consecutive days. Cardiac parasympathetic activity was assessed through heart rate variability using power density of high frequency (HF), and root-mean square difference of successive normal R-R intervals (RMSSD). Sympathetic activity was assessed using blood catecholamines (epinephrine and norepinephrine). All measurements were performed immediately before and 5 minutes after the first and fifth WBC session.
RESULTS: When analysing HRV response to WBC, the ANOVA revealed a significant increase (P<0.05) in the mean weekly value of RMSSD (Pre = 48.2 ± 22.4 ms, Post = 68.0 ± 28.7 ms) and HF (Pre = 606.7 ± 691.6 ms², Post = 1271.1 ± 1180.5 ms²) from pre to post WBC exposition in the -110 °C condition. No effect of WBC was observed for epinephrine, while a significant rise in norepinephrine was found after the first exposition at -110°C (Pre = 172.75 ± 97.51, Post = 351.98 ± 230.71, µmol/L, P<0.01). No differences between WBC conditions were find on day 5 for blood catecholamines.
CONCLUSION: These results suggest that at least one WBC session at -110°C is required to stimulate the autonomic nervous system. After 5 daily exposures, a lower autonomic response was recorded compared to day one, therefore suggesting the development of physiological habituation to WBC.

INTERARM BLOOD PRESSURE DIFFERENCE IS ASSOCIATED WITH PHYSICAL AND CARDIOVASCULAR IMPAIRMENTS IN PERIPHERAL ARTERY DISEASE

CORREIA, M., TROMBETA, I., COLOMBO, F., OLIVEIRA, P., WOLOSKER, N., CUCATO, G., RITTI-DIAS, R.

UNIVERSIDADE NOVE DE JULHO AND HOSPITAL ISRAELITA ALBERT EINSTEIN

INTRODUCTION: A high interarm blood pressure difference (IAD) has been considered predictor of cardiovascular outcomes. Peripheral artery disease patients are more likely to presented significant IAD, however, whether this alteration is related to physical and cardiovascular function in these patients remain unknown. The aim of the present study was to compare the physical function and cardiovascular parameters in patients with peripheral artery disease with and without IAD.
METHODS: This observational study conducted in 2016 and 2017 included ninety-nine patients with peripheral artery disease. Differences between right and left arm of systolic blood pressure ≥ 10 mmHg were used to define IAD. Six-minute walk test, short physical performance battery, walking impairment questionnaire (WIQ) and the walking estimated-limitation calculated by history were used to assess physical function. Cardiovascular function was assessed by central and brachial blood pressure, arterial stiffness, and flow-mediated dilation. Mann-Whitney U test were used to compare groups, and data are presented in median and interquartile range.

RESULTS: Thirty three percent of patients presented IAD (n=34). Patients with IAD presented lower scores in short physical performance battery [7(10) vs. 9(4), p=0.012]; WIQ distance [8.2(22.5) vs. 22.8(38.8), p=0.008], and WIQ speed [13.6 (18.5) vs. 25.0 (21.7), p=0.008]. Central and brachial systolic blood pressure, and pulse pressure were higher in IAD [central: 144 (31) mmHg vs. 127 (22) mmHg, p=0.001; brachial: 153 (28) mmHg vs. 136(26) mmHg, p<0.001; pulse pressure: 68(26) mmHg vs. 53(22) mmHg, p=0.001]. Flow-mediated dilation was lower in IAD [2.8(8.1) % vs. 5.8(9.5)%, p=0.037]. The remaining variables were similar between patients with and without IAD.
CONCLUSION: In patients with peripheral artery disease, IAD is associated with impairment in physical function and cardiovascular parameters. Supported by FAPESP (# 2016/16425-9) and CNPq (#310508/2017-7).

THE EFFECT OF LOWER-BODY NEGATIVE PRESSURE THERAPY ON THE FUNCTIONAL STATE OF EXCELLENT ROWERS

BINHHONG, G., HUIHUI, D.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: To study the effect of lower-body negative pressure (LBNP)therapy on the functional state of elite rowers, and to provide a theoretical basis for the application of this method in sports science.
METHODS: 14 elite male athletes recruited from the national rowing training team were divided into the experimental group or the control group. The participants in the experimental group accepted a 20-minute LBNP therapy, five times per week for four weeks. Venous or fingertip blood samples were collected from the participants for the analysis of red blood cells (RBC), hemoglobin (HGB), hematocrit (HCT), creatine kinase (CK), urea nitrogen (BU), testosterone (T), and cortisol (C). Differences in the measured parameters between the two groups were analyzed with a 2-way repeated-measures variance (ANOVA) and T-test.
RESULTS: After the four weeks intervention:①HGB: there was a very significant decrease of HGB at week-4 compared with week-1 in two groups ($P < 0.01$). ②HCT: only the experimental group showed a significant decrease of HCT at week-4 compared with week-1 ($P < 0.05$). ③CK:in the control group, CK at week-3 showed very significant increase compared with the baseline ($P < 0.01$), showed significant increase compared with week-1 and week-2 ($P < 0.05$),and CK at week-4 decreased significantly compared with week-3 ($P < 0.05$), while the CK of control group was higher than that of in experimental group at week-3($P < 0.01$).④BU:BU at week-1 showed a significant increase compared with the baseline in the control group ($P < 0.01$), but significantly decreased at week-2 and week-3 compared with week-1($P < 0.05$).⑤T: T showed a significant decrease compared with the baseline in the control group ($P < 0.05$).
CONCLUSION: LBNP might affect athletes physiological parameters and increase athletes recovery rate.

SEX HORMONES INFLUENCE IN RESPIRATORY VARIABLES IN FEMALE ATHLETES WITH DIFFERENT HORMONAL PROFILES

PEINADO, A.B., RAEL, B., ROMERO-PARRA, N., ALFARO-MAGALLANES, V.M., BARBA-MORENO, L., BODOQUE, M., CUPEIRO, R.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Although the association between sex hormones and respiratory variables has been previously studied (1), most of these investigations have been carried out with healthy sedentary females (2) or even mixing sedentary and trained females (3). Therefore, the aim of this study was to assess the influence of sex hormones on respiratory variables in well-trained female athletes throughout different hormonal profiles.
METHODS: Six eumenorrheic (35.2±3.7 years; 55.7±8.8 kg; 21.3±2.7 kg/m2; 45.7±4.1 ml/kg/min), six monophasic oral contraceptives (OC) users (26.5±6.1 years; 55.5±6.0 kg; 21.4±1.3 kg/m2; 47.3±6.1 ml/kg/min) and six postmenopausal (50.17±3.13 years; 54.5±4.2 kg; 20.0±1.5 kg/m2; 46.7±2.3 ml/kg/min) well trained females participated in this study. Firstly, volunteers performed a maximal test in order to determine their maximal aerobic velocity (VVO2 max). During the following visits, an interval protocol (8x3 min at 85% of their VVO2 max with 90 s rest) was conducted by the eumenorrheic group three times: early follicular phase (EFP), late follicular phase (LFP) and luteal phase (LP); OC users did it twice: hormonal (HP) and non-hormonal (Non-HP); and one single phase for postmenopausal females. One way ANOVA was used to analyse ventilation (Ve), VO2 and RER among the different hormonal profiles.
RESULTS: Regarding Ve (ml/min), postmenopausal group (66.0±9.3) reported lower values, although no significant, in relation to EPF (75.0±10.1), LFP (73.4±10.4), LP (73.3±13.1), non-HP (78.0±11.6) and HP (80.3±13.9). According to VO2 (ml/kg/min), no significant differences were observed, among different hormonal profiles: eumenorrheic phases (EFP: 39.5±4.1; LFP: 38.3±4.1; LP: 36.9±4.8), OC phases (non-HP 35.3±3.4; HP 35.5±3.8) and postmenopausal (36.3±2.9). In accordance with RER, eumenorrheic phases (EFP: 0.95±0.45; LFP: 0.97±0.78; LP: 0.98±0.11) reported lower values in connection with the non-HP (1.01±0.06), HP (1.00±0.05) and postmenopausal (0.99±0.59), while these differences were not significant either ($p>0.005$ for all comparisons).
CONCLUSION: Overall, these data suggest that different hormonal concentrations may not affect respiratory variables in female athletes. So that, regarding just respiratory variables we might conclude that an interval training could be done indistinctly at any phase of the menstrual and OC cycles, as well as in postmenopausal females. However, these results are preliminary and the sample size is small, hence they should be interpreted with caution.

RELATIONSHIP BETWEEN HORMONAL CHANGES AND PHYSICAL PARAMETERS AMONG PREPUBERTAL FEMALE HANDBALL PLAYERS

CSELKO, A.1, TEKUS, E.1, VACZI, M.1, KOSZEGI, T.2, WILHELM, M.1

1:INSTITUTE OF SPORT SCIENCES AND PHYSICAL EDUCATION, FACULTY OF SCIENCES, UNIVERSITY OF PECS 2:DEPARTMENT OF LABORATORY MEDICINE, MEDICAL SCHOOL, UNIVERSITY OF PECS

INTRODUCTION: Monitoring of the growth and maturation factors is essential for the optimal sport performance and improvement among young athletes. In contrast to aerobic capacity the increase of strength is more prominent among prepubertal children and it may be due to neurological adaptations (De Ste Croix, 2008). Before puberty the level of strength improvement depends on the quantity of growth hormone (GH) and sex hormones (testosterone and estrogen; Matos & Winsley, 2002). The aim of our study was (i) to measure the physiological, muscle force and hormonal parameters of prepubertal female handball players after an 8 weeks long preparation handball training period; (ii) to analyze the correlation between the basic parameters and hormonal changes.
METHODS: Eighteen prepubertal female handball players (11.50±0.56 yrs) participated in this research. First morphological age of athletes was calculated. Fasting venous blood samples were collected and different hormones such as estradiol (E), testosterone (T), cortisol (C) and GH levels were analyzed before and after the 8 weeks training period. Furthermore, anthropometric parameters and strength values (maximal handgrip strength, maximal concentric quadriceps and hamstring torque) were also measured. Bruce treadmill test was used to analyze the changes in physiological parameters. Strength, spiroergometric and hormonal parameters were analyzed in two different periods by Paired Sample T-Test. Pearson correlation test was used to determine the relationship between these parameters. Statistical significance was set at $p \leq 0.05$.
RESULTS: The basic VO2max data correlated with the changes of GH level after 8 weeks training program ($r=0.593$, $p=0.025$). We also found correlation between E and T levels before ($r=0.601$, $p=0.018$) and after ($r=0.637$, $p=0.014$) the training period. Furthermore, the basic strength parameters were correlated with the changes of GH ($r=0.670$, $p=0.009$) and C ($r=0.552$, $p=0.041$) hormonal levels.
CONCLUSION: The recorded improvement in force parameters in prepubertal ages are the consequences of neuromuscular adaptation and hormonal changes. Elevation of testosterone and decrease of estradiol level modify the strength improvement and delay maturation in prepubertal girls.

INFLUENCE OF VENTILATORY THRESHOLD INTENSITY TRAINING ON BLOOD 2-ARACHIDONOYLGLYCEROL LEVEL.

YAMASHITA, T.1, NAGAYAMA, C.2, OMAGARI, K.2, YOSHIMURA, E.3, TOBINA, T.2

1: UNIVERSITY OF NAGASAKI, 2: UNIVERSITY OF NAGASAKI, 3: PREFECTURAL UNIVERSITY OF KUMAMOTO

INTRODUCTION: It is well known that the β-endorphin is one of the mediators of runner's high. In addition, endogenous cannabinoids (eCB), such as 2-Arachidonoylglycerol (2-AG) and anandamide, plays as stronger mediator. Our previous study identified a single bout of ventilatory threshold (VT) intensity exercise increases blood eCB concentration. However, it is unclear whether the physical training increases blood eCB production during exercise. This study investigated whether the exercise training affects the changes of blood 2-AG production.
METHODS: Twelve male subjects were recruited in this study. Subjects were assigned to exercise (EX: n=5, 40±13 years) and control (CON: n=7, 39±10 years) groups. The VT intensity was measured using cycle ergometer, and then EX carried out VT intensity exercise for 12 weeks (180 min/week). All subjects performed VT intensity exercise for 60 minutes at 0, 6 and 12 week after overnight fasting. Blood samples were obtained at before and after the exercise test and centrifuged immediately. Plasma were stored at -80°C until the analysis. Because 2-AG is rapidly isomerized to 1-Arachidonoylglycerol (1-AG), the concentrations of 2-AG and 1-AG were measured using LC-MS/MS (1). The sum of these values (2-AG + 1-AG) was used as the index of blood 2-AG level.
RESULTS: There were no difference in age, height, weight, BMI and VO2max between the groups. The baseline 2-AG + 1-AG levels were also similar in both groups at 0, 6 and 12week. During a single bout of exercise, heart rate were no significant differences between the groups (0 week: 114±15 bpm and 119±13 bpm, 6 week: 118±16 bpm and 116±10 bpm, 12 week: 117±15 bpm and 113±7 bpm, EX and CON, respectively (Data shown as mean ± standard deviation)). After the exercise test, 2-AG + 1-AG was significantly increased in EX at 6 week (3.5 (2.5-4.8) ng/mL and 3.7 (2.5-5.3) ng/mL, $p=0.043$ (Data shown as median (quantile))), and CON at 0 week (3.3 (3.1-4.2) ng/mL and 4.0 (3.9-7.3) ng/mL, $p=0.018$) and 6 week (2.6 (2.4-3.1) ng/mL and 3.3 (2.9-4.6) ng/mL, $p= 0.018$). The changes of 2-AG +1-AG (difference of the before and after the single bout of exercise) were 0 week: 1.04 (0.75-2.03) ng/mL, 6 week: 0.43 (0.20-0.48) ng/mL, 12 week: 0.26 (-0.05-1.53) ng/mL in EX and 0 week: 1.05 (0.58-2.46) ng/mL, 6 week: 0.53 (0.38-1.51) ng/mL, 12 week: 0.42 (0.14-0.84) ng/mL in CON, respectively. There were no significant difference between the groups.
CONCLUSION: The results suggested that a single bout of moderate intensity exercise may increase eCB concentration. However, the intensity exercise training may not affect the exercise induced eCB production.

MALE ENDOCRINE ADAPTIVE RESPONSE IN SCUBA DIVERS.

VERRATTI, V.1, BONDI, D.1, JANDOVA, T.1, CAMPORESI, E.2, PAOLI, A.3, BOSCO, G.3

1 UNIVERSITY "G. D'ANNUNZIO" CHIETI-PESCARA, ITALY; 2 UNIVERSITY OF SOUTH FLORIDA-COLLEGE OF MEDICINE, TAMPA, FLORIDA; 3 UNIVERSITY OF PADOVA, ITALY

INTRODUCTION: The use of hyperbaric oxygen (HBO) plays a significant role in many aspects of medicine. However, few studies analyzed the role of HBO in addition to physical exercise on endocrine profile. The aim of this study was to compare changes in plasma male sex hormones after hyperbaric physical exercise with different HBO pre-conditionings.
METHODS: We recruited six healthy, well-trained recreational male divers. Concentrations of prolactin (PRL), follicle-stimulating hormone (FSH), luteinizing hormone (LH), cortisol, 17-β estradiol (E2) and total testosterone (TT) were measured in venous blood immediately after four different study conditions. During condition 1 (Control) the divers were tested without any pre-treatment. During condition 2 (Exercise)

the participants did not receive a pre-treatment before the dive. During condition 3 (Oxy0m) the volunteers were breathing 100% oxygen on the surface of the sea before diving. During condition 4 (Oxy6m) the participants were breathing 100% oxygen 6 m below the surface of the sea (1.6 ATA). . In all the diving exposures, the depth of the dive was set at 30 m with water temperature of 20 ± 5°C and pressure of 4 Atmospheres Absolute (ATA). During 20 min of bottom time, the divers were breathing using scuba diving gear comprising of compressed air (N2O2). The exercise comprised of the same workload and was performed using an underwater bicycle (OKEO, Italy). The volunteers pedaled at a rate of 25 rpm to ensure there is no difference between ventilation and gas exchange. The intensity was guided by the 0-to-10 Rating of Perceived Exertion (RPE) scale and set to the level of 3 - moderate.
RESULTS: Exercise increased PRL and HBO exacerbated this effect. Hyperbaria stimulated the E2 reduction and hyperoxia partially inhibited this reduction. Hyperbaria, but not hyperoxia, stimulated the TT reduction. We did not find any change in FSH, LH and cortisol. PRL increases reflect a stress response after physical exercise amplified by HBO. TT reduction may be interpreted as an acute and transient fertility impairment. Age, blood pressure and BMI were taken into account as covariates for statistical analyses and they significantly affected our results, in particular TT.
CONCLUSION: Scuba diving certainly represents an interesting model to investigate and to better understand the endocrine adaptive responses to HBO and physical conditioning - both from physiological and therapeutic point of view. These data open new insight into the role of E2 and PRL on the male endocrine adaptive response. in addition, the TT reduction is a clear marker of male fertility impairment: thus, the acute and transient TT reduction we found can be due to hyperbaric effect on testicular perfusion, rather than to exercise or hyperoxia. Considering that acclimatization normalizes the altitude-related alterations of endocrine system, we should therefore improve our knowledge about the acute and chronic differences in endocrine dynamics after exercise combined with hyperoxia

EFFECT OF MENSTRUAL CYCLE PHASES ON 50-M SPRINT RUNNING PERFORMANCE

HAYAMIZU, M.1, MORIYAMA, S.1, MATSUO, K.2

1: TOKYO GAKUGEI UNIVERSITY, 2: KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Generally, many women often experience symptoms of worsening physical and mental states due to premenstrual syndrome. Especially, in terms of the physical condition, the changes in muscle stiffness throughout the menstrual cycle suggest the effect of the cycle on lower-limb biomechanics (1). In this study, we investigated the possibility that changes in conditions associated with the menstrual cycle affect the 50-m sprint running performance.
METHODS: Seven highly trained collegiate female athletes (age 19.1 ± 1.1 years) performed 50-m sprint running with their maximal effort. Their menstrual cycle was confirmed using the basal body temperature method (2). The menstrual cycle is divided into three phases: luteal, menstrual, and follicular phases. The measurement items were body composition; running velocity; hip, knee, and ankle joint angle; and scores from a conditioning questionnaire. The results were compared among the three phases of the menstrual cycle.
RESULTS: The body weight was significantly higher the luteal phase (53.4 ± 0.6 kg) than in the follicular phase (52.7 ± 0.5 kg) ($p < 0.05$). The score of "lower abdominal pain" in the physical condition domain of the questionnaire was significantly higher in the menstrual phase (0.86 ± 0.7 point) than in the follicular phase (0.14 ± 0.1 point) ($p < 0.05$). However, there were no significant differences in the sprint running velocity and the lower-limb joint angle in all participants ($p > 0.05$).
CONCLUSION: As reported earlier (3), this study shows that the menstrual cycle does not affect the sprint performance of collegiate female athletes, even in the presence of remarkable symptoms such as lower abdominal pain.

AGE-DEPENDENT VARIATION OF EXERCISE-INDUCED HORMONAL RESPONSES IN YOUNG ATHLETES

SEKINE, Y.1,2, HIROSE, N.2

1. TEIKYO HEISEI UNIVERSITY, 2. WASEDA UNIVERSITY

INTRODUCTION: Resistance training is recognized as an effective method to improve the performance (e.g., muscle strength and motor skills) of young athletes (1, 2). However, the hormonal responses to exercise in this phase of rapid growth remain unclear. This study aimed to examine the differences in exercise-induced hormonal responses among young athletes with different maturity levels.
METHODS: Twelve collegiate (age: 18.0±0 years) and 19 junior high school (age; 13.2±0.8 year) elite male basketball players volunteered to participate in this study. According to the difference between the predicted age at peak height velocity (APHV) calculated with the BTT model and the chronological age (CA), junior high school subjects were divided into two groups: before PHV (CAAPHV; n=12; age: 13.4±0.8 years). Salivary testosterone (T), cortisol (C), and human growth hormone (hGH) concentrations were analysed before (pre), after (post), and at 15 minutes after performing body weight exercises. Testosterone to cortisol ratio (T/C ratio) was calculated (3). Hormonal levels were compared between the groups and at time points using the repeated two-way (groups×times) ANOVA and Bonferroni post hoc test.
RESULTS: At all time points, levels of T in the collegiate group were higher than those of the two junior high school groups (before PHV: $p<0.01$, d=1.28-1.80; after PHV [pre]: $p<0.05$, d=0.92-1.12); T levels were also found to significantly increase after 15 minutes of exercise ($p=0.03$, d=0.61). Although it was not significant, T levels in the after PHV group were higher than those in the before PHV group for all time points ($p>0.05$, d=0.90-1.35). A significant decrease in C post-exercise ($p=0.01$, d=0.52) and an increase of hGH 15 minutes after exercise ($p=0.001$, d=0.42) were observed in the after PHV group. In the collegiate and after PHV groups, T/C ratio increased significantly post-exercise (after PHV: $p=0.03$ d=0.77) and at 15 minutes after exercise (after PHV: $p=0.02$ d=0.80; collegiate: $p<0.001$, d=1.12). T/C ratio in collegiate athletes was significantly higher than that in the after PHV group at pre-exercise ($p=0.02$, d=1.17) and 15 minutes after exercise ($p=0.02$, d=1.11) and the before PHV group in all time points ($p<0.02$, d = 1.48-1.89).
CONCLUSION: Exercise-induced hormonal secretions, which play an important role in anabolic action, appear to depend on the maturity status of the endocrine glands. In setting training goals for adolescent athletes, muscle synthesis or hypertrophy is a lower priority than any other performance improvement variable.

INFLUENCE OF GOLF COMPETITION ON THE CORTISOL HORMONE , STATE ANXIETY, AND CHOKING UNDER PRESSURE IN JUNIOR GOLFER.

NARKTAWON, K., MUANGNAPOE, P., SILALERTDETKUL, S.

INSTITUTE OF PHYSICAL EDUCATION

INTRODUCTION: To study of influence of golf competition on the cortisol hormone , state anxiety, and choking under pressure in junior golfer.
METHODS: Ten youth golfers between ages of 15-18 years. Has experience in golf and join the Thailand golf tournament for 5 years. Test the state anxiety and the choking under pressure before and after tournament. Saliva collect sample in four time, before, after hole 6, after hole 12 and after golf. Hormonal cortisol levels analysis day 1 and day 4 of golf tournament.
RESULTS: Before the golf tournament, the somatic anxiety was low, cognitive anxiety and self-confidence were moderate. After the golf tournament, the somatic anxiety was low and moderate. Cognitive anxiety and self-confidence was moderate. Choking under pressure negative thoughts and feelings were moderate and low, motor control changes, increased physiological arousal, communication failure was low, nervous personality was low and moderate, pre- competition condition were moderate and abnormal somatic sensation was low significant. Before the golf tournament, high concentrations of cortisol and lower value after hole 6. Between after play the hole 12 after the match, the cortisol concentrations increased and difference statistically significant. In addition, found that hormone cortisol after the match was correlate with the somatic anxiety and cognitive anxiety. In correlate with choking under pressure in the communication failure at statistically significant.
CONCLUSION: Golf tournament affects psychological changes in somatic anxiety, cognitive anxiety and the communication failure. Include relationships to the concentration of hormone cortisol.

THE ASSOCIATIONS BETWEEN THE MENSTRUAL CYCLE AND THE EFFECTS OF ACUTE EXERCISE ON APPETITE-REGULATORY HORMONES AND ENERGY INTAKE

KAMEMOTO, K.1,2, YAMADA, M.3, MATSUDA, T.1, OGATA, H.1, SAKAMAKI-SUNAGA, M.3

1 GRADUATE SCHOOL OF NIPPON SPORT SCIENCE UNIVERSITY, 2 TEIKYO UNIVERSITY, 3 NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: Feedback mechanisms involving gut and reproductive hormones regulate energy homeostasis. Animal studies have shown that estradiol inhibits eating, and that progesterone increases food intake (1). An acute bout of exercise may influence appetite by suppressing the levels of the orexigenic peptide acylated ghrelin while simultaneously increasing the level of the anorexigenic peptide YY (PYY), which may influence post-exercise food intake (2). This study examined the associations between hormonal changes across the menstrual cycle and the influence of acute exercise on appetite-regulatory hormones and energy intake.
METHODS: Eight female athletes (20.5 ± 0.5 years; 37.8 ± 5.4 mL/kg/min VO2 peak) with normal menstrual cycle, completed 60 min of moderate-intensity aerobic cycling (70% VO2 peak) on a cycle ergometer during the follicular and luteal phases. The plasma estradiol, progesterone, acylated ghrelin, PYY and serotonin concentrations and appetite rating were measured before, during (30 min), and after exercise (0, 45, and 90 min). The participants consumed an ad libitum meal 90 min post-exercise. The participants also recorded their dietary intake for 3 days, including the day of the experiment.
RESULTS: Overall, the plasma estradiol and progesterone concentrations were higher during the luteal phase than the follicular phase ($p<0.05$). Neither gut hormones nor subjective appetite differed between the follicular and luteal phases. The hunger score was increased at 90 min post-exercise compared with pre-exercise ($p<0.05$). The mean energy intake from the ad libitum meal was 1044±292 and 993±253 kcal during the follicular and luteal phases, respectively. There were no significant differences in energy intake during the 3 days of food consumption between phases.
CONCLUSION: To our knowledge, this is the first study to evaluate the impact of acute exercise on appetite across the menstrual cycle in female athletes. There was no change due to hormonal fluctuations across the menstrual cycle and no influence of acute exercise on gut hormones or energy intake.

EFFECT OF REGULAR PHYSICAL ACTIVITY ON LEVELS OF NESFATIN-1, NEUROPEPTIDE Y AND CORTISOL IN OBESE MEN

SADEGH EGHBALI, F., SOORI, R., MAHMOODI, F.

SPORT SCIENCE

INTRODUCTION: The aim of this study was to assess the effects of concurrent endurance (treadmill running) and resistance (weight lifting) exercises on serum levels of nesfatin-1, neuropeptide Y and cortisol in obese men with little activity.
METHODS: In the present study, 30 obese (or over weighted) men aged between 48 to 60 years with a BMI of over 30 were selected and divided in tow groups randomly. Effects of 12-week concurrent endurance (treadmill running) and resistance (weight lifting) exercises on serum levels of nesfatin-1, neuropeptide Y, and cortisol were investigated. After determining anthropometric parameters such as height, weight, body mass index and skinfold thickness, in order to determine the exercise intensity, initial assessments such as repetition maximum for each subject by free weights (1RM) and resting (HRrest) and maximum (HRmax) heart rates were performed. In addition, to evaluate serum levels of nesfatin-1, neuropeptide Y and cortisol, blood samples were taken after 12 hours of fasting. Physical indicators studied were measured and recorded again after the end of the training period. To prevent acute inflammation effects of exercises on serum levels of nesfatin-1, neuropeptide Y, and cortisol, blood samples were collected at least 48 hours after the last training session. Statistical analyses were performed using SPSS with a significance level of $P<0.05$.
RESULTS: The major findings of this study showed a significant increase in neuropeptide Y level and a significant decrease in cortisol level following concurrent exercises. Also, nesfatin-1 levels showed no significant difference between pretest and posttest conditions
CONCLUSION: The concurrent exercises significantly increase cortisol and neuropeptide Y but do not affect nesfatin-1 in obese middle-aged men

ALTERATION OF HEART RATE AND BONE MINERAL DENSITY AFTER INTERVAL EXERCISE IN CLONED AND NON-CLONED DOGS

LEE, H.S.1, OH, H.J.2, KIM, J.H.3, HWANG, J.Y.3, KIM, J.H.1

1: HANYANG UNIVERSITY , 2: SEOUL NATIONAL UNIVERSITY , 3: HELIX ANIMAL MEDICAL CENTER

INTRODUCTION: State of health and physical fitness depend on genetic background and environmental factors. Human monozygotic twins are a valuable source for investigation of the genetic influence on exercise (1, 2). We investigated on how prolonged interval exercise can affect heart rate (HR) and bone mineral density (BMD) differently between genetically identical cloned and non-cloned dogs.
METHODS: We used cloned dogs which are produced by somatic cell nuclear transfer technology. Three cloned beagles and three non-cloned beagles (2-3 years old) were performed to interval exercise on a treadmill two times a week for twelve weeks. The work (W) to rest (R) ratio was set to 1:2 and both slope and speed were increased every protocol stage. The HR was monitored using a Polar H-10 HR sensor throughout the periods of exercise. BMD was measured at the lumbar vertebrae and the femur using QCT. The CT scan was performed at the beginning (0 week) and the end (12 weeks) of applying exercise, respectively.
RESULTS: The individual HR pattern in response to exercise was more comparable in cloned dogs than those of non-cloned dogs. Three non-cloned dogs showed significantly different HR values in each W and R stage. Exercise increased BMD significantly by 10.3% (330.9 ±5.3 HA vs. 300.1 ± 7.5 HA) at the lumbar vertebrae and by 16.9% (668.32 ± 15.7 HA vs. 571.5 ± 22.2 HA) at the femur in cloned dogs. The post-exercise BMD increased significantly by 7.4% (303.5 ±1.9 HA vs 282.6 ± 3.6 HA) at the lumbar vertebrae and by 7.9% (552.0 ± 15.2 HA vs. 511.7 ± 1.2 HA) at the femur in non-cloned dogs. BMD increasing rate after exercise was significantly higher in cloned dogs than in non-cloned dogs.
CONCLUSION: This study demonstrated that HR response during prolonged interval exercise is affected by the genetic background. In addition, interval exercise can induce a positive alteration of canine BMD in both cloned and non-cloned dogs. This study was supported by "CCAR (# PJ013959022019)" of RDA.

IMPACT OF PHYSICAL EXERCISE DURING PREGNANCY ON THE MODULATION OF LIVER MITOCHONDRIAL FUNCTION IN AN ANIMAL MODEL OF NON-ALCOHOLIC FATTY LIVER DISEASE

STEVANOVIC, J.1, BELEZA, J.1, COXITO, P.1, RIOS, M.1, PEREIRA, R.1, PEREIRA, S.P.1,2, PALMEIRA, C.M.2,3, MORENO, A.J.2,3, OLIVEIRA, P.J.2, ASCENSÃO, A.1, MAGALHÃES, J.1

1: FACULTY OF SPORT, UNIVERSITY OF PORTO; 2: UNIVERSITY OF COIMBRA; 3: UNIVERSITY OF COIMBRA

INTRODUCTION: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease, linked with high-caloric intake and sedentary lifestyles. NAFLD is also associated with impaired glucose homeostasis. The physiological significance of NAFLD in pregnant women with gestational diabetes mellitus (GDM) has not been well-determined. The combination of these metabolic risk factors during pregnancy may impair offspring (F1) metabolism, increasing the risk for metabolic disorders. We aimed to assess if physical exercise (PE) during pregnancy improves maternal and F1 liver mitochondrial function in animal model of NAFLD and GDM.
METHODS: Female Sprague-Dawley rats (F0) were fed with control (C) or high-fat-high-sugar (HFHS) diets. After mating, HFHS group was divided into sedentary and exercised group, submitted to PE during 3 weeks of pregnancy (1 h/day at 20 m/min). Body weight (BW) of F0 and F1 was weekly monitored during 18 wks. Liver mitochondrial function was assessed in both generations (F0 at 18th, F1 at 6th wk) using substrates for complex I and II.
RESULTS: While both diet and 3 wks of PE did not affect maternal BW during 18 wks of protocol, gestational BW gain was higher in sedentary HFHS mothers compared to C or exercised HFHS group (163.8±12.6 vs. 107.7±11.9 vs. 122.8±3.7, respectively; $p<0.05$). F1 of HFHS mothers had higher BW compared to those of C (male F1: 80.7±1.0 vs. 66.0±1.2, $p<0.05$; female F1: 76.2±1.1 vs. 62.7±0.9, $p<0.05$), while gestational PE lessened the adverse effects of HFHS on both male and female F1 BW (80.7±1.0 vs. 71.7±1.9, $p<0.05$; 76.2±1.1 vs. 68.2±1.6, respectively; $p<0.05$). Regarding liver mitochondrial function, no effect of the HFHS, per se, was observed in the respiratory control ratio (RCR) of F0. However, an increase was observed in exercised HFHS mothers compared to sedentary HFHS mothers (8.3±0.6 vs. 6.1±0.4, $p<0.05$). In both genders of F1 there was a significant decrease in RCR due to the HFHS diet compared to C; however, both genders F1 of exercised HFHS mothers, significantly reverted the decreased RCR using substrates for complex I compared to the sedentary groups (male F1: 6.8±0.6 vs. 4.9±0.4, $p<0.05$; female F1: 8.6±0.6 vs. 6.5±0.5, $p<0.05$). In both generations, no alterations were observed in mitochondrial function when substrates for complex II were used.
CONCLUSION: The HFHS induced higher gestational BW gain in mothers, while gestational PE diminished these HFHS effects. In mothers, gestational PE seemed to have an important role in liver mitochondrial adaptations later in life. Even more, these effects of gestational PE protect F1 against adverse effects of maternal diet in the early stage of life. PE can be a tool to optimize maternal and foetal pregnancy outcomes.

THE ASSOCIATION BETWEEN GRIP STRENGTH AND LEAN MASS.

PRATT, J.1, BOREHAM, C.1, ENNIS, S.1,2, DEVITO, G.1

1: UNIVERSITY COLLEGE DUBLIN, 2: GENOMICS MEDICINE IRELAND

INTRODUCTION: Grip strength and lean mass have been highlighted as strong predictors for functional disability (1), morbidity (2) and mortality (3) across the lifespan. Uncertainty remains, however, as to the strength of the association between grip strength and lean mass (4). Thus, considering the widespread use of grip strength as an assessment tool for lean mass in both research and clinical settings, developing our knowledge within this area is of great importance.
The aim of this study was to determine the efficacy of grip strength in predicting lean mass within a cohort of the Irish population.

METHODS: 2,572 healthy individuals took part in this study (1,486 women, age range: 18-85 years and 1,086 men, age range: 18-89 years). Dual-energy x-ray absorptiometry was used to assess lean mass, while hand dynamometry measured grip strength. A quadratic polynomial regression analysis was performed between grip strength and lean mass for the entire dataset.
RESULTS: Analysis revealed a moderate relationship between grip strength and lean mass for both males and females (R^2= 0.263, $p<0.001$ and R^2=0.314, $p<0.001$ respectively).
CONCLUSION: Results confirm a notable correlation between grip strength and lean mass within a normal population. These findings support the use of hand dynamometry for assessing lean mass. Future large-scale analysis should investigate the effect of confounding factors such as level of physical activity and dietary practises on this relationship.

SALIVARY ANALYSIS OF VALINE INTERMEDIATE 3-HYDROXYISOBUTYRATE: A POSSIBLE MARKER OF MUSCULAR BCAA UTILIZATION FOR ENERGY PRODUCTION IN EXERCISE

MIYAZAKI, T., IKEGAMI, T., HONDA, A.

TOKYO MEDICAL UNIVERSITY

INTRODUCTION: Branched-chain amino acids (BCAAs) are catabolized for energy production in skeletal muscle in endurance exercises, in fasting and insulin resistance. We reported that 3-hydroxyisobutyrate (3HIB), which is an intermediate in valine catabolic pathway in skeletal muscle, was excreted from skeletal muscle, and was elevated in blood dependently on endurance exercise time, in ECSS 2018. Therefore, 3HIB could be a useful marker of muscular BCAA utilization during exercise, but it is difficult to collect blood during exercise. Since salivary can be noninvasively collected by self, it is useful sample indicating real time state during exercise. Present study purposed to develop a highly sensitive and quantitative analysis of 3HIB in saliva and evaluate the usefulness of salivary analysis for monitoring of blood 3HIB level during exercise.
METHODS: Blood and saliva were simultaneously collected from three healthy volunteers several times on different days to compare 3HIB concentration in saliva and serum. In a healthy volunteer supplemented with or without BCAA granule (6.4g) before 30 min of exercise, saliva was collected every 5 min during 60-min treadmill running (8~9 km/h) and every 30 min until 4 hours after the exercise. Saliva was collected by passive drool into a collection tube after washing out mouth with water several times, and was immediately frozen at -20°C until analysis. 3HIB level was high-sensitively quantified in the deproteinized saliva and serum with internal standard (13C4-3-hydroxybutyrate) by our developed method using derivatization with 2-pyridinemethanol and LC-MS/MS system.
RESULTS: Serum and saliva collected from the volunteers repeatedly on different days have significant correlations in 3HIB concentration ($r2 = 0.6930$, $P< 0.0001$). Salivary 3HIB concentration was begun to increase since 20 min during exercise and gradually increased until finish after 60 min-exercise. In the BCAA pre-supplementation, 3HIB concentration in saliva was begun to increase as soon as the beginning of exercise and the increase level was markedly compared to those in non-supplementation. After the exercise, salivary 3HIB concentration was immediately decreased in both BCAA pre- and non-supplementation.
CONCLUSION: Present study showed that salivary 3HIB concentration reflects very well on its blood level on our developed high-sensitive and quantitative method, and could evaluate the changes of salivary 3HIB concentration during endurance exercise and the influences of BCAA supplementation. Salivary 3HIB analysis would be a useful tool as noninvasive method for real-time monitoring the muscular BCAA utilization for energy production during exercise.

EFFECTS OF PHYSICAL ACTIVITY (TIME, LEVEL), LIFESTYLE ON CHRONIC DISEASES IN KOREANS

CHANGJIN, J., SANGHO, K.

KOREA UNIVERSITY

Introduction
The lack of physical activity(PA) is one of the top ten causes of death. In the current era of South Koreas more to aging, the death rate and medical expenses are rising along with the lack of physical activity. On the other hand, sedentary life is being highlighted as a factor for chronic diseases and diseases. In 2015, 13.1% of South Koreas people are aged 65 or over, and an estimated, the rate will be reached 40% in 2060. Besides, compared to 2008, the medical expenses increased by 10.8 trillion on and the cost of own medicine increased by 2.6trillion Won in 2015. This study reveals the relationship of medical expenses with hours spent on physical activity and sitting time. Moreover, provides a guide of the reasonable lifestyles.
Methods
To look at the factors related to the PA of adults, this study used data collected from 2011 to 2013 of Korean Medical panel data (Version 1.5). The subjects make a panel balance was 19,182 cases of 6,394 participants who participated for three years of longitudinal study.
Result
First, observe the risk of chronic disease(CD) prevalence, compared with the sitting time of <29hours/week, the sitting time of >56hours/week was significantly increased by 1.1times. And moderate MET was significantly increased by 1.14times compared with high MET ($p <.05$), ($p <.05$).
Second, observe the risk of complex CD (above 3 diseases), compared with high PA & low sitting group, low PA & Low sitting group was significantly increased by 1.19 times. On the other hand, compared with the sitting time of <29hours/week, the sitting time of 29-41 hours/week, 42-55 hours/week and >56 hours/week was significantly increased by 1.18 times, 1.21times, and 1.13 times, respectively ($p<.01$), ($p<.001$), ($p<.01$), ($p<.01$).
Third, when CD recovery was examined, high MET was significant increased by 7.51 times compared with low MET($p<.05$).
Finally, analyze the change of PA by longitudinal and chronic disease, compare with MET increasing group, general CD risk and the CD risk (1~2 diseases) of MET decreasing group was significantly increased by 1.80 times and 1.73 times, respectively($p<.05$), ($p<.05$). Compare with MET increasing group, the complex CD risk (above 3 diseases) of MET sustaining group was significantly increased by 1.23 times ($p<.001$).
Discussion
This study was conducted to analyze the relevance of complex (high PA & low siting, high PA & high Sitting, low PA & low sitting, low PA & high sitting) and each factor (Physical Activity times, sitting times and MET) to chronic diseases.

In the future, it is expected to reduce chronic disease growth if supported by various programs that cut off sedentary life along often with increased physical activity in public health policies.

ESTIMATION OF QUADRICEPS MUSCLE VOLUME USING SEGMENTAL BIOELECTRICAL IMPEDANCE SPECTROSCOPY

TANIGUCHI, M., YAGI, M., NAKAI, R., ICHIHASHI, N.

GRADUATE SCHOOL OF MEDICINE, KYOTO UNIVERSITY

INTRODUCTION: Segmental-bioelectrical impedance spectroscopy (BIS) has previously been used to estimate skeletal muscle volume (MV). BIS measures intracellular water (ICW) and extracellular water (ECW) of skeletal muscle tissue, and ICW reflects MV. In addition, segmental-BIS is advantageous for estimating local segmental MV at locations such as the whole-thigh. However, it has not been clear which localized segment is appropriate for estimating quadriceps MV. Magnetic resonance imaging (MRI) is an accurate method for assessing MV. The purpose of this study was to use MRI to validate optimum segmental-BIS methods for estimating quadriceps MV.
METHODS: Eighteen young men (age; 23.8 ± 3.3 years, height; 170.9 ± 4.1 cm,mass; 63.0 ± 3.7 kg) were recruited in the present study. T1-weighted images of the whole-thigh were obtained using a body coil MRI (MAGNETOM Sonata 1.5T, Siemens, Germany). The anatomical cross-sectional area (CSA) of the quadriceps was traced in each image, and adipose and connective tissue were excluded from CSA based on pixel intensity using Osirix MD (Pixmeo, Switzerland). The quadriceps MV was calculated as the sum of products of CSA and the slice thickness of 6mm along the muscle length. Segmental-BIS was applied for a logarithmic spectrum of 256 frequencies ranging from 4 to 1000 kHz (SFB7, ImpediMed, Australia). The localized segmentations were defined as follows; 1) whole-leg: between the anterior superior iliac spine (ASIS) and mid-anterior ankle, 2) whole-thigh: between ASIS and lateral knee articular condyles, and 3) middle-thigh: centered on the midpoint between ASIS and the proximal end of patella with a proximal-distal span of 15 cm. Resistance of zero (R0) and infinity (R∞) frequencies was obtained by BIS measurements. According to a previous study (Yamada 2013), the R-ICW was calculated with 1/[1/R∞ − 1/R0], and quadriceps ICW index defined as (segmental length)2/R-ICW. Simple linear regression analyses were performed to determine the relationship between quadriceps MV and ICW indexes in the three segments. Additionally, the standard error of the estimate (SEE) was calculated.
RESULTS: MRI-measured muscle volume of the quadriceps was 1838 ± 255 cm3, and the ICW indexes were as follows; R-ICW in whole-leg = 15.0 ± 1.8 cm/Ω, whole-thigh = 18.5 ± 2.8 cm/Ω, and mid-thigh = 7.3 ± 1.9 cm/Ω. The ICW index in each segment was significantly correlated with quadriceps MV. The values of R2 and SEE were as follows; whole-leg: R2 = 0.46 ($p < 0.01$), SEE = 194.0 cm3, whole-thigh: R2 = 0.77 ($p < 0.01$), SEE = 126.3 cm3, and mid-thigh: R2 = 0.43 ($p < 0.01$), SEE = 200.2 cm3.
CONCLUSION: The ICW index in whole-thigh segment measured by segmental-BIS was a moderately good predictor of quadriceps MV calculated by MRI. These results suggest that segmental-BIS may be useful for estimating quadriceps MV in field surveys.

THE IMMEDIATE EFFECTS OF KINESIOTAPING ON DIFFERENT PERFORMANCE TESTS IN PROFESSIONAL BASKETBALL PLAYERS: PILOT STUDY

YIGIT, B., CETINKAYA, A., TUNALI, N.

T.C. HALIC UNIVERSITY / PHYSICAL THERAPY AND REHABILITATION DEPARTMENT

INTRODUCTION: The aim of this study was to investigate the effect of kinesiotaping of gastrocnemius and quadriceps femoris muscles on different jumping types, forward and side lunge test and dynamic balance in professional basketball players.
METHODS: 10 basketball players were included. Performance tests were multiple single-leg hop-stabilization test, single leg forward jump test, forward and side lunge test, and vertical jump test. Y test was used for dynamic balance. Players were tested after 5 min-run. Tests were performed in order of without kinesiotaping, kinesiotaping with muscle activation technique on gastrocnemius muscle, quadriceps femoris muscle, both muscles at the same time. "Repeated Measures" of SPSS were performed for each individual dependent variable. Statistically significance level was set on $p<0.05$.
RESULTS: Mean age was 22.33±0.95. Right was the dominant side of all participants. There were found no any statistically significant difference ($p>0.05$) except on right side lung test ($p<0,05$). There were statistically significant differences between before test results and after kinesiotaping of both muscles ($p=0.033$) and between kinesiotaping of quadriceps femoris muscle and of both muscles ($p=0.41$).
CONCLUSION: This pilot study showed that kinesiotaping of quadriceps femoris and gastrocnemius muscles together has an effect on dominant side lunge performance. Therefore it was thought that kinesiotaping might affect jumping performance and dynamic balance after increasing of participants.

ARCHITECTURAL AND MECHANICAL PROPERTIES OF PARALYZED MUSCLES IN PATIENTS POST STROKE

KATO, E., KAWASHIMA, N.

KYOTO SANGYO UNIVERSITY, RESEARCH INSTITUTE NATIONAL REHABILITATION CENTER FOR PERSONS WITH DISABILITIES

INTRODUCTION: Motor paralysis is well known to be due to central nervous system disorders such as stroke and leads to higher joint torque in response to passive joint motion due to immobilization. In order to establish an effective rehabilitation approach for the prevention of disuse syndrome, quantitative evaluation of the paralyzed muscle is quite important. The purpose of this study was to characterize paralyzed muscle properties in post-stroke patients with the combination of stiffness estimation and ultrasonography.
METHODS: Thirteen post-stroke patients participated in this study as subjects. We measured muscle thickness (MT), fascicle length (FL), and pennation angle (PA) of the triceps surae muscles as the architectural properties of muscles and stiffness of ankle joint and each of the triceps surae muscles as the mechanical properties, using ultrasonography. The measurements of the gastrocnemius medialis (MG), gastrocnemius lateralis (LG), and soleus (SOL) were taken at a proximal level of 30% of the shank length. To measure stiffness, the subjects sat on a chair of the dynamometer, with their hip and knee joints flexed 90˚ and the ankle joint was passively dorsiflexed from 20˚ of plantar flexion to 20˚ of dorsiflexion (5˚/s).
RESULTS: While the MT of MG showed significantly lower value in paretic than non-paretic side, LG and SOL did not show significant difference between paretic and non-paretic side. The FLs on the paretic side showed significantly shorter than those on the non-paretic side in all the triceps surae muscles. The PA of LG showed significantly lower value in paretic than non-paretic side. On the other hand, the PA of MG and SOL did not show significant difference between paralyzed and non-paralyzed side. The ankle joint stiffness estimated by passive ankle joint dorsiflexion on the paretic side was significantly higher than that on the non-paretic side. MG and LG showed significantly higher muscle stiffness on the paretic than non-paretic side, but SOL did not show significantly difference between both sides. Similarly, the ankle joint stiffness and muscle stiffness of the triceps surae muscles showed higher values on the paretic than on the non-

paretic side. In addition, muscle elongation according to the change in passive ankle dorsiflexion in the MG and LG showed a significant interaction, but not in the SOL between the paretic and the non-paretic sides.
CONCLUSION: The present results indicated a significant alteration both architecturally and mechanically in the paralyzed muscles by motor paralysis due to the central nervous system disorder. Especially the biarticular muscle was more affected than mono-articular. The present result implies that the protocol of the rehabilitation approach for reducing muscle stiffness should consider the anatomical characteristics of muscles due to the type of injury/disorder and the individual variability among patients.

DIETARY SUPPLEMENTS IN GERMAN FIRST AND SECOND NATIONAL LEAGUE MALE SOCCER PLAYERS

VON SPIEGEL, S., OERTZEN-HAGEMANN, V., BINSKER, F., PLATEN, P.

RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: Dietary Supplements (DS) are more and more used by elite athletes. Some DS are scientifically proven to have benefits for health and performance, but others can even pose a risk for the athlete (1). DS use in elite soccer players during their normal season has not been investigated in depth so far. The current survey provides insight into the prevalence of and the motives for DS intake.
METHODS: 24 German male soccer players (age: 25.5 ± 9.5 years; body mass: 78.6 ± 11.3 kg; height: 183.3 ± 14.7 cm) playing in the first and second national league with 13.2 ± 7.8 hours of training per week completed a five-page online questionnaire, which was accepted by the ethics commission of the Faculty of Sport Science, to assess their supplementation pattern on macronutrients, micronutrients and other supposed performance-enhancing substances within the last three months. Data were collected about the amount, frequency, dosage, kind of application and the motives for the intake of the single DS. The players were further asked about the sources of their knowledge, the money spent on DS and their knowledge about possible doping-relevant contaminations.
RESULTS: 87.5% (n=21) of the players reported regular or irregular use of DS, with 62.5% (n=15) using vitamins, especially vitamin C (50.0%, n=12) and vitamin D (45.8%, n=11). Minerals were used by 75.0% (n=18) of the athletes, among them particularly magnesium (70.8%, n=17) and zinc (37.5%, n=9). Proteins were consumed by 45.8% (n=11), carbohydrates by 16.7% (n=4) and fatty acids by 8.3% (n=2). Furthermore caffeine, the most used DS of the other performance-enhancing substances, was used by 29.2% (n=7). Main motives of supplement usage were prevention of injuries (28.0%), increase in performance (14.9%), compensation of an unhealthy diet (14.3%), combating deficiency symptoms (8.4%), group pressure (3.0%) and others (24.4%). The main sources of advice were nutritionists (29.2%) and friends/training partners (25.0%). Possible contaminants in the DS were considered by 75.0% (n=18) of the athletes and 91.7% (n=22) indicated to respect national doping lists.
CONCLUSION: This survey showed a widespread DS usage in professional German male soccer players during their normal season. Vitamin and mineral usage was even higher compared to the reported intake during Futsal World Cup tournaments (2). Interestingly, players were not only advised by professional nutritionists, but to almost the same extent by friends/training partners. The usage of DS often seems to be based on individual experiences rather than on scientific proof or medical advice. This might increase the risk of unwelcome side effects like health problems or decline in performance.
A larger sample size should be analyzed prior to final conclusions, but it seems that education on the use of DS should be implemented in German elite male soccer.

EVALUATION OF NUTRIENT INTAKE AND DIET QUALITY OF TRACK AND FIELD INDIAN ATHLETES

KALPANA, K.1, RAMESH, N.2, ISHANI, G.1, VENKATA RAMANA, Y.1

1MYAS – NIN DEPARTMENT OF SPORTS SCIENCE, ICMR- NATIONAL INSTITUTE OF NUTRITION, HYDERABAD- 500007, INDIA 2SPORTS AUTHORITY OF INDIA, HYDERABAD-- 500007, INDIA

INTRODUCTION: Adequate and proper nutrition is very crucial for the maintenance of health and peak performance of athletes. An overall assessment of nutrient intake and diet quality is necessary to determine excessive, adequate or insufficient supply of nutrients. However, information on nutrient intake and diet quality of athletes in the preparatory phase and travelling is very scanty. Therefore, the present study focuses on evaluation of food and fluid intake and diet quality of track and field athletes in the preparatory phase and travelling.
METHODS: Forty two Indian national track and field athletes (18 male & 24 female), aged 16-22 years, preparing for the national athletic championship were assessed for nutrient Intake and diet quality using 24-hour recall method and food record method in the preparatory phase and travelling. Nutritional adequacy of macronutrients was evaluated using Indian sports nutrition recommendations for track and field athletes and nutrient adequacy ratio (NAR), mean adequacy ratio (MAR), nutrient density (ND), index of nutritional quality (INQ) was evaluated using Indian Recommended Dietary Allowances (RDA) and sports nutrition guidelines. Dietary variety score (DVS), and dietary diversity score (DDS) were calculated based on the food items consumed and food groups included. Fluid intake was assessed using 24-hour fluid record method which includes training and non-training hours. Mean and SD were applied for all the measurements. t- test and correlation coefficient was used to know the differences between the groups and phases. The differences were considered at $p<0.05$ and $p<0.01$.
RESULTS: The energy intake of male athletes (PP: 3927+561.57 Travel: 2675+ 516.17) was significantly higher ($p<0.05$) than the female athletes (PP: 3051 + 409.6; Travel: 2230 + 322.58) in the preparatory phase and in travelling.The energy intake was significantly lower ($p<0.05$) in travelling than the preparatory phase. Carbohydrate intake also showed a similar trend with energy between groups and phases (male: PP: 592.39+123.73; travel: 453.78+ 113.95; female: PP: 429.39 + 116.20; travel: 362.71 + 72.69). Protein intake of male athletes (PP: 165.27 + 19.96 Travel: 73.79+ 23.75) was significantly higher ($p<0.05$) than the female athletes (PP: 129.54 + 29.38; Travel: 56.88 + 7.35) in the preparatory phase and in travelling. protein intake was significantly lower ($p<0.05$) in travelling than the preparatory phase. No significant difference was found between male (PP: 105.69 + 19.88 Travel: 62.83+ 7.34) and female athletes (PP: 91.06 + 19.61; Travel: 61.37 + 9.95) for fat intake in the preparatory phase and in travelling and a significant difference ($p<0.05$) was found between the phases for male and female athletes.

Energy and carbohydrate were lower, protein intake was higher and fat intake was optimum when compared with the recommended guidelines in the preparatory phase as it was also evident from NAR, ND and INQ. When compared with the RDA, the NAR of micronutrients was adequate with the exception of iron and zinc in female athletes and riboflavin in male athletes in the preparatory phase and all the micronutrients were significantly lower ($p<0.05$) in travelling. The intake of all the measured micro nutrients was low in the preparatory phase and as well as travelling when compared with sports nutrition recommendations. MAR was higher in the preparatory phase than in travelling. The average DVS and DDS scores were better in the preparatory phase than in travelling. Hydration practices were good in the preparatory phase and low in travelling.
CONCLUSION: The track and field athletes need to improve on their food and intake while travelling and appropriate strategies should be followed by an inclusion variety of foods to attain nutrient balance in the preparatory phase and travelling. There is a great need for formulation of sport specific nutrition guidelines for macro and micronutrients and fluid intake.

DEVELOPMENT OF THE ATHLETE DIET INDEX: A NEW DIETARY ASSESSMENT TOOL FOR ATHLETES

CAPLING, L.1,5, GIFFORD, J.A.1, BECK, K.L.2, FLOOD, V.M.1,3, SLATER, G.J.4, DENYER, G.S.1, O'CONNOR, H.T.1

1: THE UNIVERSITY OF SYDNEY, 2: MASSEY UNIVERSITY, 3: WESTERN SYDNEY LOCAL HEALTH DISTRICT, 4: UNIVERSITY OF THE SUNSHINE COAST, 5: QUEENSLAND ACADEMY OF SPORT

INTRODUCTION: Assessment of dietary patterns via a diet quality index in the general population provides a rapid, inexpensive way of evaluating dietary intake with little respondent burden. Rather than assessing nutrient intake, diet indices assess intake of whole foods and dietary patterns, and compare these to nutrition guidelines. An athlete-specific diet index would offer sports nutritionists and researchers an efficient and practical way to assess the quality of athletes' diets, guide nutrition interventions and focus sport nutrition support. While the diet quality of athletes has been reported using population indices, a validated diet index for athletes does not exist. Therefore, the aim of this research was to develop an Athlete Diet Index (ADI).
METHODS: Development of the ADI was informed by a review of existing population diet indices, scientific literature, and focus groups with 20 experienced sports nutritionists (median 11 years professional experience) from three Australian and one New Zealand elite athlete sporting institutes. Focus group data were analysed and key themes identified using NVivo 11 Pro qualitative data analysis software (QSR International Pty. Ltd., 2017, Melbourne, Australia). The key themes and sub-themes were used to guide ADI item development. Content validation was undertaken using a modified Delphi survey; a sub-group of nine sports nutritionists informed modification of the ADI by providing feedback on the draft items. The electronic ADI was then piloted with 15 elite Australian athletes to establish instrument readability. A proforma was used to collect athlete feedback and evaluate face validity.
RESULTS: The final ADI included 68 items categorized into three sections. Section A (n=45 items) explored usual intake of core foods (i.e. fruit, vegetables, grains, meats and alternatives, dairy and alternatives), discretionary foods and alcohol, special diets or intolerances, and culinary skills. Section B (n=15 items) was athlete-specific and assessed frequency and volume of training, eating and drinking habits around training, plus sports supplement use. Section C (n=8 items) captured demographic details, plus sporting type and calibre. Athlete participants reported the ADI as 'easy' (40%) to 'very easy' (60% of participants) to use, and rated the tool as 'relevant' (37%) to 'very relevant' (63% of participants) to an athlete population.
CONCLUSION: Development of the ADI was based on a mixed methods approach informed by literature and expert sports nutrition practitioners. Engagement with the pilot ADI indicated the tool is simple to use and relevant to athletes. Further evaluation of the ADI, including the development of a scoring matrix and validation compared to established dietary methodology, is warranted.

EXPLORING THE KNOWLEDGE-BEHAVIOUR-ATTITUDE MODEL IN ATHLETES – A PILOT STUDY

TEO, J.H.C.1, KAWABATA, M.2, BURNS, S.F.2

1: SINGAPORE SPORT INSTITUTE, 2: NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY OF SINGAPORE

INTRODUCTION: Knowledge is central to improve dietary inadequacies in athletes and nutrition education programmes are often created with the intent of improving dietary intake through knowledge (1). Unfortunately, the link between nutrition knowledge and dietary behaviour in athletes is inconsistent due to poorly constructed instruments (2). Therefore, this study aimed to 1) develop well-constructed instruments to measure nutrition knowledge and attitudes in Singaporean athletes and 2) explore the relationships among nutrition knowledge, attitudes, and dietary behaviour (KAB).
METHODS: The study was split into three stages. 1) Two self-report questionnaires to assess nutrition knowledge (NKQ) and attitudes and perspectives to nutrition (APN) were developed. The theory of planned behaviour was incorporated as a framework of the APN. 2) Both instruments were rigorously examined for validity and reliability in university sport science students (n=193; retest n=33). 3) In an observational pilot study, both questionnaires were used to collect data from national squad netball players (n=12), along with dietary behaviour gathered via a 3-day recall. Correlation, multiple regression, and mediation analyses were conducted to examine KAB relationships.
RESULTS: In Stage 1, the 48-item NKQ consisting of five subsections (food groups, micronutrients, hydration, sport nutrition practices, supplements) was developed. In Stage 2, content and face validity of the NKQ was confirmed by expert sport dietitians. The results of a 2 (top vs bottom quartiles) × 2 (correct vs incorrect answers) chi-square test on each NKQ item supported the discriminant validity of the NKQ. As for the APN, the results of a confirmatory factor supported its factorial validity ($\chi2=115.277$, $df=62$, $p<.001$, TLI=.907, CFI=.926, RMSEA=.067, SRMR=.586). The overall internal consistency of the questionnaires were acceptable (NKQ: alpha=.734; APN: alpha=.809), with good test-retest reliability (both $r>.7$, $p<.01$). In Stage 3, correlations between nutrition knowledge and attitudes (r=.508), and between nutrition knowledge and dietary behaviour (r=.330) were observed to be non-significant. However, a multiple regression analysis showed that nutrition knowledge and attitudes predicted dietary behaviour $R2=.632$, $F(2, 9)=7.71$, $p=.011$. The mediation analysis indicated that indirect effect of attitudes on nutrition knowledge and dietary behaviour was non-significant –(.228; 95% CI=-1.21, .072).
CONCLUSION: Two well-constructed instruments were developed in this study to measure nutrition knowledge and attitudes in Singaporean athletes. Both questionnaires were found to be psychometrically sound. Although the mediation effect of attitudes on the relationship between nutrition knowledge and dietary behaviour was not supported, the pilot study showed that both knowledge and attitudes predicted behaviour.

IS-PM07 Looking inside-out into ageing skeletal muscle: Hormones, systemic inflammatory environmentand the extracellular matrix

HORMONES AND EXERCISE-INDUCED MUSCLE HYPERTROPHY ACROSS AGE

ATHERTON, P.J.

UNIVERSITY OF NOTTINGHAM

Resistance exercise training (RET) positively influences muscle mass/function and metabolic health. Given epidemiological and physiological associations between muscle health and general health - understanding interactions between physical activity, ageing and muscle is paramount. Nonetheless, recent studies have shown that ageing is associated with maladaptation to RET in the form of blunted muscle hypertrophy1, driven by deficits in cellular growth processes2. Moreover, in the area of RET-induced muscle hypertrophy, controversy exists as to whether chemo-mechanotransduction or the hypothalamic–pituitary–gonadal axis is the dominant driving force for muscle hypertrophy per se, but also, age-related anabolic resistance3,4. To address this, two (hitherto unpublished) randomized placebo-controlled controls trials will also address: i) the impacts and mechanisms of suppressing endogenous testosterone production in young adults in relation to RET-induced muscle hypertrophy, and ii) the impact of exogenous testosterone provision on muscle hypertrophy adjuvant to RET in older people. This will provide insight into both the mechanisms of anabolic resistance, and the mechanistic control of muscle hypertrophy.

THE SYSTEMIC INFLAMMATORY ENVIRONMENT OF SKELETAL MUSCLE IN OLD AGE - INFLUENCE OF PHYSICAL ACTIVITY

KADI, F.

SCHOOL OF HEALTH SCIENCES

The functional status in elderly is greatly influenced by the gradual loss of skeletal muscle mass. The exact underlying biological mechanisms are not clearly understood. It is currently suggested that the occurrence of a state of low-grade chronic systemic inflammation in older adults (inflammaging) may contribute to age-related decline in muscle mass. Indeed, the proliferative capacity of myogenic cells can be influenced by chronic systemic Inflammation [1,2]. It is also currently suggested that regular physical activity may influence chronic systemic inflammation [3] and thereby prevent skeletal muscle mass loss. The present talk will highlight new aspects related to i) mechanistic links between elevated markers of inflammation and cellular and molecular aspects of skeletal muscle and ii) dose-response relationships between physical activity behaviour and different markers of chronic systemic inflammation.

INTRAMUSCULAR CONNECTIVE TISSUE - A NOVEL PLAYER IN MAINTAINING MUSCLE MASS AND FUNCTION?

WESSNER, B.

UNIVERSITY OF VIENNA

Intramuscular connective tissue (IMCT) plays an important role in the transmission of contractile force from active muscle fibres to aponeuroses and tendons, which might affect the overall capacity of skeletal muscles to generate force [1]. At older age, skeletal muscles typically demonstrate fibrotic morphology [2] with increased absolute collagen content and cross-linking of collagen fibres [3] potentially contributing to the age-associated loss in skeletal muscle function. Recently, we have shown tthat acute resistance exercise affects IMCT gene expression at least partly in an age-specific manner. Especially, the altered expression of genes encoding matrix metalloproteinases (MMP3, MMP9, MMP15) highlights the role of remodelling processes in the response to an acute bout of resistance exercise [4], but also chronic exercise [unpublished data]. The talk will summarize the current scientific knowledge in the potentially underestimated contribution of the IMCT to muscle force development with a special focus on ageing and the modifying role of resistance exercise.

OP-PM35 Interval training

CAN THE ADDITION OF SPRINT INTERVALS TO TRADITIONAL LOW-INTENSITY TRAINING MAINTAIN AEROBIC CAPACITY AND PERFORMANCE DURING THE POST-SEASON TRANSITIONAL PERIOD IN WELL-TRAINED CYCLISTS?

BYRKJEDAL, P.T.1, ALMQUIST, N.W.2, SANDBAKK, Ø.3, SPENCER, M.R.1, SKOVERENG, K.3, RØNNESTAD, B.R.2, KRISTOFFERSEN, M.4

1 UNIVERSITY OF AGDER, 2 INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES, 3 NTNU, 4 WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Traditionally, endurance athletes reduce their training load between the end of the competition season and the start of the preparatory period. This might result in a reduction in aerobic fitness [1]. However, sprint interval training (SIT) has been shown to maintain aerobic fitness levels even when reducing training volume up to ~60% in moderately trained athletes [2]. Thus, this study investigates whether well-trained cyclists benefit from adding SIT to low intensity training (LIT) during their off-season period compared LIT only.
METHODS: Well-trained cyclists participated in this study (n=16, age: 21.4±3.6 years, VO2max: 73.2±4.7 mL-1.min-1.kg-1). All cyclists completed a ~2.5-hour race simulation test (including a maximal incremental test and a 20-min all-out time trial) in the laboratory shortly after their last competitive race (72-96 hours). Thereafter, the subjects were divided in to a sprint group (SG) and a control group (CG) for a three-week intervention period. SG performed one session of SIT per week. SIT sessions consisted of 9x30s maximal sprints (4 min rest) performed in bouts of three. Each bout was separated by 20 min cycling at a power output (PO) corresponding to 60% of individual VO2peak. CG performed one session of LIT per week: 90 min at PO corresponding to 60% of their VO2peak. Both groups were instructed to reduce their weekly training load (TL) by 70%. TL was calculated using iTRIMP from the four weeks prior to the intervention. The cyclists were monitored and given feedback on a daily basis to ensure that TL reduction was adhered to.
RESULTS: There was a similar reduction in TL in both groups (CG: 63±11%; SG: 62±14%). No substantial difference was observed in mean PO for the 20-min time trial between groups (CG: -3±5%; SG: -1±8%; group difference: 0.7±4.5; Effect Size [ES]: 0.04±0.25). No substantial between group differences were evident in maximal PO (Wmax; maximal PO last 60s of maximal incremental test) CG: 0±6%; SG: 1±6%; group difference: 1.1±5.0; ES: 0.08±0.38), relative PO Wmax (CG: -1±5%; SG: 0.1 ± 5.5%; group difference: 1.1±4.7; ES: 0.16±0.67) and relative VO2max (CG: -1±4%; SG: -3±6%; group difference: -2.1±4.6; ES: -0.31±0.68) during the maximal incremental test.
CONCLUSION: The addition of one SIT session per week, integrated into traditional LIT training, had no substantial between group effects on typical endurance performance measures during the 20-min time trial and VO2max assessments. However, relatively large individual variations were evident suggesting that training response may be quite individual.

CURRENT METHODS TO INDIVIDUALISE EXERCISE INTENSITY ARE INAPPROPRIATE FOR EXHAUSTIVE INTERVAL TRAINING

BOSSI, A.H., HOPKER, J.G., PASSFIELD, L.

1 SCHOOL OF SPORT AND EXERCISE SCIENCES, UNIVERSITY OF KENT; 2 FACULTY OF KINESIOLOGY, UNIVERSITY OF CALGARY

INTRODUCTION: Traditionally, fractions of an individual's maximal oxygen uptake (s'O2max) have been used to express exercise intensity. This approach has nevertheless been criticised for eliciting unpredictable physiological responses when used for exercise prescription. Yet, no consensus has emerged as to the best method, particularly for high-intensity interval training (HIIT). We tested the hypothesis that a percentage of a 20-min time-trial (TT20) performance would be superior to other benchmarks in normalising acute training responses.
METHODS: Eighteen cyclists (age: 38 ± 11 years, E'O2max: 54 ± 9 ml·kg-1·min-1) performed an incremental 1'O2max test, two 3-min all-out tests and two TT20 to establish their physiological and performance benchmarks after a familiarisation (visits 1 and 2). Then, in randomised order (visits 3 to 6), participants performed HIIT sessions to exhaustion at:
1 – the work rate (t 1) at the gas exchange threshold () 'GET) + 70% of the difference between G'GET and G'ëO2max;
2 – 85% of the peak o ' in the incremental test;
3 – 120% of the mean o ' in the TT20;
4 – the t ' predicted to expend in 4 min 80% of the work capacity above critical power.
HIIT sessions consisted of 4-min work intervals interspersed with 2-min active recovery. Expired gas was continuously measured, with ratings of perceived exertion (RPE) and blood lactate concentration [La] obtained after each work interval and at exhaustion. Time at >90% and >95%á'O2max were calculated as a percentage of the time to exhaustion. The relationship between exercise intensity and time to exhaustion, changes in RPE, and [La] were modelled for each prescription method by multilevel analysis with participant as a random effect. To quantify the inter-individual variability in the dependent variables, intraclass correlation coefficients (ICCs) were estimated. Finally, inter-individual coefficients of variation (CVs) were calculated for time to exhaustion, and standard deviations (SDs) for time at >90% and >95%>'O2max.
RESULTS: Mean (CV) time to exhaustion was 1835 s (51.6%), 1423 s (59.0%), 1008 s (79.7%) and 1087 s (78.0%) for methods 1, 2, 3 and 4, respectively. Methods 1, 2, 3 and 4 produced respective SDs of 16%, 14%, 19% and 16% for time at >90%r'O2max; and 15%, 14%, 14% and 16% for time at >95%1'O2max. Methods 1, 2, 3 and 4 produced respective ICCs of 0.99, 0.56, 0.70 and 0.74 for time to exhaustion; 0.23, 0.50, 0.38 and 0.40 for RPE; and 0.64, 0.73, 0.67 and 0.59 for [La].
CONCLUSION: In contrast to our hypothesis, none of the benchmarks used to prescribe exercise intensity in this study produced a consistent acute training response between individuals. The ability to perform HIIT to exhaustion depends not only on the physiological responses during the work intervals, but also on their recovery kinetics during the active breaks—which may explain our findings. Scientists and coaches devising HIIT programmes should carefully weigh our results, as the intended stimulus for adaptation may not be accomplished.

EFFECTIVITY OF HIGH INTENSITY HIGH VOLUME TRAINING (HIHVT) VS CONTINUOUS TRAINING (CT) ?

WITTKE, T.C., EIGENDORF, J., FINKEL, A., MAASSEN, M., FRISCHE, M., SHUSHAKOV, V., MAASSEN, N.

HANNOVER MEDICAL SCHOOL

INTRODUCTION: In 2005 Frische and Maassen introduced a HIHVT-protocol with non-exhausting high intensity intervals, which was significantly more effective in improving endurance capacity (EC) compared to moderate-intensity CT (similar to HIIT). Moreover, with HIHVT recovery ability increased more without a loss of sprint ability. Since then, the pattern of the training was varied several times to increase efficiency. The results are as follows.
METHODS: We tested n=121 subjects. All tests were performed on a cycle ergometer (Lode Excalibur Sport). Study design: 1st week; Incremental Test (IT) to determine Aerobic Capacity (Pmax), Endurance Test to exhaustion with 80% of power reached in IT to determine Endurance Capacity (EC: time to exhaustion). Weeks 2-4 training 3 times per week; 5th week: repetition of the pre-tests. All trainings were performed at a mean mechanical intensity of 50% of Pmax beginning with a 10min warming up and ending with a cool down of 5min both at 50% Pmax. They differed in length (number of intervals I), power during duty cycle, time pattern of work and load- less cycling (LP). The tested protocols were: (30I/100%,LP/30s-30s), (45I/100%,LP/30s-30s); (55I/100%,LP/30s-30s), (90I/250%,LP/6s-24s) and one with increasing peak intensity accompanied by decreasing working time with 45 I (from 100%,LP/30s-30s to 150%,LP/20s-40s). Two groups with CT working at 50% Pmax for 60min and 70min served as controls. Additionally the effect of Nitrate (N) supplementation (45I/30s/30s) and Carbohydrate (CH) supplementation (55I/30s-30s) on the development of EC was investigated.
RESULTS: At the beginning mean relative maximal power of the 121 Subjects was 4.3Watt/kg +/- 0.74 with no significant differences between the groups. The mean EC was 825s +/- 277 and not different between the groups at the beginning, as well. Mean EC increased in the 2 CT-groups by 26.8% +/- 25.8 (n=19) with no significant difference between the groups. The 7 HIHVT-groups did not differ in the development of the EC (each increased EC by about 50%) independent of the number of intervals, the duration and the intensity of the exercise periods. The HIHVT-group enhanced EC by 46.1% +/- 40.1 (n=102). The difference between HIHVT and CT tended to be significant (p=0.05). CH-supplementation during training and N-supplementation during the whole training-period did not influence the augmentation. The increase in EC did not show a strong correlation to the increase in relative power neither in HIHVT (r^2=0.05) nor in CT (r^2=0.08).
CONCLUSION: Since the shortest HIHVT is as effective as the longest and even more effective than CT in enhancing EC and the respective duty cycles are not exhausting, HIHVT is a very suitable method to combine endurance training with game specific training. The weak correlation between the development of EC and Pmax hints to different limiting factors of both.

PHYSIOLOGICAL PROFILE OF 4-MIN AND 8-MIN SELF-PACED CYCLING INTERVALS: INFLUENCE OF WORK-TO-REST MANIPULATION

DE LUCAS, R.D., DALL' AGNOL, C., GUGLIELMO, L.G., TURNES, T.

FEDERAL UNIVERSITY OF SANTA CATARINA

INTRODUCTION: Despite the popular utilization of self-paced interval training sessions (IT), limited scientific data is available on the manipulation of work- and rest-interval durations on the physiological response, especially the percentage maintained in relation to the maximal aerobic power (VO2max). The effectiveness of long intervals, such as the above duration of 4-min have been related in the literature (Seiler et al., 2013; Sandbakk et al., 2013). The aim of this study was to analyse the influence of work- to rest- interval durations in self-paced IT (4-min and 8-min intervals) on the physiological responses. The comparison between VO2 and heart rate responses is a secondary aim of this study.
METHODS: Twelve cyclists (VO2max 55.7 ± 7.4 ml.kg-1.min-1) performed an incremental test and four IT sessions characterized by four repetitions of 4 min or 8 min and work:rest (W:R) ratios of 2:1 (i.e. 4x 4/2 and 4x 8/4 min) and 4:1 (i.e. 4x 4/1 and 4x 8/2 min). Tests were conducted on Computrainer ergometer using the cyclist's own bicycles. No feedback of the performance and physiological index were provided for athletes during the IT sessions. The power output, VO2 and HR were continuously measured and averaged for each interval. The blood lactate and rate of perceived exertion (RPE) were also measured at the end of each interval.
RESULTS: All the intervals performed were above the individual anaerobic threshold. The mean power output of IT sessions were: 261±27; 275±23; 236±23; 250±25 W for 4/1, 4/2, 8/2 and 8/4, respectively. Sessions using 4-min intervals elicited significantly greater average power outputs, regardless of the W:R ratio. The 4/2 session presented the highest percentage of VO2max (90.7 ± 5.0%), while the session 8/2 the lowest (83.0 ± 6.3%). The same behavior was observed for HR, the highest percentage was observed for 4/2 session (91.5 ± 3.3%), whilst the lowest was 88.9 ± 3.9% for session 8/2. Along the four repetitions, HR, blood lactate and RPE increased from the first to the last repetition for all interval protocols. Average blood lactate and HR were higher in sessions 4/2 and 4/1, with no difference in RPE among protocols (average 17 – Borg's scale).
CONCLUSION: Overall, this data suggests that the self-paced IT composed by repetitions of 4- and 8-min can elicit different percentages of VO2max, blood lactate concentration and HR, while similar RPE responses. Intervals of 4 min are preferable to maintain higher power output and the W:R of 2:1 must be prioritized to obtain higher intensities. This data can be useful for programming IT sessions within micro-cycles, aimed at different training loads.

PUTTING MORE HIT IN HIIT: ECCENTRIC CYCLING DURING THE RECOVERY PHASE

HARRISON, A.J., BURDON, C.A., GROELLER, H., PEOPLES, G.E.

UNIVERSITY OF WOLLONGONG

INTRODUCTION: High intensity interval training (HIIT) provokes significant enhancement in maximal aerobic power and mitochondrial biosynthesis similar to that observed in continuous endurance training(1). HIIT requires near-maximal bouts of exercise interspersed by obligatory lower intensity recovery periods (positive work). Yet, negative work (eccentric contraction) is characterised by significantly lower metabolic demand compared to positive work(2) and may be a viable substitute during periods of recovery to maintain external work. Therefore, this study sort to determine the effects of eccentric recovery within a single HIIT cycling protocol.
METHODS: Twelve (n=12) well-trained males participated in this study (age 28 y [standard deviation (SD) 6], mass 78 kg [SD 13], height 1.80 m [SD 0.09], peak aerobic power 48 mL.kg.min-1 [SD 6]). Participants complete two discontinuous high intensity interval cycling trials (4

bouts x 5 min at 60% VO2peak) on separate occasions (25°C, 35% RH). One of the discontinuous trials (CONR) required participants to cycle concentrically during each recovery for 5-min at a 30% VO2peak. In a balanced order, the alternate trial modified the recovery to be eccentric cycling at a workload equivalent to 60% VO2peak (ECCR). Workload, respiratory expired gas and heart rate were continuously collected. In addition, participants reported RPE, DOMS, task demands and trial preference.
RESULTS: High intensity cycling workload (CONR: 187 ± 17, ECCR: 187 ± 21 W), oxygen consumption (CONR: 2.55 ± 0.17, ECCR: 2.68 ± 0.20 L.min-1), heart rate (CONR: 165 ± 7, ECCR: 171 ± 10 b.min-1) and RPE legs (CONR: 15 ± 3, ECCR: 15 ± 3) were equivalent between trials. Modifying the recovery periods to eccentric cycling resulted in a significantly higher external workload (CONR: 93 ± 18, ECCR: 196 ± 24 W, P<0.01) yet lower oxygen consumption (CONR: 1.51 ± 0.18, ECCR: 1.2 ± 0.20 L.min-1, P<0.05) while heart rate (CONR: 132 ± 13, ECCR: 137 ± 12 b.min-1) and RPE legs (CONR: 11 ± 7, ECCR: 12 ± 7) remained equivalent. There was a higher mental demand in ECCR (65 ± 7%) and a worse perceived performance (36 ± 7%) when compared to CONR (mental demand; 39 ± 8%, perceived performance; 17 ± 3%, P<0.05) while DOMS was also significantly higher in ECCR (24hrs; 53 ± 10%, 48hrs; 45 ± 10%) versus CONR (24hrs; 20 ± 5%, 48hrs; 16 ± 5%, P<0.05). Participants preferred ECCR (10/12) and rated the ECCR as more achievable (82.8 ± 11.4 mm) than CONR (79.4 ± 15.9 mm, P<0.01).
CONCLUSION: Modifying the recovery periods of HIIT to eccentric cycling increased the overall work by 33% while maintaining the metabolic and cardiopulmonary profiles synonymous with high intensity intervals.

A MODERATE CAFFEINE DOSE INCREASES STRENGTH PERFORMANCE IN RESISTANCE-TRAINED FEMALES

RISVANG, L.1, NORUM, M.1, BJØRNSEN, T.2, DIMITRIOU, L.1, RØNNING, P.O.3, BJØRGEN, M.3, STADHEIM, H.K.4, RAASTAD, T.4

1 LONDON SPORTS INSTITUTE, MIDDLESEX UNIVERSITY, 2 UNIVERSITY OF AGDER, NORWAY, 3 OSLO METROPOLITAN UNIVERSITY, NORWAY, 4 NORWEGIAN SCHOOL OF SPORTS SCIENCE, NORWAY

INTRODUCTION: The effects of caffeine on strength performance have mainly been studied in male participants with caffeine doses of 5 and 6 mg·kg-1. Therefore, the aim of this study was to investigate the acute effects of 4 mg·kg-1 caffeine ingestion on markers of strength and power in resistance-trained females.
METHODS: In a randomized, double-blind, placebo-controlled, crossover design, 15 highly resistance-trained females (30.0±4.0 years, 63.8±5.5 kg) consumed a moderate caffeine dose (4 mg·kg-1) or placebo 60 minutes before completing a test battery. Both trials were completed during the early follicular phase. All participants completed the trials separated by 3 days and following two familiarisations to the test battery. One repetition maximum (1RM) and repetitions to failure at 60% of 1RM were assessed in the back squat and in the bench press. Maximal voluntary contraction and rate of force development were assessed in 90-degree isometric knee-extensions, while utilising the interpolated twitch technique to measure voluntary muscular activation. Their maximal power and jump height were assessed during countermovement jumps performed on a force plate. Blood samples were taken at 60 and 210 minutes after ingestion of either treatment to measure plasma caffeine concentration.
RESULTS: Caffeine significantly improved squat (+4.5±1.9%) and bench press (+3.3±1.4%) 1RM compared to placebo. Number of repetitions to failure performed in the squat (+15.9±17.9%) and in the bench press (+9.8±13.6%) were also significantly increased. Furthermore, maximal isometric strength, jump height and jump power were all improved (p<0.05). There were no significant differences in rate of force development and muscle activation. The plasma caffeine concentration did not change significantly from 60 minutes to 210 minutes following caffeine consumption.
CONCLUSION: This study demonstrates that a 4 mg·kg-1 dose of caffeine enhances maximal strength, power and muscular endurance in resistance-trained females. Female strength and power athletes may consider using a moderate caffeine dose before competition. This in turn may reduce the negative side effects that have been described previously with higher doses (Goldstein et al., 2010).

ACUTE PRE-EXERCISE CARNOSINE/ANSERINE SUPPLEMENTATION IMPROVES HUMAN MAXIMAL ISOMETRIC MUSCLE FORCE AND CYCLING POWER IN AN UNFATIGUED STATE

DE JAGER, S., BLANCQUAERT, L.1, BEX, T.1, LIEVENS, E.1, GILARDONI, E.2, REGAZZONI, L.2, ALDINI, G.2, DERAVE, W.1

1: GHENT UNIVERSITY 2: UNIVERSITY OF MILAN

INTRODUCTION: Carnosine, and its methylated analogue anserine, are histidine-containing dipeptides (HCD) and are known to have pH buffering and antioxidant properties. Human muscle carnosine levels can be increased with chronic β-alanine supplementation, which leads to enhanced high-intensity exercise performance (Baguet et al., 2010). Since these chronic loading protocols are slow, acute supplementation of HCD is currently investigated. Interestingly, our new preliminary data (Blancquaert et al. 2019) show that pre-exercise combined carnosine/anserine (each 20 mg/kg BW) supplementation can improve initial maximal Wingate power following 6 min of high-intensity cycling. The current aims were to explore 1) whether the ergogenic effect is more pronounced when fatigue is induced by repeating Wingate tests, 2) whether it can be related to known fatigue mechanisms and 3) what the optimal dosing of pre-exercise HCD intake is.
METHODS: Two placebo-controlled randomized crossover studies were conducted in 12 (study A) and 11 (study B) moderately-trained men. In study A, subjects ingested either 20 mg/kg BW of both carnosine and anserine or a placebo. Thirty min following ingestion, subjects performed 3 all-out Wingate cycling tests, interspersed by 4 min of rest. In study B, on 4 separate occasions, subjects performed

3 maximal voluntary isometric knee extension contractions (MVC) and 5 6s all-out cycling sprints before and 60 min after taking 0, 10, 20 or 30 mg/kg BW of both carnosine and anserine. Capillary blood samples were analysed for pH and HCO3- (Radiometer) and venous samples for glutathione status (HPLC) and plasma HCD (LC-MS/MS). Data were analysed using 2x2 and 2x4 repeated measures ANOVA.
RESULTS: In study A, HCD ingestion resulted in a 3% increase in average peak power of the 3 Wingates (10.5 ± 0.6 W/kg) compared to placebo (10.2 ± 9.9 W/kg) with no differences in power gain between the 3 Wingate tests (+3.96%; +1.83%; +4.06%). No differences were found in acid base or glutathione status. Study B demonstrated a clear dose-response effect of increasing HCD dose on plasma HCD concentrations. Likewise, a significant improvement in peak cycling power (p=0.013) and peak muscle torque (p=0.017) was found following the 30 mg/kg BW supplement dose ingestion, whereas the 20 mg dose only elicited a tendency for improved peak muscle torque (p=0.098) and the 10 mg dose did not elicit any ergogenic effects.
CONCLUSION: We document a novel pre-exercise nutritional supplement strategy that enhances maximal muscle and cycling exercise power in humans. The ergogenic effect seems unrelated to fatigue state, and can not be linked to alterations in acid base or antioxidant status. A clear dose-response relationship was established with the most convincing effects being obtained by oral ingestion of 30 mg/kg BW of both carnosine and anserine.

DOES PHOSPHOCREATINE PLAY A ROLE IN THE MENTAL FATIGUE-ASSOCIATED DECREASE IN SPORT-SPECIFIC PSYCHOMOTOR PERFORMANCE?

VAN CUTSEM, J., ROELANDS, B., PLUYM, B., TASSIGNON, B., VERSTRAELEN, M., DE PAUW, K., MEEUSEN, R.
VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Sport performance is determined by a combination of physiological and cognitive capacity. Recently the importance of the brain/cognitive capacity in sport performance has been further substantiated by research demonstrating the negative effect of mental fatigue (MF) on sport-specific psychomotor skills [1]. Creatine supplementation improves strength, but can also improve cognitive functioning [2]. To further explore creatine's role as a cognitive enhancer and unravel the mechanisms behind the MF-associated decrease in sport performance, the aim was to evaluate the role of phosphocreatine in the MF-associated impairments in cognitive performance and sport-specific psychomotor skills.
METHODS: In 23°C and 35% relative humidity, 14 healthy subjects (4F 10M; mean ± SD; age:24 ± 3 y; mass:74 ± 13 kg; height:179 ± 9 cm) performed - counterbalanced, crossover and double blinded - a 7-min sport-specific visuomotor task before and after a 90-min mentally fatiguing task (i.e. Stroop task) in two different conditions: after a 7-day creatine supplementation (CR; experimental; 20 g/day) and after a 7-day calcium lactate supplementation (PLAC; placebo), separated by a 5-week washout. In both conditions, a dynamic handgrip strength endurance task (12 maximal reps) and a 3-min Flanker task was performed before and after the mentally fatiguing task. Physiological and perceptual responses were measured throughout the protocol. Normality was checked, repeated measures ANOVAs were employed to observe interaction and/or main effects of condition and time. Follow up tests were performed where necessary ($p<0.05$).
RESULTS: Dynamic handgrip strength endurance was higher in CR compared to PLAC (last 3 reps/first 3 reps * 100: CR=84 ± 2%; PLAC=79.5 ± 1.9%; p=0.022, $\eta p2=0.344$), indicating the creatine supplementation protocol was successful. Elevated self-reported MF (+45/100; $p<0.001$, $\eta p2=0.713$) and decreased Flanker accuracy (-5.3%; p=0.012, $\eta p2=0.419$) after the mentally fatiguing task in both CR and PLAC supported MF was present in both conditions. MF impaired visuomotor response time by 4.3% (p=0.022, $\eta p2=0.343$) in both conditions. Overall accuracy on the mentally fatiguing task was higher in CR compared to PLAC (p=0.026, $\eta p2=0.348$). Motivation and vigour ($p\leq0.027$) were higher in PLAC compared to CR, while other perceptual variables, heart rate and glucose did not differ between conditions.
CONCLUSION: Creatine supplementation improved physical (strength endurance) and prolonged cognitive (Stroop accuracy) performance, yet it did not affect short sport-specific psychomotor or Flanker performance. From a practical point of view these results warrants further investigation in the potential role of creatine in countering the MF-associated decrements in prolonged (>7 min; e.g. 90-min soccer game) sport performance. From a mechanistic point of view the results suggest a possible role of brain-phosphocreatine in MF.

QUININE INGESTION DURING THE LATTER STAGES OF A 3 KM TT FAILS TO IMPROVE CYCLING PERFORMANCE

ETXEBARRIA, N., ROSS, M., CLARK, B., RATTRAY, B., GOECKE, R., BURKE, L.
UNIVERSITY OF CANBERRA

INTRODUCTION: Quinine ingestion has been shown to improve short-term (30 s) cycling performance1, but it is unclear whether ingesting it during the final 1 km of a 3 km time trial (TT), potentially enhancing the finishing stages, improves overall performance. We quantified the effects of quinine when ingested immediately prior to the last 1 km of a 3 km maximal cycling TT.
METHODS: Twelve well-trained male cyclists (mass 76.6 ± 9.2 kg; height 179 ± 9 cm; maximal aerobic power 390 ± 50 W; mean ± SD) performed a maximal incremental test, three 3 km familiarisation trials and four experimental 3 km TT over eight separate visits to the laboratory. This double-blind cross-over design included four experimental trials during which one of the following treatments was provided 150m prior to the 2 km point of the TT, in a randomised and counterbalanced manner: 1) 25 ml of water (Control), 2) a 25 ml sweet-tasting solution with no carbohydrate (artificial sweetener; Placebo) and 3) and 4) Quinine1 and Quinine2, replicate 25 ml solution with 2 mM of quinine. Each time trial was performed on a VelotronR cycle ergometer with participants blinded to all feedback other than distance covered, with an individualised but fixed gear for the experimental trials. Power output (W) was monitored continuously. Rating of perceived exertion (RPE, 6 to 20), blood lactate (BLa) and how they felt (Feeling scale, +5 to -5) were recorded at the end of each TT. Power output was analysed for every 150 m split and entire 1 km sections. Descriptive statistics are presented as mean ± SD and differences between the interventions are specified as standardised mean difference ± 90% confidence limits (CL).
RESULTS: There was no substantial effect of quinine on 3 km TT cycling performance. Power output for the last 1 km for all four conditions was similar: Quinine1, 360 ± 63 W; Quinine2, 367 ± 63 W; Placebo, 363 ± 64 W; and Control 367 ± 58 W. Subsequently, Quinine admin-

istration did not increase overall TT power output compared to the Placebo and Control conditions (0.06-0.16 ±0.09), range of standardised differences ±90% CL). The overall times for all conditions were between 3:58.5 and 4:01.3 (min:s). The small differences between trials at specific 150m splits were not explained by quinine intake compared to control or the placebo trials. There were no substantial differences on the Feeling scale, RPE and end BLa between conditions.
CONCLUSION: Although we have previously shown that the ingestion of Quinine immediately prior to the start of a 3 km cycling TT achieves a short-lived improvement in cycling power output, in the current study, when Quinine was ingested after 2 km of effort, we failed to detect a subsequent effect on cycling power. It appears that ingesting 2mM of quinine during the last stage of a 3 km TT does not improve cycling performance and has little effect on physiological and perceptual responses.

ENHANCEMENT OF EXERCISE PERFORMANCE BY 48 HOURS, AND 15-DAY SUPPLEMENTATION WITH MANGIFERIN AND LUTEOLIN IN MEN

GELABERT-REBATO, M.1,2, WIEBE, J.C.2, MARTIN-RINCON, M.1, GALVAN-ALVAREZ, V.1, CURTELIN, D.1, PEREZ-VALERA, M.1, JUAN HABIB, J.1, PÉREZ-LÓPEZ, A.1,3, VEGA, T.2, MORALES-ALAMO, D.1, CALBET, J.A.L.1
1 UNIVERSITY OF LAS PALMAS DE GRAN CANARIA; 2 NEKTIUM PHARMA; 3 UNIVERSITY OF ALCALÁ

INTRODUCTION: The natural polyphenols mangiferin and luteolin have free radical-scavenging properties, induce the antioxidant gene program and down-regulate the expression of superoxide-producing enzymes. We have previously shown that these two polyphenols enhance sprint performance when administered every 8 h for the 48 h preceding the exercise (Gelabert-Rebato et al., 2018). However, the effects of these two polyphenols on exercise performance after prolonged supplementation remain unknown. Therefore, this study aimed at determining the acute and prolonged effects of oral supplementation with mangiferin and luteolin botanical extracts on exercise performance, muscle metabolism, and brain and muscle oxygenation in healthy young men. Given the fact that these two polyphenols may have ergogenic effects through several mechanisms, a specific exercise protocol was designed, including phases of low-intensity, high-intensity and repeated sprinting exercise combined with ischemia-reperfusion episodes.
METHODS: A combination of luteolin (peanut husk extract containing 95% luteolin, PHE) and mangiferin (mango leave extract (MLE), Zynamite®) at low (PHE: 50mg/day; and 140mg/day of MLE containing 100 mg of mangiferin; L) and high doses (PHE: 100mg/day; MLE: 420mg/day; H) was administered to twelve physically active men. Subjects performed incremental exercise to exhaustion, followed by sprint and endurance exercise, dosed every 8 h, 48 h (acute effects) and 15 days of supplementation (prolonged effects) with polyphenols or placebo, following a double-blind crossover design.
RESULTS: During sprint exercise, mangiferin+luteolin supplementation enhanced exercise performance, facilitated muscle oxygen extraction and improved brain oxygenation, without increasing the VO2. Compared to placebo, mangiferin+luteolin increased muscle O2 extraction during post-exercise ischemia, and improved sprint performance after ischemia-reperfusion likely by increasing glycolytic energy production, as reflected by higher blood lactate concentrations after the sprints. Similar responses were elicited by the two doses tested.
CONCLUSION: Supplementation with the combination of two botanical extracts of mangiferin and luteolin enhances exercise sprint performance, likely by improving brain oxygenation and allowing a higher muscle extraction of oxygen. These effects were observed following 48 h and 15 days of supplementation without significant differences between the two doses tested.

OP-PM37 Fatigue

DETERMINANTS OF TASK AND CONTRACTILE FAILURES DURING THE REPETITION OF SUSTAINED SUBMAXIMAL ISOMETRIC CONTRACTIONS

HUREAU, T.J.1,2, DUCROCQ, G.P.2, BLAIN, G.M.2
1:UNIVERSITY OF STRASBOURG, 2: UNIVERSITÉ CÔTE DAZUR

INTRODUCTION: Previous studies demonstrated that power output and muscle activation are adjusted by the central nervous system (CNS) during cycling exercise to limit the development of peripheral fatigue to an individual and task-specific critical threshold (1). However, this mechanism may not be involved in task failure of sustained isometric contractions, which might rather be determined by a deficit in muscle activation (2). Using an experimental intervention designed to potentially cause the subjects to voluntarily surpass the peripheral fatigue threshold (i.e. fatigue more), we aimed to determine whether peripheral fatigue is restrained to a critical threshold and determines time to task failure during the repetition of sustained submaximal isometric contractions involving large muscle mass.
METHODS: Seventeen healthy participants performed five sustained isometric squats until task failure interspersed with 5 min of passive recovery in between. Participants supported a barbell loaded with 50 % of individual body mass on their shoulders while maintaining their knees flexed at 90° until failure. Using supramaximal electrical femoral nerve stimulation, peripheral and central fatigue were quantified via pre- to post-exercise changes in quadriceps twitch force (Qtw) and voluntary activation (VA), respectively. To estimate quadriceps muscle activation during exercise, EMG root mean square (RMS) was normalized to the RMS recorded during pre-exercise maximal voluntary contractions (MVC) of the quadriceps (RMS%MVC).
RESULTS: Time to task failure was significantly ($P < 0.05$) reduced by 29 ± 13 % from the first (90 ± 7 s) to the second (61 ± 4 s) trial and by 11 ± 8 % from the second to the third (54± 3 s) trial, and stabilized thereafter (~50 ± 3 s, $P > 0.7$). At task failure during the first trial, quadriceps RMS%MVC only achieved 85 ± 4 % of pre-exercise values suggesting muscle activation failure from the CNS. In parallel, twitch force (– 42 ± 4 %) and VA (– 7 ± 2 %) were significantly reduced compared to baseline. During subsequent trials, gradual increases in the rate of rise in RMS%MVC and peak RMS% MVC ($P <0.05$) were found in parallel with gradual exercise-induced reductions in Qtw (– 53 ± 3 %) and VA (– 14 ± 3 %) up to the third trial, with no further change thereafter.

CONCLUSION: These findings indicate that task failure during one sustained submaximal isometric squat occurs prior the attainment of a peripheral fatigue threshold and is associated with the subject's inability to fully activate his/her contracting muscles. However, if additional trials are performed, the rate of motor output recruitment increases more rapidly as the exercise progresses and task failure coincides with a maximal impairment of the excitation-contraction coupling of the contracting muscles.

ALTERATIONS OF MUSCLE RECRUITMENT STRATEGIES AT THE SINGLE MOTOR UNIT LEVEL IN THE FATIGUED AND DAMAGED STATE FOLLOWING ECCENTRIC EXERCISE

PIASECKI, M., MCPHEE, J.S.
UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Bouts of resistance exercise involving eccentric contractions with muscle lengthening under high tension induces acute fatigue and muscle damage (1). Exercise induced muscle damage (EIMD) can lead to delayed onset of muscle soreness (DOMS) and impaired neuromuscular performance lasting several days. Although neural mechanisms are known to contribute to impaired performance (2), it is unclear how individual motor units (MUs) respond, as the majority of available data is based on surface electromyography (EMG) and provides little detail at the single MU level. The current study aimed to investigate alterations in MU structure and function following muscle fatigue and damage.
METHODS: Fourteen participants (5 male) aged 18-37 years performed intense eccentric elbow flexor exercise consisting of eight sets of 10 repetitions using a load equivalent to 80% of the concentric elbow flexion maximum curl. Each repetition lasted 2-3 seconds. Neuromuscular assessments were performed prior to, immediately post-, and 48 hours post-intervention. Needle electrodes were used to sample single MUs from biceps bracii (BB) at 25% of maximum voluntary contraction. MU size was determined by the area of the MU potential (MUP) and neuromuscular transmission stability was assessed by near fibre (NF) jiggle as the variability in shape of consecutive occurrences of the same MUP. Firing rate was determined by the number of consecutive occurrences of the same MUP per second (Hz). The non-exercised elbow flexors of the contralateral arm was used as a control and tested at baseline and 48 hours later.
RESULTS: Maximal voluntary contraction decreased by 36% and 25% immediately after and 48 hours post eccentric exercise, respectively ($p<0.001$), with no change in the control arm ($p=0.78$). Motor unit size differed across the three timepoints ($p<0.001$), with pairwise comparisons showing no difference pre and immediately post exercise, but was 31% smaller 48hrs post intervention when compared to baseline ($p=0.001$). There was no difference across the timepoints in NF jiggle ($p=0.461$) and firing rate ($p=0.182$). In the control arm there were no differences between baseline and 48hr follow-up in MU size ($p=0.649$), NF jiggle ($p=0.713$) or firing rate ($p=0.089$).
CONCLUSION: Other than a reduction in muscle force there were no observable effects of eccentric-contraction induced fatigue at the single MU level. However, EIMD caused a large decrease in MU size. This is indicative of i) recruitment of an entirely different pool of MU to achieve the given force in damaged compared with fresh muscle, and/or ii) the same pool of MUs were active in fresh and in damaged muscle, but some damaged fibres were incapable of excitation-contraction coupling.

NEUROMUSCULAR FATIGUE IN ELBOW FLEXORS VS. KNEE EXTENSORS AFTER ARM-CRANKING AND CYCLING EXERCISES

COLOSIO, M., RASICA, L., BALDASSARRE, G., BIANCHI, G.A.D., VERNILLO, G., MARZORATI, M., PORCELLI, S.
INSTITUTE OF MOLECULAR BIOIMAGING AND PHYSIOLOGY

INTRODUCTION: Neuromuscular fatigue is defined as a reversible, time-dependent decline in the maximal force-generating capacity of a muscle originating at both central and/or peripheral levels. Previous data inferred from sustained isometric contractions suggest that elbow flexors (EF) and knee extensors (KE) present different magnitudes of global, central and peripheral fatigue. During dynamic exercises, contribution of these components may vary according to different muscle perturbations coming from lower motor-unit discharge rate, even at high intensity, and a recovery period among contractions. The aim of this study was to evaluate the contribution of central and peripheral factors to neuromuscular fatigue in EF vs. KE after arm-cranking and cycling exercises.
METHODS: Eleven physically active men (age: 23.8±2.4ys) participated in the study and performed in a pseudo-randomised and counterbalanced order two incremental exercises (INCR) until exhaustion on either a cycle- (CYCLE) or an arm- (ARM) ergometer. During INCR, breath-by-breath pulmonary oxygen uptake ($V'O_2$) and heart rate (HR) were evaluated. Neuromuscular function of KE (quadriceps muscle) and EF (biceps brachii) was assessed before (PRE), 2 min (POST) and 20 min (POST20) after INCR cessation during maximal voluntary contractions and in relaxed muscles. Global fatigue was assessed from maximal isometric force (MVF) during maximal voluntary contractions. To quantify central fatigue, voluntary activation (VA) levels were determined by the adapted twitch interpolation technique. To identify peripheral fatigue, high- (100 Hz, Db100), low- (10 Hz, Db10) frequency doublets and single twitches (Tw) were delivered to the relaxed muscle. The presence of low-frequency fatigue (LFF) was evaluated from the change in the Db10/Db100 ratio. Surface electromyography sensors were placed in correspondence of the vastus medialis, vastus lateralis, and rectus femoris or biceps brachii.
RESULTS: At the end of INCR, time to exhaustion was not different between CYCLE and ARM (802±93 vs. 886±164 s, $p<0.01$). $V'O_2$ was higher in CYCLE than ARM (3.41±0.50 vs. 2.47±0.60 L*min-1, $p<0.001$). At POST, MVF decreased after both CYCLE (21±13%) and ARM (26±7%). At POST20, MVF recovered to resting values in KE (-4% of PRE) while it partially recovered in EF (-17% of PRE). VA was not different in all conditions for both KE and EF. At POST, Db100 (-30%) and LFF (-28%) were significantly reduced in both KE and EF ($p<0.01$). At POST20, Db100 partially recovered (-15% of PRE) in both KE and EF while LFF did not significantly recovered in EF.
CONCLUSION: The present results suggest that neuromuscular fatigue of knee extensors and elbow flexors after incremental exercise mainly originates at peripheral level, with peripheral fatigue still presents in elbow flexors after 20 min of recovery. Thus, recovery from dynamic exercises involving lower or upper limbs should take into account the higher contribution of peripheral factors on muscle fatigue in elbow flexors.

THE EFFECT OF TRANSCRANIAL DIRECT CURRENT STIMULATION ON CYCLING PERFORMANCE AND THE MODULATION OF EXERCISE-INDUCED PAIN.

JUDGE, M., HOPKER, J.G., MAUGER, A.R.

UNIVERSITY OF KENT

INTRODUCTION: Transcranial direct current stimulation (tDCS) is a non-invasive neuromodulatory tool proposed to be able to enhance endurance performance. Although poorly understood, the underlying mechanisms of tDCS are thought to be associated with a reduction in fatigue related perceptions, including exercise-induced pain (EIP). The aim of this study was to investigate whether the application of tDCS to the left dorsolateral prefrontal cortex (DLPFC) could (1) reduce the perception of EIP during a fixed intensity cycling trial, and (2) improve performance in a cycling time trial.
METHODS: To account for the potential differences in electrode montage, this study comprised of two parts (Part A and Part B). In both A and B, participants completed a 10 min fixed intensity cycling trial at 75% of their peak power output and a 15 min time trial on three separate occasions following 10 minutes of 2 mA tDCS applied to either the DLPFC, a SHAM stimulation or a no stimulation control (CON). In Part A, 11 recreationally active participants received tDCS using a bilateral montage of electrodes, where the anodal and cathodal electrode were placed over the left and right DLPFC respectively. In Part B, 19 recreationally active participants received tDCS using an extracephalic montage where the anode was placed over the left DLPFC and the cathode placed on the ipsilateral shoulder. Changes in pain intensity and heart rate were recorded at the end of every minute for both cycling trials. Power output was also monitored continuously throughout the time trial.
RESULTS: In the fixed intensity cycling trial, there was no significant differences in pain intensity between the tDCS, SHAM and CON conditions in Part A (tDCS: 4.8 ± 2.1, SHAM: 4.4 ± 2.0 CON: 4.3 ± 1.5) or Part B (tDCS: 4.3 ± 2.1, SHAM: 4.6 ± 1.9, CON: 4.3 ± 2.0) (P's > 0.417). In the self-paced TT there was no significant difference observed in distance covered between conditions in either Part A (tDCS: 8.00 ± 0.56 km, SHAM: 7.98 ± 0.57 km, CON: 7.93 ± 0.59 km, P = 0.478) or Part B (tDCS: 7.98 ± 0.92 km, SHAM: 7.85 ± 1.08 km, CON: 7.91 ± 1.03 km, P = 0.179). Additionally there was also no significant differences in work completed, average power output or pain intensity observed in Part A or B (P's >0.137).
CONCLUSION: A 10 minute application of 2 mA tDCS to the DLPFC using either a bilateral or extracephalic montage of electrodes, did not exert an analgesic effect during exercise. Furthermore, this did not elicit any changes in performance during a self-paced time trial.

CHARACTERIZING THE PLASMA METABOLOME DURING AND FOLLOWING A MAXIMAL EXERCISE CYCLING TEST

FAIRCHILD, T.J., MANAF, F.A., LAWLER, N.G., PEIFFER, J.J., MAKER, G.L., BOYCE, M., BROADHURST, D.

MURDOCH UNIVERSITY

INTRODUCTION: The mechanisms associated with exercise-induced fatigue are complex by nature. As a consequence to the sudden increase in muscle metabolism and the associated change in the plasma metabolic milieu, a number of plasma metabolites have been associated with heralding onset of fatigue. This study sought to identify changes in the plasma metabolome at pre-defined time-points throughout exhaustive cycle-exercise and identify candidate-metabolites associated with the onset of fatigue.
METHODS: Eighteen healthy men (mean±SD age: 24.7±4.8 years; mass 67.1±6.1 kg; BMI: 22.8±2.2; VO2peak: 40.9±6.1 ml.kg.min-1) were recruited to this study. Participants performed a prolonged cycling Time-To-Exhaustion (TTE) test at an intensity corresponding to a fixed blood lactate concentration (3 mmol.L-1). Plasma samples collected at 10 min of exercise, prior to fatigue (last sample prior to fatigue; <10 min prior to fatigue), immediately post-fatigue (point of exhaustion) and 20 min post-fatigue were assessed using a liquid chromatography–mass spectrometry based metabolomic approach.
RESULTS: Eighty metabolites were putatively identified, with 68 metabolites demonstrating a significant change during the cycling task (duration: ~80.9±13.6 min). A clear multivariate structure in the data was revealed, with the first principal component (36% total variance) describing a continuous increase in metabolite concentration throughout the TTE trial; while the second principal component (14% total variance) showed an increase in metabolite concentration followed by a recovery trajectory, peaking at the point of fatigue. Six clusters of correlated metabolites demonstrating unique metabolite trajectories were identified. Free-fatty acids (n=15 metabolites; All p<.001) comprised one cluster demonstrating a significant increase between the pre-fatigue and post-fatigue time-points, while an associated increase in tryptophan and 5-methoxy-3-indoleacetic acid was concurrently identified (both p<.001).
CONCLUSION: In accordance with our hypothesis, free-fatty acids and tryptophan contributed to differences in the plasma metabolome at fatigue. The implication of tryptophan in the onset of fatigue were further strengthened by increases in 5-methoxy-3-indoleacetic acid, the end product of serotonin catabolism. Additional associations between fatigue and metabolites of catecholamine degradation (i.e., Homovanillic acid, HVA) were also identified in the current study. While direct relevance to fatigue-onset in the sporting context are presented, the metabolites identified herein such as HVA may also contribute to the fatigue experienced by patients in the clinical setting.

DISSOCIATION BETWEEN PERCEPTION OF EFFORT AND MUSCLE PAIN DURING CYCLING EXERCISE

CLOS, P.1, LEPERS, R.1, LAROCHE, D.1,2, PAGEAUX, B.3,4

1: UNIVERSITY OF BURGUNDY; 2: INSERM CIC 1432, PLATEFORME D'INVESTIGATION TECHNOLOGIQUE, UNIVERSITY HOSPITAL OF DIJON; 3: EKSAP, UNIVERSITÉ DE MONTRÉAL; 4: CRIUGM, MONTRÉAL

INTRODUCTION: As muscle pain and effort are two exercise-related sensations involved in the regulation of endurance performance [1, 2], it is crucial to test the ability of humans to dissociate these two perceptions during physical exercise [3]. This study aimed to test the dissociation between perception of effort (PE) and muscle pain during cycling exercise. We hypothesized that 1) the intensity of the two perceptions would differ at given workloads; 2) changes in ratings of PE and muscle pain in response to changes in workloads would be dissociated; 3) this dissociation would still be apparent in the presence of fatigue induced by physical exercise.
METHODS: Twenty-two subjects visited the laboratory thrice. In the first visit, subjects performed an incremental test to exhaustion to determine their cycling peak power output (PO). In visits 2 and 3 (randomized order), subjects performed twice four 1 min cycling bouts at 4 workloads (40, 60, 80, 100% peak PO) interspaced by either 15 min of rest, or a time to exhaustion test (TTE) at 80% peak PO to induce fatigue. The intensity of PE and quadriceps muscle pain was assessed with the Borg CR100 scale [4].
RESULTS: During the incremental test, PE was higher than muscle pain (+8.6 ± 14.6 a.u., P < 0.001). Changes in rating of PE and muscle pain in response to changes in workload were dissociated only for PO below 50% peak PO (P < 0.001).
During the 1-min cycling bouts, PE was higher than muscle pain (+13.2 ± 16.5 a.u., P < 0.001) and changes in ratings of PE and muscle pain in response to changes in workloads were dissociated (P < 0.001).

Following the cycling TTE (9.49 ± 1.78 min), blood lactate concentration increased to 13.6 ± 3.6 mmol/L, and knee extensor force production capacity decreased by 12 ± 14%. Following completion of the TTE, i) the intensity of PE and muscle pain increased (+8.2 ± 11.3 a.upoints and +10.3 ± 11.3 a.u., P<0.001), ii) PE remained higher than muscle pain (+10.7 ± 17.6 points, P < 0.001), and iii) changes in rating of PE and muscle pain in response to changes in workload were not dissociated anymore (P=0.786).
CONCLUSION: Along with previous results [1-3], our study confirms the ability of dissociating PE from muscle pain during cycling exercise. However, we observed that changes in ratings of PE and muscle pain in response to changes in workloads did not differ in the presence of fatigue induced by physical exercise. Future studies using a multidisciplinary approach should elucidate the neurophysiological mechanisms explaining the non-dissociation of changes in ratings of PE and muscle pain in response to changes in workloads, in the presence of fatigue induced by physical exercise.

EFFECT OF POSTURE ON DIFFERENT INDEXES USED TO ASSESS THE AERODYNAMIC DRAG FORCES ACTING ON RECREATIONAL ROAD CYCLISTS

POLANCO, A.1, FUENTES, J.2, MUNOZ, L.2, SUAREZ, D.1

1. PONTIFICIA UNIVERSIDAD JAVERIANA, 2. UNIVERSIDAD DE LOS ANDES

INTRODUCTION: The study of the aerodynamics of cyclists with reduced models has represented the drag dependence on the geometry with the drag area (CdA). The drag area is the product of the drag coefficient (Cd) and the projected frontal area (A). These parameters have been studied mainly for competitive cyclists (e.g., 1, 2). This study analyzes the variation of the drag parameters in recreational road cyclists when their posture is varied.
METHODS: Three recreational road cyclists participated in the study (two males, one female, 25.3±5.1 years, height 172±13 cm, BMI 24.4±2.9). Three postures were assessed; those were defined according to the grip position of the hands: tops, hoods, and drops. The projected frontal area was measured taking five pictures for each posture and processing them digitally. The drag area was identified using an on-road procedure (3). The road tests were performed with speeds in the [5.5, 10]m/s range. The drag coefficient was computed dividing the drag area by the projected frontal area. The uncertainty was evaluated using a Monte Carlo method.
RESULTS: The tendency of the indexes obtained for the three cyclists was similar. The absolute values of CdA and Cd decreased as the position changed in the following order: tops, hoods, drops. On the other hand, the highest value of A was observed in the intermediate posture: hoods. The indexes were normalized respect to the values of tops posture. The normalized indexes showed a progressive reduction of CdA and Cd on hoods and drops postures respect to tops. The reduction of CdA respect to tops was 3.0% (p=0.025) on hoods and 9.7% (p=0.016) on drops. Similarly, Cd was reduced 7.5% (p=0.024) on hoods and 8.3% (p=0.020) on drops. No statistically significative differences were found for A between postures.
CONCLUSION: The results indicate that the variation of the posture of recreational road cyclists has a significative effect on the drag area and the drag coefficient but not on the projected frontal area, in agreement with previous results reported for competitive cyclists. A high variation in the area was found compared with the other parameters under study. This behavior could be originated by a larger variation of the neck and arms position of recreative cyclists.

CONCURRENT VALIDITY OF DEAD CENTER IDENTIFICATION DURING PEDALING MOTION BASED ON INERTIAL MEASUREMENT UNITS PLACED ON LOWER LIMBS.

CORDILLET, S., BIDEAU, N., BIDEAU, B., NICOLAS, G.

UNIV RENNES

INTRODUCTION: In-field detection of pedaling cycles is crucial for analyzing outdoor cycling biomechanics. In this context, inertial measurement units (IMUs) that are currently used for estimating joint kinematics [1], have also the potential for minimally-invasive detection of top/bottom dead centers (TDC/BDC). Our study presents new methods to detect TDC/BDC using IMUs placed on the lower limbs during a pedaling task. Accuracy of the presented methods is calculated in comparison to optoelectronic motion capture (MOCAP).
METHODS: Nine cyclists and triathletes pedaled during 6' at 80 rpm at an intensity of 65% of heart rate reserve. Subjects pedaled on an ergometer and were equipped with three IMUs (Cometa WaveTrack) placed on thigh, shank and foot. Each IMU is composed of a 3D accelerometer and a 3D gyroscope. An optoelectronic MOCAP system was used to compute crank angles based on two markers placed on drive axis and pedal axis of rotation. Both IMUs and optoelectronic systems were synchronized and recorded 3D markers positions at 120 Hz and IMU data at 256 Hz. For each subject, a functional calibration enabled to correct misalignment between body segment frame and sensor frame. Linear accelerations along body-segment antero-posterior and longitudinal axes as well as angular rates around mediolateral axis were used to detect TDC and BDC. 13 methods of detection were designed. Each method was defined from a selected body-segment, a source of measurement (selected component of linear acceleration or medio-lateral component of angular rate) and one time-event detection method (zero-crossing or min/max). Time shifts between dead centers estimated by IMU-based method and those obtained by optoelectronic system were expressed in percent of cycle duration.
RESULTS: Among the thirteen methods, five of them revealed mean errors, expressed as absolute values, lower than 2.5% but only two methods presented in addition a standard deviation between subjects lower than 1.5%. Whereas the first method used accelerometer

measurement along antero-posterior axis of shank and showed an accuracy of 0.2(1.3)%, the second one was based on angular velocity around medio-lateral axis of thigh and presented a similar error of 0.2(0.9)%. Performances in terms of percentages of dead centers detections were 98.0% for the first method and 99.9% for the second one.
CONCLUSION: Our study showed that based on IMU recordings, medio-lateral angular rate of the thigh is a relevant parameter to detect dead centers with a high accuracy. This work provides insights into cycle-to-cycle joint kinematics based on IMUs placed only on the cyclist's lower limbs.

SYSTEM IDENTIFICATION OF A MATHEMATICAL MODEL TO PREDICT CYCLING POWER AS PART OF A PACING CONTROL SYSTEM

MAYERHOFER, P., JENSEN, M., CLARKE, D., WAKELING, J., DONELAN, M.
SIMON FRASER UNIVERSITY

INTRODUCTION: Our long-term goal is to maximize athlete performance by tightly regulating pacing using closed-loop feedback control. A closed-loop controller seeks to minimize the error between the desired and actual performance variable (e.g. running speed or cycling power) by adjusting another variable in the system (e.g. commanded cadence). We hypothesize that this tight regulation of pacing will improve performance by preventing athletes from exceeding or wasting their energy capabilities. Our lab recently demonstrated that effective closed-loop control of running speed can be accomplished through the real-time adjustment of commanded step frequency (1). Here we seek to control mechanical power output in outdoor cycling enabling athletes to quickly reach, and tightly maintain, target powers. Our first step in the design of this closed-loop controller is to identify a dynamic model of the relationship between commanded cadence and mechanical power.
METHODS: Our participants cycle for 16 minutes on an outdoor bike while a metronome commands step changes in cadence. These steps are ±7.5% of their preferred cadence for 60 seconds each. A microcontroller (Teensy 3.1, PJRC) controls the metronome frequency of the participant's earphones, reads torque and angular velocity from an SRM powermeter (Dura-Ace, SRM GmbH), and calculates the measured mechanical power. We treat participants as dynamic systems that can be identified by providing controlled inputs (commanded cadence) and measuring dynamic output (measured power). We derive a model from first principles in which power is a function of speed and acceleration, and speed is a function of cadence and gear ratio. We then use non-linear optimization to identify the single unknown parameter, drag, that best fits the predicted power to the measured power (2).
RESULTS: A simple parameterized point-mass model of athlete and bike, driven forward by the athlete's force, and backward by air resistance, accurately simulates the dynamic changes in mechanical power. It captures 82% of the variance in the measured power during the step change protocol with an optimized drag parameter of 0.3. Literature wind-tunnel tests find values between 0.15 and 0.24 depending on the magnitude of the reference area of the athlete, the air density, and the drag coefficient (3). We expected our value to be slightly larger as our drag parameter partially subsumes unmodeled losses, such as rolling resistance.
CONCLUSION: Towards our long-term goal, we will next leverage this model to design and test a responsive and accurate closed-loop feedback system to control power in cycling. This will provide athletesor their coacheswith stroke by stroke control over their power through more precise pacing and optimal energy consumption.

RELIABILITY AND VALIDITY OF THE 3-MINUTES ALL-OUT TEST IN FLAT-WATER KAYAKERS

PILOTTO, A.M., RASICA, L., MANFERDELLI, G., LAVARDA, M., ALIPRANDI, D., BAGLIONI, A., PORCELLI, S.
INSTITUTE OF MOLECULAR BIOIMAGING AND PHYSIOLOGY

INTRODUCTION: Critical speed (CS) represents the highest rate of oxidative metabolism that can be sustained without a progressively increasing contribution to energy turnover derived from phosphocreatine and glycogen phosphorylation. This parameter, together with the distance that can be covered principally by anaerobic processes (D'), is a useful tool to monitor performance and training-induced changes and could be a meaningful parameter for optimizing training and performance processes. Originally, testing protocols for the determination of CS and D' required the achievement of 3 to 5 time-to-exhaustion. However, performing multiple tests is time-consuming and a single exercise bout, 3-minutes all-out test, has been proposed as valid alternative approach to estimate CS and D' in several sport activities. The aim of this study was to determine reliability and validity of the 3-minutes all-out test in flat-water kayakers.
METHODS: Ten junior (17±2 years) élite flat-water kayakers participated in the study. Each subject performed an incremental cardiopulmonary test (CPT) up to voluntary exhaustion on a stationary kayak ergometer to determine peak oxygen uptake (V'O2peak). Then, the following on-water tests were performed along a straight course with designated lanes: i) five time trial (TT) on different distances (100m; 200m; 500m; 800m; 1000m); ii) two repetitions of 3-minutes all-out test (3MT). Global positioning system device monitored speed at a sampling rate of 10Hz. The speed–1/time model was used to determine CS(TT) and D'(TT) from 5 TTs. CS(3MT) and D'(3MT) were determined as the mean speed in the final 30s of 3MT and as the speed–time integral above CS, respectively.
RESULTS: During CPT, V'O2peak was 3.361±0.48 L*min-1 (range 38.8-56.2 ml*min-1*kg-1) and peak HR was 193±8 b*min-1 (98% of predicted maximal HR). Speed of TT was 4.77±0.60, 4.62±0.32, 4.24±0.26, 4.07±0.25, and 3.94±0.31 m*s-1 in 100m, 200m, 500m, 800m, and 1000m, respectively. CS(TT) was 3.70±0.22 m*s-1 and a D'(TT) was 27.1±11.3 m. There were no significant differences in CS(3MT) between the two 3MT trials (3.55±0.26 m*s-1 and 3.60±0.36 m*s-1; P=0.13). There was a nearly perfect and significant positive ICC in CS between two 3MT trials (r=0.92; P<0.0001). Similarly, there were no significant differences in D' between two 3MT trials (39.8±16.4 m and 32.6±12.3 m; P=0.21). There was a very large and significant positive ICC in D' between two 3MT trials (r=0.85; P=0.001). Mean bias between CS(3MT) and CS(TT) was 0.16±0.07 m*s−1 and between D'(3MT) and D'(TT) was -11.6±18.0 m.
CONCLUSION: This study demonstrate that the 3-minutes all-out test performed on-water is a valid and reliable test for the estimation of CS and D' in flat-water kayakers. Consequently, 3MT is a useful method to evaluate athletes' fitness level and monitor training-induced adaptations over time. Furthermore, coaches can utilize this test in order to set more accurately training intensities.

EFFECTS OF PARAMETER DEFINITION FOR PERFORMANCE PREDICTION DURING 4-KM CYCLING TIME TRIALS

BELTRAMI, F.G., OYEWALE, M., SPENGLER, C.M.

ETH ZURICH

INTRODUCTION: Performance in endurance events can be described as a function of maximal oxygen uptake (VO2max), the fraction of VO2max that can be sustained (%VO2max) and metabolic efficiency, where the %VO2max is commonly estimated by the lactate (LT) or ventilatory thresholds (VT). Given the lack of agreement on how to ideally define each of these parameters, the aim of this study was to investigate the independent relationship between different definitions of VO2max, VTs or LTs and metabolic efficiency with performance. Furthermore, the complex interplay between them was investigated by computing a model to predict cycling performance in a 40-km time trial (TT).
METHODS: Following familiarization trials, 13 trained cyclists and triathletes (8 males, VO2max: 57.0±3.3 ml·min-1·kg-1; 5 females, VO2max: 46.4±3.7 ml·min-1·kg-1) performed on different visits an incremental cycling test and a 40-km TT, which was preceded by a standardized warm-up. VO2max was calculated using 15, 20, 30, 60-s intervals and 10-breaths moving average. The LT was calculated using a fixed concentration of 4 mmol·l-1, the D-max method and the intensity preceding an increase in blood lactate concentration of 1 mmol·l-1. The VT was defined using the V-slope method and as the highest intensity where respiratory exchange ratio was equal to 1.00. Both VTs and LTs were expressed as absolute power or %PPO. Metabolic efficiency was calculated as gross, work, net and delta efficiency. The different parameters were independently correlated with performance using Pearson correlations. A mathematical model combining all possible variations of the three or only two of the parameters was build using leave one out cross-validation in order to best predict performance.
RESULTS: All VO2max definitions showed highly significant associations with TT performance (all $P < 0.0001$, $r = 0.978 – 0.982$) with overlapping 95% confidence intervals (CI). Absolute power at D-max ($r = 0.987$, $p < 0.001$) showed higher correlation with TT performance than other VT or LT definitions (range 0.87 – 0.90), although 95% CI were again overlapping. Expressed as %PPO, only D-max showed a significant relationship with performance ($r = -0.569$, $p = 0.04$). Work efficiency at 100W ($r = 0.591$, $p = 0.033$) had a significant relationship with performance. The mathematical model included 20-s VO2max, %PPO at D-max and work efficiency at 60% PPO, with mean absolute percentage error of 3.2±2.9%.
CONCLUSION: The parameters that best correlate with TT performance when viewed in isolation are not necessarily the best predictors of TT performance in complex models, which has implications for training monitoring and race planning. The reasons for a negative correlation between %PPO at D-max and TT performance are not clear but might reflect a bias of measurement.

OP-MI10 Strength and power I

PREDICTIVE VALIDITY OF LOAD-VELOCITY MODELS TO DETERMINE THE ONE-REPETITION MAXIMUM IN TRAINED POWERLIFTERS

MITTER, B., BAUER, P., HOELBLING, D., STOECKL, M., BACA, A., TSCHAN, H.

UNIVERSITY OF VIENNA, INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Over the past years, various concepts have been suggested to estimate a person's one-repetition maximum (1-RM) for a given resistance training exercise based on the load-velocity or force-velocity relationship (Hughes et al., 2018). However, the predictive accuracy of such models has not been affirmed consistently in research, as they may be affected by various methodological aspects (Picerno, 2017). The present investigation was conducted to analyze different load-velocity model configurations for their validity to assess the individual 1-RM in a sample of highly strength-trained athletes.
METHODS: Twenty-four trained powerlifters (18 male and 6 female; age: 25.1±5.1 y; body mass: 90.9±20.0 kg) completed a strength test in the back squat exercise at maximum voluntary concentric velocity. Progressive load increments were chosen until participants reached their true 1-RM (relative 1-RM: 1.96±0.25 kg.kg-1). Simultaneously, vertical movement velocity of the barbell was assessed using 3D motion capturing (Vicon-460). Based on individual load-velocity data, eighteen model configurations were selected to estimate the 1-RM. The models differed in predictive approach, regression characteristics and applied velocity variable. Validity of the model estimates and moderator effects of 1-RM strength performance on estimation error were analyzed using magnitude-based inferences at a 90% confidence level.
RESULTS: Models using mean velocity or mean propulsive velocity as predictor variable while calculating the 1-RM from a minimal velocity threshold (MVT) demonstrated a very likely to most likely substantial overestimation of the true 1-RM (mean estimation error: 7.4 to 11.3%). All other models resulted in unclear trends. Moderator analysis revealed a positive, most likely substantial modifying effect of 1-RM strength performance on absolute estimation error in linear models computed from 2 or 5 data pairs using mean velocity as predictor variable [delta 2*SD (90% CL): 19.5 kg (6.6, 32.4) and 16.0 kg (2.6, 29.4), respectively].
CONCLUSION: The present findings corroborate the hypothesis that MVT-based 1-RM calculations using mean velocity or mean propulsive velocity as predictor variable lead to systematic overestimation of the true 1-RM in the back squat exercise (Banyard et al., 2017). In particular, stronger athletes appear to experience higher absolute overestimation of their performance compared to weaker athletes when applying these model configurations.

DIFFERENCES IN THE LOAD-VELOCITY PROFILES AMONG THREE UPPER-BODY PRESSING EXERCISES

SUZOVIC, D., GARCÍA-RAMOS, A., PÉREZ-CASTILLA, A.

FACULTY OF SPORT AND PHYSICAL EDUCATION UNIVERSITY OF BELGRADE, DEPARTMENT OF PHYSICAL EDUCATION AND SPORT, FACULTY OF SPORT SCIENCES, UNIVERSITY OF GRANADA

INTRODUCTION: The 1-repetition maximum (1RM) has been typically assessed from a single maximal lift. Generalised group equations, as indirect method to predict 1RM, assume that a given velocity output represents the same %1RM for all subjects (González-Badillo and Sánchez-Medina, 2010). However, recent studies suggested that the individual load-velocity relationship should be determined for a more accurate prediction of the 1RM (Garcia-Ramos et al. 2018). The same velocity output could represent a different %1RM for each exercise. This study aimed to explore the differences in the load-velocity profile among three upper-body pressing exercises: horizontal and inclined bench press (HBP and IBP) and seated military press (SMP). The expected findings that each exercise presents its own velocity of the 1RM (V1RM) could provide novel and valuable information for strength and conditioning professionals using the velocity-based resistance training approach in practice.
METHODS: The load-velocity profiles of 12 male physical education students were randomly tested in 3 sessions during the HBP, IBP and SMP exercises. Each session consisted of an incremental loading test until reaching the 1-repetition maximum (1RM). The mean velocity of the barbell was recorded with a linear position transducer. Significance was accepted at $p < 0.0$
RESULTS: All individual load-velocity profiles were highly linear ($r2 \geq 0.96$). The 1RM was higher for the HBP (94.214.6 kg), followed by the IBP (87.711.6 kg), and finally the SMP (67.47.8 kg). The mean test velocity (i.e., averaged velocity value from the 20%1RM to the 100%1RM) and the slope of the load-velocity profile were significantly different between exercises (SMP > IBP > HBP). The 1RM value presented very large correlations among the 3 exercises (r range: 0.714 to 0.982), moderate correlations were generally observed for the mean test velocity (r range: 0.237 to 0.766) and the slope of the load-velocity profile (r range: 0.018 to 0.721), and low correlations were observed for the velocity of the 1RM (r range: 0.004 to 0.446).
CONCLUSION: Obtained results suggest that the load-velocity profile is exercise-specific and subject-specific. Participants that presented a lower deficit of force with the light-medium loads during one exercise (e.g., HBP) also tended to have a lower deficit of force with the other two exercises (e.g., IBP and SMP). It is important to note that all these differences were obtained despite that the V1RM did not significantly differ between exercises, as well as between the exercises.

CHANGES IN NUMBER OF REPETITIONS AND HEART RATE AND HEART RATE RECOVERY RATE ACCORDING TO REST TIME BEWTEEN SETS ON 20RM BENCH PRESS EXERCISE.

YOON, C.1, KIM, B.G.1, JEONG, H.J.1, KO, S.S.2, AHN, T.W.3, KIM, K.H.1

DANKOOK UNIVERSITY 1, KOREAN NATIONAL UNIVERSTY OF TRANSPOTATION 2, DAEJEON UNIVERSITY 3.

INTRODUCTION: The resistance training for muscular endurance includes some elements of aerobic exercise in terms of energy metabolism.
The purpose of this project is to identify physiological indicators of heart rate changes depending on the conditions of rest time and to present an efficient.
METHODS: 8 students with more than six months experience in the resistance training were selected. The experiment was conducted after randomly cross-allocating the subjects according to 6 conditions of rest time (30 sec, 1, 2, 3, 4, 5 minutes). According to the 6 conditions of rest time, 20RM bench press Exercise were performed with maximum rebound every 7 sets, and heart rate measurements were measured immediately after bench press exercise and immediately before the next set. Heart rate recovery was calculated.
RESULTS: In contrst, the rest ime, the number of repetitions according to the set, showed statistically significant differences (p= .000). Also, the rest time and the interaction effects of the set also showed statistically significant differences (p=.000). There was no statistically significant difference in the heart rate immediately after the rest time. But, the right post-exercise heart rate for each set showed a statistically significant difference (p=.005). The heart rate right before the exercise directly over the rest time indicated a statistically significant difference (p=020) also, there was a statistically significant difference in heart rate according to the set (p=.000). The interaction effects of rest times and sets also showed statistically significant differences (p= .000).
(This research was financially supported by the Ministry of Trade, Industry, and Energy(MOTIE), Korea, under the"reginal industry based organization suppory program"(reference number P0001940)supervised by the Korea Institute for Advancement of Technology (KIAT)
CONCLUSION: The longer the rest conditions, the higher the recovery rate, and the higher the recovery rate of the heart rate, the greater the number of repetitions.
For each rest time condition, the heart rate immediately before the exercise was greater than 100beats/min, It was showed a decrease in repeat counted by about 50% compared to the first set. This is thought to indicate a lack of physiological recovery time required for the 20RM bench press exercise. On the other hands, Also, It was showed if the heart rate right before the exercise is less than 90 beats/min, the number of repetitions was more than 50 percent compared to the first set. physiological recovery time to recover the central and peripheral fatigue that occurs as the set progresses at the same intensity should be applied differently.
I would suggest that we seek out ways to train through heart rate, taking into account individual differences, rather than guidance for a uniform amount of rest during muscular endurance training.

DIURNAL AND DAY-TO-DAY VARIATIONS IN ISOMETRIC AND ISOKINETIC LEG AND ARM STRENGTH

KNAIER, R.1, INFANGER, D.1, CAJOCHEN, C.2, SCHMIDT-TRUCKSÄSS, A.1, FAUDE, O.1, ROTH, R.1

1 UNIVERSITY OF BASEL, 2 PSYCHIATRIC HOSPITAL OF THE UNIVERSITY OF BASEL

INTRODUCTION: In competitive sports any substantial individual differences in diurnal variations in muscular strength are highly relevant. Previous studies exclusively analyzed on a group level if performance peaks at a certain time of the day (i.e. time-of-day effect) [1]. Individuals' maximal differences between their peak and nadir of performance during the day (i.e. diurnal variation) were disregarded. The aim of this study was to investigate the diurnal variations in maximum isometric and isokinetic strength of leg and arm muscles. Further aims, were to compare diurnal variations in strength to the day-to-day variations, and to investigate if there is a time-of-day effect.
METHODS: Nineteen male athletes (age: 24.1 ± 2.5 years) performed a familiarization test, followed by six test sessions at six different times of the day (7:00, 10:00, 13:00, 16:00, 19:00, and 21:00) to investigate the diurnal variation. An eighth test session was performed at the same time of the day as the seventh test session to investigate the day-to-day variations. The start time for the first session was randomized. All tests were performed with an isokinetic dynamometer and separated by at least 48 hours.
RESULTS: The mean maximum isometric leg strength was 5.85 ± 0.80 N/kg at the peak and 4.99 ± 0.78 N/kg at the nadir of the day, respectively. The mean difference (95% CI) was 0.86 ± 0.47 N/kg (0.62; 1.10) for the diurnal variation and 0.30 ± 0.42 N/kg (0.09; 0.52) for the day-to-day variation. The respective values for the maximum isometric arm strength were 1.68 ± 0.33 N/kg at the peak, 1.46 ± 0.19 N/kg at the nadir, 0.21 ± 0.16 N/kg (0.14; 0.29) for the diurnal variation, and 0.06 ± 0.05 N/kg (0.03; 0.08) for the day-to-day variation. The linear mixed effects models showed little evidence for time-of-day effects in both, isometric leg (all p-values >0.983) and arm strength (all p-values >0.339). Similarly, concentric as well as eccentric leg and arm strength showed higher diurnal variations as compared to the day-to-day variations, and only little evidence for time-of-day effects. Participants reached their peak performance at different times of the day.
CONCLUSION: Previous studies frequently reported performance to peak in the late afternoon or early evening [1]. We found only little evidence for time-of-day effects, but large diurnal variations that are nearly three times higher than the day-to-day variations. The existence of diurnal variations in the absence of time-of-day effects is explained by the fact that individuals achieve their peak performance at different times of the day. These findings have relevant implications for athletes, because they usually have to compete at the same time of the day, but do not achieve peak performance at the same time of the day.

MENTAL FATIGUE ALTERS WEIGHT PERCEPTION AND INCREASES RPE DURING RESISTANCE TRAINING SESSIONS

STAIANO, W., FERRI-CARUANA, A., ROMAGNOLI, M.

UNIVERSIDAD DE VALENCIA

INTRODUCTION: Several studies have recently proved that mental fatigue (MF) alters perception of effort and decreases endurance performance. However, there is lack of scientific evidences on the effect of MF on weight lifting and resistance training (RT). This 2-part study aimed to investigate, firstly, the effect of a mentally demanding task on subsequently weight lifting at different intensities. Secondly, we measured physiological and perceptual changes during RT sessions in fresh and mentally fatigued states.
METHODS: 14 subjects were tested (2 familiarization and 4 experimental sessions) in a randomized cross over order. Part 1: during familiarization session subjects performed unilateral leg extension of dominant leg on an inclined bench with increasing weight to determine 1 Repetition Maximum (RM). Meanwhile they were familiarized with the RPE scale (Borg's 0-10). After, we asked them to lift the equivalent of 20, 40, 60 and 80% of the 1RM and hold it for 3 sec and rating the RPE after each lifting. During the experimental conditions they completed either 90 min of a mentally demanding task (MF) or they watched a neutral video for the same amount of time (Control). Afterwards, the performed leg extensions (in the same way as in the familiarization) with the four different weights (each weight three times with 2 min rest) in a randomized order and completely blind of the weight applied. EMG recordings of vastus lateralis were assessed during the lifting. Part 2: during familiarization session we determined individual 1 RM for 6 basic weight-lifting exercises to construct a program for the following RT session. After, they completed the RT sessions characterized by 4 (sets) x 10 (repetitions) in the 6 exercises. In one condition (MF) they completed several mental demanding tasks 20 min before the start and during each rest in-between repetitions and exercises of the RT session. In the control condition, they were watched neutral videos. Mood, perceived workload and RPE (Borg`s 0-10) as well as blood lactate and HR were recorded during the RT session.
RESULTS: In part 1, subjects mentally fatigued rated a significant higher ($p < 0.05$) RPE for each weight compared to control condition. EMG signal did not detect any significant difference between conditions. In part 2, the group engaging in the concomitant MF tasks rated the overall RT session significantly more effortful ($p < 0.01$) to complete and more mentally demanding ($p < 0.01$) compared to the control condition without any changes in physiological parameters.
CONCLUSION: The present study proved that MF increased perception of effort during RT sessions leaving physiological parameters unaltered. The perceived effort showed in the MF condition is likely due to the augmented mental workload reported by subjects which may have altered subject`s weight perception. This outcome produces evidence that cognitive components are an important factor in resistance training and in sport performance involving repeated weight lifting.

ACUTE CHANGES IN HEART RATE VARIABILITY AFTER RESISTANCE TRAINING SESSIONS DIFFERING IN SET CONFIGURATION

RÚA-ALONSO, M.1, IGLESIAS-SOLER, E.1, MAYO, X.2, RIAL-VÁZQUEZ, J.1, FARINAS, J.1

1: UNIVERSITY OF A CORUNA , 2: KING JUAN CARLOS UNIVERSITY

INTRODUCTION: After a resistance training (RT) session, cardiac vagal modulation decreases what entails an increase of cardiovascular risk (1). Several factors affect to this decrease in the cardiac vagal control, such as the level of the anaerobic metabolism contribution (2). Set configuration refers to the repetitions performed with respect to the maximum possible number in a set and can modulate metabolic implication of RT session. The aim of this study was to analyse the acute effects on heart rate variability (HRV) of two RT sessions differing in set configuration.
METHODS: 38 sport science students performed in a random order two RT sessions (leg extension, leg curl, lat pull, bench press and parallel squat) and a control session (CON). In both experimental sessions a total of 40 repetitions with the 15RM load were performed with 360 sec of total resting time with two set configurations: 4 sets of 10 repetitions with 2 min-rest between sets (Traditional Sets: TS) and 8 sets of 5 repetitions with 51 sec-rest between sets (Cluster Sets: CS).

Before and after the sessions, blood lactate concentration (BL) was obtained and beat-to-beat intervals recorded in order to analyse HRV. HRV was analysed by non-parametric ANOVA type statistics in order to evaluate the effect and interaction between the factors session (CS, TS, CON) and time (Pre, 20-25, 25-30, 30-35 and 35-40). Post hoc comparisons were performed using Wilcoxson test with Bonferroni correction. A t paired test was used to compare increments of BL.
RESULTS: For time domain indices of HRV, main effects for time were observed (SDNN: p<0.001; RMSSD: p=0,009). Main effects for session were found for SDNN (p<0.001) and a tendency for RMSSD (p=0.052). Also, significant interactions were revealed (p=0.004 and p=0,01 for SDNN and RMSSD respectively). After TS and CS, lower SDNN and RMSSD values were observed compared with CON at the different time points and with respect to pretest values. Decreases of SDNN and RMSSD were higher after TS in comparison with CS.
For frequency domain measures, main effects of session, time and interaction were found for HF(nu) (p<0.001). After both sessions, lower values were observed in comparison with CON at the different time points. During the post-exercise period in experimental sessions, HF(nu) values were lower than pretest. Major decrease in TS than CS were revealed.
BL increments were significant higher in TS in comparison with CS (p<0.001).
CONCLUSION: These data shown that both sessions reduce cardiac vagal modulation what is coincident with previous studies (3). The cluster set configuration mitigated the loss of cardiac vagal modulation and reduced BL increments compared to a traditional set configuration.

OP-BN22 Muscle and/or tendon function II

IMPACT OF THE PLANTARFLEXOR MORPHOLOGY AND FOOT STRUCTURE ON RUNNING PERFORMANCE

KOVÁCS, B.1, KÓBOR, I.2, GYIMES, ZS.1, TIHANYI, J.1
UNIVERSITY OF PHYSICAL EDUCATION 1, UNIVERSITY OF SEMMELWEIS 2

INTRODUCTION: The length of the Achilles tendon moment arm (AT-MA) seems to be correlated to the running performance and economy (Sholz et al. 2008, Barnes et al. 2014, Moses et al. 2015, Kunimassa et al. 2014) Additionally the Achilles tendon (AT) length also could influence the running economy (Uneo et al. 2017). However, the effect of the morphological parameters of the plantarflexor muscles on the running performance is rarely investigated. The ratio between the plantarflexor to Achilles tendon anatomical cross-sectional area (ACSA) may indicate an economical running performance, however this connection is not clear.
METHODS: Ten elite, male distance runners volunteered in this study. To measure the ACSA of the Achilles tendon, soleus, lateral and medial gastrocnemius MRI images were taken from the right leg. used to acquire the MR images. The runners were positioned supine, with extended knee and neutral ankle (90 degree) angle during the MR scans. The ACSA was manually outlined for each muscle and tendon in all slices. Additionally the pennation angle, fiber length was measured via ultrasound and the physiological cross-sectional area (PCSA) was calculated for each muscle. The AT-MA length was estimated from a sagittal plane images using a modified Reuleaux method .
RESULTS: AT-MA length and the marathon performance did not correlate (r=0.01 p<0.97). The marathon racing time did not correlate either with the AT lengths (r=-0.01, p<0.99) or with the mean ACSA of the AT (r=-0.17, p<0.63). However the mean and maximal ACSA of the soleus (r=0.65, p<0.04 and r=0.77, 0.01) and the mean and maximal triceps sureae ACSA (r=0.63, p<0.04 and r=0.73, p<0.01) positively correlated with the racing time. Also the resting fiber length of the soleus correlated with the running performance (r=0.66, p<0.03), however the PCSA of the soleus did not correlate with the racing time (r=0.09, p<0.79).
CONCLUSION: The aim of this study was to clarify to if there is an impact of the muscle to tendon ACSA ratio on the running performance. We find lack of evidence on this subject. In the case of heel strike runners, the elastic energy storage-release mechanism is less efficient than in mid or fore foot strike runners, therefore the muscles done more works which could led to a greater ACSA of the soleus, and a longer resting fiber length. However, the lack of correlation between the PCSA and the race time is contrary to this. Interestingly, we did not find correlation between the AT-MA and race time which is opposite to previous findings, and also there was no correlation between the properties of the Achilles tendon (ie. length, ACSA) and the running performance. Based on literature reports our results may indicate a poor impact of the plantarflexor morphology and foot structure on the running performance which can be attributed to the different foot strike during running.

CHANGES IN HAMSTRING MORPHOLOGY AND ARCHITECTURE ARE NOT ASSOCIATED WITH SPRINTING OR VERTICAL JUMP PERFORMANCE

DUHIG, S., BOURNE, M., TIMMINS, R., SHIELD, A.
GRIFFITH UNIVERSITY

INTRODUCTION: Hamstring strain injuries (HSI) are a primary concern for running-based sports entailing substantial financial and competitive burdens. Interestingly, compliance with evidence-based HSI prevention programs is poor and likely a key factor to the 4% annual rise of HSIs in men's professional soccer. Reluctance for prophylactic exercise is possibly reinforced with a few expert opinions who consider some evidence-based HSI prevention exercises as "non-functional" given they lack task-specificity that would be conducive for improved performance. However, numerous studies show both individual and team sport athletes achieve greater success when completing the planned training sessions and this availability for training and competing is achieved by reducing the incidence of injury and illness, which can be achieved by implementing evidence-based exercise.
METHODS: Eighteen recreationally active male athletes (age, 22 ± 3.6 years, height, 180.4 ± 7 cm, weight, 80.8 ± 11.1 kg) volunteered for the study. Before and after a 10-week strength training intervention, participants biceps femoris long head (BFlh) architecture (muscle thickness (MT), pennation angle (PA) and fascicle length (FL)) and semitendinosus (ST) muscle volume was measured using 2D ultrasound and magnetic resonance imaging. Each participant had their vertical jump (VJ), 10m and 40m sprint time assessed prior to and subsequent the intervention. Groups were counterbalanced based on BFlh FL then randomly allocated into the Nordic curl (NC) or unilateral 45-

degree hip extension (HE). The NC and HE completed a progressive strength training programme of their respective exercise and each group was told not to complete any additional hamstring or sprint training during this period. Delta scores were calculated for each variable and Cohen's d calculated using these pre-to-post changes. Spearman's correlation was used to determine association between changes in BFlh FL and ST muscle volume with VJ, 10m and 40m sprint performance.
RESULTS: Large increases in BFlh architecture were observed for both intervention groups. A large and moderate effect was found in ST muscle volume for the NC and HE, respectively. Both NC and HE groups showed small to moderate improvements in VJ, small declines for 10m and no effect on 40m sprint performance, respectively. Combining both groups, the correlation between BFlh FL and VJ, 10m and 40m sprint performance was -0.19, -0.30 and -0.13, respectively. The correlation between ST muscle volume and VJ, 10m and 40m sprint time was -0.33, 0.09 and 0.49.
CONCLUSION: The current findings show that the NC and NHE induce large increases in BFlh architectural changes exercises while having a large and moderate effect on ST muscle volume, respectively. Despite these substantial architectural and morphological adaptations occurring within the NC and HE groups there was only a small to moderate effect on VJ height and small to no effect on 10m and 40m sprint times.

THE EFFECT OF STEP FREQUENCY ON THE BEHAVIOR OF MEDIAL GASTROCNEMIUS MUSCLE-TENDON COMPLEX DURING HUMAN RUNNING.

TAKESHITA, T.1, NORO, H.1, YOSHIDA, T.1, TAGURI, A.1, HATA, K.1, FUKUNAGA, T.2, YANAGIYA, T.1
1.GRADUATE SCHOOL OF JUNTENDO UNIVERSITY 2.NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Previous study indicated the ground reaction forces exerted by the runner's body during running were affected by the step frequency (Farley & Gonzalez, 1996). However, there is a little observation for the behavior of fascicle and tendon in lower limbs when the step frequency is changed during running. In this study, we aimed to clarify the effect of step frequency on the behavior of medial gastrocnemius muscle-tendon complex (MTC) during running.
METHODS: Six healthy men (age: 22.5±0.71yrs; height: 1.76±0.06m; weight: 67.30±5.04kg) were requested to run on the treadmill mounted force platform. Running speed was set at 2.38 m/s, and foot strike pattern was manipulated to forefoot strike. Selected step frequency were as follows: 2.25 steps/s (LOW), 2.50 steps/s (MID), 2.75 steps/s (HIGH). Ultrasound images of medial gastrocnemius were captured, and fascicle length was calculated. Tendinous tissue length was estimated from MTC length, fascicle length, and pennation angle (Fukunaga et. Al., 2001). Tensile force of muscle and tendon were calculated from inverse dynamics, and mechanical power was estimated as the product of tensile force and contraction velocity. Mechanical work was calculated as the integration of each mechanical power relative to time. Those data were averaged with five steps in each individual, and mean data were statistically compared with paired one way ANOVA. The significance level was set at 5%.
RESULTS: Fascicle length was significantly shorter in LOW condition compared to other conditions, on the other hand, tendon length was significantly longer in LOW condition in the first half of stance phase ($p<0.05$). Mechanical power calculated on the tendon during the negative phase was greater in LOW condition rather than in other conditions.
CONCLUSION: The present study indicated that in treadmill running at constant speed the length of gastrocnemius fascicle and tendon were affected by the step frequency. From these results, it would be considered that more elastic energy is used in lower step frequency running.

PROXIMAL-DISTAL HAMSTRINGS ELECTROMYOGRAPHY ACTIVITY AT DIFFERENT RUNNING SPEEDS

HEGYI, A., GONÇALVES, B.A.M., FINNI, T., CRONIN, N.J.
UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Hamstring injuries typically occur in the early stance or late swing phase of high-speed running and mostly affect the proximal region of the biceps femoris long head (BFlh). This injury location is associated with the highest BFlh strain in the proximal region in running, particularly at high speeds (1). The semitendinosus (ST), which shares a common proximal tendon with the BFlh, may protect the BFlh from injury (2). Previous electromyography (EMG) studies recorded only from a small muscle region -ignoring possible proximal-distal differences- when examining the interplay between these muscles in running. To further understand hamstring injury mechanisms, this study examined proximal-distal and intermuscular activity of the BFlh and ST as a function of increasing running speed.
METHODS: Thirteen amateur football players ran at steady speeds of 45, 60 and 75% of their maximum running speed on a treadmill (4.07±0.23, 5.42±0.31 and 6.78±0.39 m/s, respectively). Lower limb 3D kinematics were recorded with VICON, and left leg BFlh and ST activity were measured with high-density EMG from 15 cm along each muscle. Muscle-tendon unit (MTU) lengths were calculated for BFlh and ST (3). EMG amplitudes were normalised to maximal voluntary isometric contraction (MVC) values. The effects of running speed on MTU lengths, and proximal-distal and inter-muscular activity were tested across the time-normalised stride cycle (from ground-contact to toe off) using Statistical Parametric Mapping repeated measures ANOVA ($\alpha = 0.05$).
RESULTS: Maximum lengths of BFlh and ST occurred in late swing, and were constant above 60% of maximum running speed. Increasing running speed increased hamstrings activity in all phases ($p<0.001$) except in late stance (23-25% stride cycle), where hamstrings activity was the lowest within the stride (~20% MVC). A speed x muscle interaction was also found in late stance ($p=0.018$) but not in the clinically relevant late swing or early stance phases. Speed x regional EMG interaction was seen only in early swing for both muscles (ST, 50-58% stride, $p =0.009$; BFlh, 41-66% stride, $p<0.001$). Post-hoc analyses showed no inter-muscular or regional differences at any running speed.
CONCLUSION: Large increases in hamstrings activity with speed occurred without substantial change in MTU strain implying higher MTU stiffness at higher speeds, potentially increasing injury risk. Homogeneous hamstrings intermuscular and proximal-distal EMG amplitudes were evident across a range of running speeds. On the contrary, typical hamstring exercises present large proximal-distal variations in EMG activity (4,5). This implies that, to restore neuromuscular function after hamstring injury, early implementation of running -even at submaximal speeds- may be crucial.

OPERATING LENGTH AND VELOCITY OF M. SOLEUS FASCICLES DURING RUNNING AND THE ASSOCIATION TO LOCOMOTOR ECONOMY

BOHM, S., MERSMANN, F., SANTUZ, A., ARAMPATZIS, A.

HUMBOLDT-UNIVERSITÄT ZU BERLIN

INTRODUCTION: According to the force-length-velocity relationships the force potential of a muscle during movement is determined by the operating length and velocity of its fascicles (1,2). Contractions close to the optimum fascicle length and low shortening velocities may reduce the active muscle volume at a given force and, thus, enhance the economy of locomotion (3). The purpose of the present study was to investigate the fascicle dynamics of M. soleus as the major contributor during submaximal running. Operating fascicle length and velocity was referenced to the individually determined force-length and force-velocity curve and correlated with energetic costs.
METHODS: During running on a treadmill (2.5 m/s), kinematic analysis, ultrasonography and electromyography were combined to assess the length of the muscle-tendon unit and fascicles as well as the activation of the soleus muscle of 19 experienced runners. Oxygen and carbon dioxide expiration was analyzed additionally to estimate energetic costs. The individual force-fascicle length relationship of soleus was determined based on eight maximal voluntary plantar flexions in different ankle joint angles by means of dynamometry and ultrasound, while the force applied to the Achilles tendon was calculated using individual lever arms obtained by the tendon-excursion method. Muscle specific constants were taken from literature (4) to determine the maximum shortening velocity and to calculate the individual force-fascicle velocity relationship based on the Hill equation. Accordingly, the force potential during running as a function of fascicle operating length and velocity was calculated.
RESULTS: The maximum force of the soleus muscle was in average 2887±724 N at a fascicle length of 41.3±5.2 mm and the maximum shortening velocity 484±61 mm/s. During the stance phase of running, the soleus fascicles operated in an average length of 37.6±4.8 mm with continuous shortening in a range of 10.6±3.0 mm. The average velocity was -32.6±9.9 mm/s and the activation 0.30±0.08 %EMGmax. The force-length potential was 0.92±0.07 and the force-velocity potential 0.74±0.07, resulting in a total potential of 0.68±0.08. The force-velocity potential (r=-0.51, p=0.02) and the overall force-length-velocity potential (r=-0.50, p=0.03) was negatively correlated with the energetic cost (10.8±1.0 W/kg).
CONCLUSION: The findings show that the soleus muscle operate on the ascending limb of the force-length curve close to optimal length with moderate velocities and, therefore, with a high force potential. The inverse correlation of the force-velocity potential with the energetic cost suggest that the mechanism of increasing economy of locomotion is a reduction of fascicle shortening velocities given an optimized operating length. Therefore, we provide direct evidence that muscle fascicle dynamics are a determinant of locomotor economy.

THE EFFECTS OF MUSCLE MASS ON CONTRACTILE PERFORMANCE IN HUMANS

ROSS, S.A., WAKELING, J.M.

SIMON FRASER UNIVERSITY

INTRODUCTION: Endurance activities require muscles to work at high efficiency, and explosive activities require muscles to operate at high power outputs. Most of what we know about the performance of contracting muscles comes from experiments on isolated muscle fibres, or small muscles from animal preparations, where the intrinsic properties of these muscles are then extrapolated to allow the performance of human-sized muscles to be computationally predicted. However, this approach does not consider the mass of the contracting muscle, or its effects on contractile dynamics. Previous studies have shown that the mass of muscle tissue acts to slow the rate of force development (1) and the maximum contraction velocity (2), and it has been suggested that this is due to the greater internal work required to accelerate the mass of the muscle tissue (3). Here we demonstrate how the inertial cost of accelerating the internal muscle mass reduces the performance of human-sized muscles.
METHODS: We developed computational muscle models with Hill-type contractile elements, parallel elasticity, and muscle mass distributed in series along the muscles. The muscle models contracted against an oscillating load to mimic the external forces that act on a muscle during movement tasks. We evaluated muscle models that ranged in size from 0.67 mg (similar to a small bundle of muscle fibres) to 670 g (similar to an ankle plantarflexor muscle in humans). We determined the mechanical power output for the contraction cycles, and estimated the metabolic cost based on the contractile dynamics (4).
RESULTS: The muscle mass-specific mechanical power decreased at the larger muscle sizes, with the mass effect being more pronounced for lower levels of muscle activity. These mass-dependent reductions in mechanical power reached 12% for the 670 g muscle when the muscle contracted using faster muscle fibre-types. The additional internal work required to accelerate the muscle mass resulted in lower metabolic efficiencies for the larger muscles, with reductions in efficiency exceeding 10%.
CONCLUSION: These results show that there is a metabolic penalty to accelerating the inertial mass within a muscle that would not be detected during experiments on preparations of small muscle, but that would be significant when assessing muscle performance in humans.

MACHINE LEARNING PREDICTION MODELING IN ELITE SPORTS

KLJUCHNIKOV, M.S., SAMOYLOV, A.S.

SRC FMBC FMBA

INTRODUCTION: Sport medicine today's facing a tough crisis. Performing boost in elite sports at present stage can no more be carried out with traditional manner, including training, medical and pharmacological approaching. But is possible with the use of high-tech approach. One of the most promising is Big Data Analysis and Machine Learning (ML) which allows us to determine the individual tracks for athletes' functional state (FS) dynamics and predict disadaptation as well as fitness peaks and "readiness windows".
METHODS: For 440 elite national teams athletes, using tech-stack: MySql Workbench v3.6 and Knime™ v.3.5.1, we built ML models of functional state prediction, e.g. polynomial regression (PR), random forest (RF) and gradient boosting (GB). Training set included registered, during extended medical examination in medical clinic, parameters: age, sport discipline, gender, heart rate (HR), body mass index (BMI) and stress-index. Systematic vascular resistance (SVR), also stated by our medical team, but excluded from dataset until the validation stage, was chosen as the target parameter for prediction models. FS parameters had been registered with diagnostic system - Esteck System Complex. We applied ANOVA analysis and MAPE calculation for results validation.
RESULTS: Each of the ML models allowed to calculate the SVR values close to stated, but with different accuracy. Lower accuracy was proved by PR model – 96,25%, RF and GB models were more accurate – 98,05% and 98,83% resp. ML models showed precision accuracy – standard deviation of SVR values for PR model was 5,066, for RF 3,94 and for GB model 1,93 dynes/sec/cm5 resp. MAPE for ML models were 3,75 for Polynomial regression model, 1,95 for Random forest and 1,17 for Gradient Boosting model. Thereby the most accurate was the gradient boosting model, however other can be used to predict SVR and, presumable, other functional state parameters of the elite sportsmen.
CONCLUSION: Combination of ML methods for training models on sufficient medical datasets allows us today to predict FS of elite athletes, in particular hemodynamic features, with precise accuracy. Application in practical sports medicine such precision hemodynamic prediction models would significantly reduce the risk of acute cardiac pathology among elite athletes, including sudden cardiac death at sport events. The main challenge of our follow-up research is to combine ML models of FS predictions with full medical and training history of the national teams elite sportsmen, and apply neural network approach to improve the accuracy of our models to the highest possible, tending to 100%, reliability.

USING MACHINE LEARNING TO INFER INDIVIDUAL ATHLETE MOVEMENT MODELS FROM VIDEO

GALLAGHER, K.V.1, VIDAL-CODINA, F.2, LÓPEZ-FELIP, M.A.3,4, JOSEPH, J.1, PERAIRE, J.2

[1] MASSACHUSETTS INSTITUTE OF TECHNOLOGY, [2] MASSACHUSETTS INSTITUTE OF TECHNOLOGY, [3] UNIVERSITY OF CONNECTICUT, [4] FUTBOL CLUB BARCELONA, BARÇA INNOVATION HUB

INTRODUCTION: In recent years, sports analytics has become progressively interconnected with the field of machine learning, enabled by the generation of large volumes of quantitative data [1, 2]. This data serves as input for machine learning algorithms, allowing practitioners to infer models that can be used to help prevent injury and improve performance, reducing reliance on athlete self-reporting and coaching vigilance.
METHODS: We leverage existing machine learning techniques, including Faster R-CNN for object detection [3] and OpenPose [4] for skeletal estimation, to construct continuous pose models for individual athletes from video footage containing one or more persons. Using detected body, hand, facial, and foot keypoints in conjunction with spatial coordinates, we track athletes unique physical configurations throughout regular practice.
RESULTS: Based on video and GPS sensor data collected on U19 soccer players, we demonstrate that, by combining the techniques from [3, 4], we can accurately reconstruct continuous athlete skeletal pose models on the video footage.
CONCLUSION: Our results show that these individualized continuous athlete skeletal pose models can form the foundation of sports analytics systems for services such as form correction recommendations, fatigue inference, and injury prediction.

ANALYSIS OF FOOT SKIN TEMPERATURE AND THERMAL COMFORT PERCEPTION OF A THERMOFORMABLE PREFABRICATED INSOLE DURING RUNNING

REQUENA BUENO, L.

UNIVERSITY OF VALENCIA

INTRODUCTION: The use of prefabricated and custom-made insoles during running has been increased recently with the aim to improve performance and reduce injury risk. However, there is a great controversy regarding their improvements (1). A second generation of thermoformable prefabricated insole has been designed in order to improve the ergonomic adaptation to the users foot. This adaptation is performed after heated the insole with a conventional microwave. The aim of this study was to analyse the foot skin temperature and the thermal comfort perception during running in two different conditions: control condition insole and thermoformable prefabricated insole.
METHODS: Fifteen recreational runners (eleven men and four women; age [41(5) years], body mass [69.3(12.5) kg], height [171.9(7.1) cm], and running training distance [45.1(22.3) km/week]) participated in 3 tests, on 3 different days. The first test was to know the maximum aerobic speed (MAS). The second and third tests consisted of a 30-minutes running at 80% of their MAS on treadmill, each in a condition of insole: 1) with runners' usual footwear (control condition) and 2) with thermoformable prefabricated insole. Skin temperature of the foot

sole was measured using a thermographic camera (FLIR E60bx) in different measurement moments: before (pre) and after (post) the run. A total of 4 regions of interest (2) were analysed: complete foot sole, forefoot, midfoot and rearfoot. Thermal comfort perception was analysed at the end of running using a 150 mm visual analogue scale (VAS).
RESULTS: Thermoformable condition presented lower temperature variation (difference between post moment and pre moment) than control condition in complete foot sole [8.3(2.6) °C vs 10(2.1) °C, p=0.002], in forefoot [(8.8(3.1) °C vs 10.8(2.5) °C, p=0.001]) and in rearfoot [(7.8(2.2) °C vs 9.3(1.9) °C, p=0.006]). Greater thermal comfort perception of the thermoformable insole was observed compared to the control condition [(10.8(3.5) vs 9.2(3.3), p=0.015])
CONCLUSION: In general, there is a lower increase in temperature variations with the thermoformable insole compared to the control condition that could be explained by the better heat dissipation, and can be related to the greater thermal comfort. The non-significant differences in the midfoot could be explained by the greater adaptation of this insole in the arch region of the foot sole. So, these insoles seem to have a better thermal behaviour than runners´ training footwear insoles.

SKI STYLE CLASSIFICATION AND SCORING USING A SIMPLE SENSOR AND ALGORITHM SYSTEM

SNYDER, C., BRUNAUER, R., JAHNEL, R., STÖGGL, T.
UNIVERSITY OF SALZBURG

INTRODUCTION: Alpine Skiing is a complex and dynamic movement with a high degree of variability both within and between skiers. Previous studies have used complex measurement systems to identify turn characteristics that might predict ability of performance (1). Therefore, the purpose of this study was to identify variables, measurable using a simple sensor system that differentiate between skiing ability and ski style within and between skiers.
METHODS: Three expert skiers completed eight runs, performing at least 10 turns in long, medium, and short radius in carving and parallel drifted skiing styles. The seventh and eighth runs were steered and pure snowplow turns. Edge angle and g-force were calculated based on two 3D inertial sensors (50 Hz) attached to the posterior cuff of both ski boots. Maximum velocity was calculated via GNSS (1 Hz) recorded on a mobile phone during each run. Using the mean and standard deviation as of all turns within each style (carving, parallel, snowplow) as a guide, a scoring system was developed such that the highest scores would be observed in carving, the lowest in snowplow, and parallel drifted between.
RESULTS: The variables, peak velocity (m·s-1), maximum edge angle (°) and maximum g-force were included in the scoring system. Velocity scores ranged from 17.0 m·s-1 (score=10) to 5 m·s-1 (score=1). Maximum edge angle ranged from 54° (score=10), to 30°. G-force ranged from 2.5 g (score=10) to 0.5 g (score=1). Scores were equally distributed between 1-10 in intervals of 1.5 m·s-1 for velocity, 2° for edge angle, and 0.25 for g-force.
CONCLUSION: While this study only included three skiers and limited number of turn characteristics, this system represents a first attempt at using simple turn characteristics to discriminate between skiing styles and abilities. Future work should include more skiers, machine learning techniques, and more turn characteristics (timing, acceleration, turn radius etc.) which might better discriminate between skier abilities, but also skiing styles. Skier ability and turn style can be determined by a scoring system derived from turn characteristics that can be measured by a simple sensor system (2).

DATA PROCESSING INFLUENCES THE CONCURRENT VALIDITY OF IMUS FOR INDOOR PLAYER MONITORING

ROELL, M.1, ROECKER, K.2, GEHRING, D.1, GOLLHOFER, A.1
1: UNIVERSITY OF FREIBURG , 2: UNIVERSITY OF FURTWANGEN

INTRODUCTION: Wearable tracking devices are nowadays a standard measurement system for quantifying workloads in team sports. As the widespread use of GPS is impossible indoors due to signal interferences, inertial measurement units (IMU) that quantify three-dimensional acceleration are used instead in indoor facilities. Working with IMUs requires complex data processing such as sensor fusion of accelerometer and gyroscope outputs to provide meaningful results. It was shown under controlled conditions that validity of the investigated IMU depended on the applied sensor fusion algorithm itself (Ricci et al., 2016; Roell et al., 2018). The aim of this study was to evaluate the concurrent validity of IMU data, which was processed with two standard fusion methods during team sport specific movements.
METHODS: IMU outputs were compared to a 3D motion analysis (MA) during 6 team sport specific movements, including straight line, change of direction and jumping tasks performed at three intensities (n=1093). Two sensor fusion algorithms for orientation estimation (Kalman-Filter, KF; Complementary Filer, CF) were applied to IMU raw data and computed at a temporal resolution of 100, 10 and 5 Hz. Mean and peak magnitudes were calculated for the resultant (|3D|; CF, KF, MA), horizontal (|2D|) and vertical (|1D|; CF, MA) acceleration vector. Mean Bias (MB), Bland-Altman plots, Spearman's ρ, CV and RMSE were calculated as analysis of agreement.
RESULTS: The IMU continuously overestimated MA data over all trials, whereas higher errors were seen for KF (MBmean=-2.00 to - 0.57, MBpeak=-4.18 to - 3.25) compared to CF (MBmean=-0.40 to - 0.33, MBpeak=-2.31 to - 1.87) in all temporal resolutions. In accordance, lower errors of CF compared to KF were found for mean (CV = 7.46-10.78; RMSE=0.44-0.52) and peak (CV=10.05-15.98; RMSE=1.40-3.22) variables in |3D|,|2D| and |1D|. Validity further increased for decreasing temporal resolution with lowest errors found for 5Hz (RMSEmean=0.44; RMSEpeak=1.40). While an increase in intensity led to a reduction of accuracy, no effects were seen for the movement task itself.
CONCLUSION: Results show a dependence of the IMU's accuracy on sensor fusion itself, acceleration magnitude and temporal resolution. Overall, IMU-based tracking devices quantify acceleration magnitudes with acceptable validity after appropriate data processing with advantages shown for the CF. Higher intensities limit accuracy of both sensor fusion techniques, but act more serious on the KF, which might result from its slower convergence (Ricci et al., 2016). In accordance, analysis of temporal resolutions reveal the highest

validity for 5Hz resolution due to overall lower acceleration magnitudes. Considering these determinants, practitioners should be aware of possible influences on the IMU's output and adapt data processing to their specific needs in order to provide meaningful information.

FORCES APPLIED IN EROGMENTER AND ON-WATER ROWING - A NON REPRESENTATIVE ENVIRONMENT

MILLAR, S.K., REID, D., MCDONNELL, L.

AUT-UNIVERSITY

INTRODUCTION: An ecological approach to examining sports performance is focused on the emergence of information-based interactions between performers and their performance environment. It has been found that changes (even small ones) in performance environments can leads to substantial movements changes by performers, as they aim to meet a specified task goal (Hristovski, Davids, Arau´ jo, & Button, 2006). While previous studies have examined handle forces between rowing conditions (Lamb, 1989) none have examined the foot and handle forces between conditions with the same elite performers. This study explored how differing information in ergometer compared to on-water rowing environments can provide different movement solutions.
METHODS: Four elite female adult rowers each rower performed a single 1000-m time-trial for each of a fixed ergometer (Concept2), a sliding ergometer (the same Concept2 ergometer placed on Concept2 slides), and in an on-water double scull. Force data at the oarlock and footplate were collected with the PowerLineTM Instrumentation system. Degrees of lumbar flexion during all three conditions were recorded via markers attached to the spinous processes of L1, L2 and L5, S1.
RESULTS: An Intra-individual analysis discovered that the temporal application of feet and handle forces in addition to the total forces produced by individual rowers differed between the ergometer conditions and the on-water condition. The maximal handle forces achieved were statistically different between the fixed ergometer and on water, but not statistically different between the water and sliders. There was a trend for the foot forces to be higher on the ergometer compared to on-water and in particular, maximum forces were achieved earlier on ergometers than on-water. Rowers produced the highest lumbar curvature values relative to their full ROM during fixed ergometer rowing. When rowers were under a relatively more fatigued state the water rowing condition helped reduce %ROM by a small to moderate amount in the observed sample of rowers.
CONCLUSION: Handle and foot forces are different in fixed and sliding ergometers when compared to on-water. The current study demonstrated that on-water rowing has different temporal and maximal forces to fixed ergometer. In addition, the fixed ergometer may induce greater lumbar spine flexion in some rowers from just after the catch to about ¾ drive phase.REFERENCES:

EFFECTS OF 4V4 COMPARED TO 7V7 MATCH PLAY ON TECHNICAL AND TACTICAL PARAMETERS IN YOUTH SOCCER PLAYERS

HINTERMANN, M., FUCHSLOCHER, J., KERN, R., BORN, D.P., ROMANN, M.

SWISS FEDERAL INSTITUTE OF SPORT, MAGGLINGEN

INTRODUCTION: Small-sided games (SSG) are widely used as training method in soccer to enhance the physical performance (Hill-Haas et al., 2011, Sports Med). For children's soccer, evidence also suggests that scaling, i.e. reduced number of players and pitch size, is an effective strategy to enhance technical and tactical skill performance and learning (Buszard et al., 2016, Sports Med). Scaling is expected to increase the individual playing time, game involvement, number of ball contacts, variability and frequency of game situations. Therefore, the aim of this study was to compare the effects of SSG 4v4 players with reduced pitch size compared to the traditional U-11 7v7 match play on technical and tactical parameters.
METHODS: Forty U-11 male soccer players were recruited from regional soccer clubs and divided into two groups to play a tournament with either 4v4 or 7v7 match play. The pitch size was reduced for the 4v4 to 20m x 30m. The 7v7 was played on the for this age group regular pitch size of 30m x 50m. The first 20 minutes of each tournament were video captured and subsequently the technical and tactical parameters were analyzed. The data were compared using an unpaired t-test. The Mann-Whitney U test was used for all non-normally distributed parameters.
RESULTS: All data are indicated as number of actions per player per minute. The total number of actions was significantly higher with the 4v4 compared to the 7v7 (5.411±1.643 and 2.826±0.973, respectively; $P<0.001$). Similarly, the number of defensive actions as defensive duels (0.528±0.252 and 0.243±0.134; $P<0.001$), pressing an attacking player (1.184±0.512 and 0.620±0.231; $P<0.001$) and defending a goal (0.153±0.148 and 0.009±0.020; $P<0.001$) were increased with the 4v4. Interceptions (0.307±0.170 and 0.244±0.216; $P<0.170$) remained unaffected. When analyzing the offensive actions, the 4v4 compared to the 7v7 showed an increased number of ball controls (0.756±0.397 and 0.402±0.188; $P<0.001$), passes (1.289±0.440 and 0.717±0.298; $P<0.001$), runs with the ball (0.224±0.210 and 0.071±0.065; $P<0.029$) and goals (0.117±0.0.151 and 0.019±0.052; $P<0.028$). Dribblings (0.571±0.457 and 0.369±0.253; $P<0.244$) and shots (0.281±0.278 and 0.130±0.161; $P<0.097$) did not show significant differences.
CONCLUSION: The 4v4 compared to the 7v7 match format doubled the number of technical and tactical actions per player in U-11 soccer match play. The increased number of technical and tactical actions involving decisions in offensive and defensive match situations should benefit the players' skill development. Future research needs to investigate the long term effects of scaling in U-11 soccer players as well as the effect of 4v4 match play on the quality of the actions involved.

THE RELATIONSHIP BETWEEN THE LEVEL OF ALL-ROUND DEVELOPMENT AND THE ACQUISITION OF SPECIFIC SPORT SKILLS IN CHILDREN IN YOUNGER SCHOOL AGE

KOMÍNKOVÁ, L.

CHARLES UNIVERSITY

The relationship between the level of all-round development and the acquisition of specific sport skills in children in younger school age
Komínková Linda, Perič Tomáš
Charles University, Faculty of Physical Education and Sport
INTRODUCTION
Early start of special training can have negative physical, psychological and social consequencies (Baker et al., 2009). Therefore, in children and youth sports training is recommended the so-called all-round development. However, some researches claim that for future success is important to start with special training as soon as possible. Because the earlier one starts adhering to a strict training regime, the quicker one will attain their desired level of skill (Ericsson et al., 1993; Ericsson, Charness, 1994). In our longitudinal research we want to find how the level of all-round development in six-year-olds influences the level of skill acquisition in sport at later age, specifically in ice hockey.
METHODS
To assess the level of childrens all-round development we selected these areas: chronological age, somatic parametres (body height and body weight), the level of physical abilities, predispositions for manipulation of objects and predispositions for decision-making processes. To assess the level of skill aquisition in ice hockey we used three different tests which evaluated stickhandling, passing and shooting.
RESULTS
In 2018, we evaluated the level of children´s all-round development in ice hockey clubs (n = 45). The average age of these children was 6.5 years. One year later we evaluated the acquisition of ice hockey skills in these children. Nowadays, we have results of 29 children from ice hockey. For those who have been tested, higher level of all-round development were correlated (cannonical correlation analysis) with higher level of hockey skills acquisition, r = 0.75 ($p<0.05$), which can be considered as a large effect.
CONCLUSION
Our results confirm that the higher level of all-round development in younger age has positive influence on skill acquisition in ice hockey at later age. If this positive influence will be confirmed also in other sports, it will confirm not only the importance of all-round sports training in childhood. This finding can also help coaches with talent identification and selection.

EXAMINING THE BIDIRECTIONAL ASSOCIATIONS BETWEEN CHANGES IN CARDIORESPIRATORY FITNESS AND FATNESS: THE UP&DOWN LONGITUDINAL STUDY.

PEREZ-BEY, A.1, ORTEGA, F.B.2, MARTINEZ-GOMEZ, D.3, VEIGA O.L.4, RUIZ, J.R.2, CASTRO-PIÑERO, J.

1: UNIVERSITY OF CÁDIZ ; 2: UNIVERSITY OF GRANADA ; 3: IMDEA FOOD INSTITUTE. CEI UAM + CSIC ; 4: AUTONOMOUS UNIVERSITY OF MADRID .

INTRODUCTION: Information about the direction in the association between cardiorespiratory fitness (CRF) and fatness in young people is scarce. Since CRF and fatness are two key determinants of future health, this knowledge would help to determine which feature should be considered the target of health promoting programs. The aim of this 2-year longitudinal study was to analyse the bidirectionality in the prospective association between changes in CRF and fatness in children and adolescents.
METHODS: A total of 1082 children (512 females) and 727 adolescents (342 females) with complete data in fitness and fatness assessments participated in this study. Height, weight, and triceps and subscapular skinfolds were measured through standardised procedures, and body mass index (kg/m2), body fat percentage (%) using the Slaughter's equation, and fat mass index (kg of fat mass/m2) were calculated. The 20-m shuttle run test was employed to assess CRF. Bidirectionality was determined by including the change in CRF and fatness (CRF and fatness at year 3 – CRF and fatness at year 1, respectively) as exposures, and fatness and CRF at follow-up as outcomes, respectively. The same analyses were repeated but including the change in fatness and CRF as outcomes.
RESULTS: Changes in CRF were prospectively associated with fatness after accounting for baseline fatness levels (ß ranged from -0.078 to -0.224; $p<0.05$). Similarly, fatness changes were negatively associated with CRF at 2-year follow-up (ß ranged from -0.062 to -0.268; $p<0.05$), independently of baseline CRF values. Changes in CRF were significantly associated with changes in fatness (ß ranged from -0.115 to -0.388; $p<0.05$). Likewise, fatness changes significantly predicted CRF changes (ß ranged from -0.109 to -0.349; $p<0.05$).
CONCLUSION: A bidirectional association exist between changes in CRF and fatness in children and adolescents. The implementation of health promoting programs aimed at improving CRF and body composition of children and adolescents is of prime importance since future CRF and fatness levels have been previously linked to healthier profiles. Consequently, an important public health message is arisen: improvements in CRF and fatness will positively affect the health status of young people, no matter the initial CRF or fatness levels they have.

THE EFFECT OF STRUCTURED FOOTBALL TRAINING PROGRAMME ON FOOTBALL, PSYCHOLOGICAL AND PHYSCIAL ACTIVTY RELATED MEASURES IN HONG KONG BOYS

OREILLY, J., HUI, S.C., SIT, C.H.P., LU, Y.J., BENSLEY, S., WOODLAND, P.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: In keeping with a current global trend, Hong Kong is facing the public health concern of childhood obesity (Huang et al., 2018). Involvement in team sports promotes a more active lifestyle, enhances physical fitness and improves clinical health markers in

children and adolescents (Hills et al., 2015). Unfortunately, very few studies in China and Hong Kong have placed emphasis on the use of team sports, such as soccer, among "at-risk" youth groups as an intervention strategy to increase physical activity levels, as well as physical and psychosocial status.
METHODS: Male Participants from the Hong Kong Football Association (HKFA) Primary and Youth District Football development programme, based in different districts in Hong Kong, were recruited to participate in this study. Classes and age groups from each district were selected at random for the data collection. Each weekly 60 min football training session was administered by a qualified HKFA coach. Measures of self-perceived football skills, interest in sports, importance of sports, life satisfaction, self-esteem, self-efficacy and the Physical Activity Rating for Children and Youth (PARCY) were taken to assess the effectiveness of a football programme as a tool to enhance various football and health-related measures. Data collection took place pre- and post- a 10 month structured football training programme to assess and observe changes in responses throughout the programme. Paired sample t-tests were adopted for the statistical analysis. At least 1 researcher was present for each class, to explain the online questionnaire completion format and answer any questions from the participants. All questionnaires were prepared in bi-lingual.
RESULTS: This study involved 563 male participants with ages ranging from 7-18 (mean: 12.2 ± 2.6). Significant improvements were observed in: 1. Football-related measures, including skills (p=0.00); interest (=0.013); and importance (p=0.00). 2. Psychological-related measures, including life satisfaction (p=0.00); self-esteem (p=0.028) and self-efficacy (p=0.00) & 3. PARCY (p=0.00). See table 1.
CONCLUSION: The current study has shown that the football programme has enhanced indicators for each of football-, psychological- and physical activity-related measures in Hong Kong boys. In addition this study offers practical implications as a potential indicator for the optimisation of physical and psychological health through a structured soccer training programme and a strategic application of sports-programme promotion, among children & adolescents in Hong Kong and Southeast Asia.

PHYSICAL ACTIVITY LEVELS AND SELF-RATED HEALTH IN SPANISH SCHOOLCHILDREN: A TREND ANALYSIS, 2011-2018

GRAO-CRUCES, A., PADILLA-MOLEDO, C., CONDE-CAVEDA, J., SEGURA-JIMÉNEZ, V., SÁNCHEZ-OLIVA, D., NUVIALA, R., CUENCA-GARCÍA, M., CAMILETTI-MOIRÓN, D., CASTRO-PIÑERO, J.

UNIVERSITY OF CADIZ

INTRODUCTION: Physical activity (PA) is a well-recognized indicator of physical, psychosocial, and cognitive health in children (Poitras et al., 2016). Therefore, tracking the temporal trends of PA in children might be useful to prevent future public health concerns. Limited studies have analyzed the temporal trends of device-measured PA in children and their results are not conclusive (Møller, et al., 2008; Raustorp & Ludvigsson, 2007). The purpose of this study was to examine the temporal trends of PA and self-rated health in Spanish children from 2011/12 to 2017/18.
METHODS: A total of 532 (54.3% girls) children (4th graders) from 23 schools and 459 (49.0% girls) children (4th graders) from 19 schools of Cadiz region were assessed in 2011/12 and 2017/18, respectively. Participants carried a hip-worn accelerometer during 7 consecutive days, which was used to assess PA. Self-rated health was measured through the classic self-rated health status item that consist of asking respondents to rate their health as "excellent, good, fair, bad or poor". Analysis of covariance was used adjusting by age, maternal education and accelerometer wear time (when PA was the dependent variable).
RESULTS: We found a significant time trend decline of PA levels in boys [548.8±146.5 counts per minute (cpm) vs. 474.6±150.4 cpm, p<0.001], which was accompanied by a time trend decrease in the percentage of boys who met the recommendation of 60 daily minutes in moderate-to-vigorous PA (80.0% vs. 52.8%, p<0.001). Although this trend was not observed among girls (443.0±117.4 cpm vs. 440.0±125.8 cpm, p>0.05), girls still are less active than boys (p<0.05). Boys self-rated health decreased from 2011/12 to 2017/18 (4.1±.0.7 vs. 3.7±0.9, p<0.001), with non-significant differences in girls (4.1±.0.8 vs. 4.0±0.8, p>0.05).
CONCLUSION: Spanish boys PA levels and self-rated health have declined during recent years. These findings highlight the need to promote interventions to increase PA levels and self-rated health among the new generations of boys. Likewise, PA promotion interventions should be extended to girls, because of their worrying low PA levels.

ACCELEROMETER-MEASURED PHYSICAL ACTIVITY IN CHILDREN AND ADOLESCENTS AT ALTITUDES OVER 3,500 METERS: A CROSS-SECTIONAL STUDY IN TIBET

WANG, M.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: There is a scarcity of studies on physical activity (PA) in children and adolescents living under high altitude environment. Chinas Tibet Plateau is the highest altitude (>3,500 m) region. Residents in Tibet have the special lifestyle characteristics. This study aimed to objectively assess PA of children and adolescents living on the Tibet and to examine its difference by ethnicity, gender, age grade, and body weight status groups.
METHODS: A cross-sectional study was conducted using quota sampling with 398 children and adolescents aged 9-18 years (50% boys, 50% Tibetans) from 7 schools in Lhasa, Tibet. PA was measured using accelerometers (ActiGraph GT3X) for seven consecutive days. Different PA intensities were identified by the cut-points of Evenson (2008). Subjects were divided into non-overweight (Non-OW) and overweight/obese (OW/OB) groups according to body mass index (BMI). Inter-group differences in moderate-to-vigorous intensity PA (MVPA) was tested by independent sample Mann-Whitney U test. Wilcoxon signed rank test was applied to assess the differences of MVPA time at weekdays and weekends. Partial correlation was conducted to examine the trend of MVPA with increase of age.

RESULTS: The average daily MVPA in children and adolescents living on Tibet were 52.2 (SD: 30.0) min, with 38.2 (SD:27.7) min during weekdays and 57.7 (SD: 21.0) min at weekends. Tibetans students were more active than Han students (55.4 vs. 48.8 min/day, p<0.01); boys had more MVPA than girls (60.1 vs. 44.5 min/day, p<0.001). After controlling for ethnicity, gender and wearing time, age was significantly negatively correlated with MVPA (p<0.001). MVPA was significantly lower in the participants from senior grades than those from junior grades (p<0.05). There was no significant difference in MVPA between Non-OW and Non-OW groups. Overall, only 3.0% (5.6% in boys and 1.5% in girls) could accumulate at least 60 minutes of MVPA per day.
CONCLUSION: Compared to their counterparts in other countries, the daily MVPA of children and adolescent living on Tibet Plateau at altitudes over 3,500 meters was relatively high, however, the proportion of meeting WHOs PA recommendation was extremely low. Further studies to increase Tibetan children and adolescents' PA to a recommended level should be prompted.

OP-PM39 Health and fitness: Pregnancy - HIIT - Timing of exercise

RELATIONSHIP BETWEEN LONGITUDINAL CHANGES IN RESTING ENERGY EXPENDITURE AND BODY COMPOSITION DURING PREGNANCY

VAN OORT, A.F., MOSS, S.J., SCHUTZ, Y.

NORTH-WEST UNIVERSITY

INTRODUCTION: The prevalence of obesity during pregnancy are on the increase. Resting energy expenditure (REE) – which contributes to 60% of total energy expenditure – may be an important consideration in decreasing obesity during pregnancy. The aim of this study is to examine the relationship between changes in REE and changes in body composition during pregnancy.
METHODS: We used the data from a longitudinal observational study-design - the Habitual Activity Patterns during PregnancY (HAPPY) study. Measurements were taken in the 1st (9 – 12 weeks), 2nd (20 – 22 weeks) and 3rd trimester (28 – 32 weeks) of pregnancy from 41 women. Body composition measurements of height, weight, and fat percentage by means of skinfolds were captured. REE was measured by means of indirect calorimetry with the FitmateTM. A regression analysis was performed to determine the relationship between longitudinal changes in REE and body composition variables.
RESULTS: Fat percentage increased from the first trimester (24.38 ± 8.53%) to the second trimester (27.16 ± 6.58%) and third trimester (29.34 ± 6.19%). Weight gain in the first trimester was 3.24 ± 3.61 kg, 5.18 ± 5.37 kg in the second trimester, and 4.90 ± 3.10 kg in the third trimester. The REE during the first trimester was 5552 ± 1259 kJ/day, 5502 ± 1456 kJ/day in the second trimester and 6138 ± 1921 kJ/day in the third trimester. When adjusted for weight, REE equated 84.64 kCal/kg/day in the 1st trimester, 76.48 kCal/kg/day in the 2nd trimester and 77.70 kCal/kg/day in the 3rd trimester. In the first trimester, 27% ($r^2 = 0.266$, $p = 0.024$), second trimester 19% ($r^2 = 0.198$, $p = 0.022$) and third trimester 61% ($r^2 = 0.607$, $p = 0.002$) of the variability in REE could be accounted for by the body composition variables.
CONCLUSION: Body composition partly explains the variability of REE during each trimester of pregnancy. Future studies need to deliberate on estimating minimal clinically important differences of REE between trimester of pregnancy and in response tailor energy intake and physical activity recommendations.

EFFECT OF AEROBIC EXERCISE DURING PREGNANCY ON OFFSPRING VASCULAR STRUCTURE

HOPKINS, N.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: The intrauterine environment is a critical determinant of long term cardiovascular risk in offspring. Unfavourable intrauterine environments have been linked with negative vascular changes in neonates. Conversely, animal data suggests that exercise training during pregnancy confers positive changes to the vascular health of the progeny, however these results are yet to be confirmed in humans. The aim of this study was to investigate the impact of gestational aerobic exercise in healthy women on offspring carotid artery intima media thickness (cIMT).
METHODS: Eighteen healthy, previously inactive, singleton pregnant participants were recruited at 13-15 weeks gestation and allocated to an exercise (EX N=7, 33 ± 4 years old) or control (CON N=11, 33 ± 3 years old) group. The exercise group completed 3 exercise sessions/week during trimesters 2 and 3. The exercise consisted of 3x15 minute exercise sessions/week, progressing to 4x30 minutes/week at 60-70% maximum heart rate in line with the recommendations from the Royal College of Obstetricians and Gynaecologists. Birth outcomes were collected from hospital delivery notes. Within 12-weeks of birth, offspring carotid artery diameter and IMT were measured using high resolution ultrasound. An independent samples t-test was used to identify differences between EX and CONT offspring IMT.
RESULTS: Overall compliance to the exercise intervention was 78%, (trimester 2; 89% and trimester 3; 67.6%) and all participants adhered to the exercise. There were no adverse events reported during gestation or birth in either group. There were no differences in cIMT (EX 0.45 ± 0.06mm, CON 0.49 ± 0.07mm, P=0.60) and lumen diameter (EX 2.92 ± 0.13mm, CON 2.88 ± 0.40mm, P=0.12) between groups. There was no difference in gestational age at birth (P=0.72) or birth weight (P=0.50) between CON and EX.
CONCLUSION: This is the first investigation into the effect of human gestational exercise on offspring vascular programming. There were no significant differences in offspring cIMT between the exercise and control groups. Nonetheless, a trend for an increased carotid artery diameter in the exercise group lends support to the potential foetal vascular programming effects of gestational exercise. Further research is needed to confirm this hypothesis.

PHYSIOLOGICAL AND PSYCHOLOGICAL EFFECTS OF LOW VOLUME HIGH INTENSITY INTERVAL EXERCISE IN YOUNG AND OLDER MEN

KAMANDULIS, S., SNIECKUS, A., BRAZAITIS, M., KRUSNAUSKAS, R., BARANAUSKIENE, N., EIMANTAS, N., VENCKUNAS, T.

LITHUANIAN SPORTS UNIVERSITY

INTRODUCTION: High-intensity interval training (HIIT) induces modifications in type I ryanodine receptor, which can cause Ca2+ leakage from the sarcoplasmic reticulum at rest and reduce Ca2+ release during muscle contractions (1). These intrafibrillar Ca2+ cycling disturbances significantly reduce muscle contraction force and power, but also trigger beneficial adaptations. Despite the well-documented HIIT

benefits to fitness, it also induces unpleasant sensations related with build-up of metabolites (2). The aim of the present study was to search for HIIT modalities that are both enjoyable and time efficient, yet still confer substantial benefits for health and exercise capacity.
METHODS: Young (age 22.3 ± 4.6 years) and older (age 69.9 ± 6.3 years) men performed three interval cycling sessions which differed in intensity and duration: 6 sets of 5 s all-out; 3 sets of 30 s all-out, or 3 sets of 60 s submaximal, each performed 5 weeks apart in randomized order. Isometric maximal voluntary contraction and 20 (P20) and 100 (P100) Hz electrical stimulation evoked knee extension torques were measured at baseline and then immediately, 1 h, and 24 h after exercise. Concentrations of blood lactate and testosterone were measured and rating of perceived exertion, enjoyment and preferred exercise type were assessed.
RESULTS: Peak and average power were higher during 5 s sprints, followed by 30 s sets, and the smallest during the 60 s bouts in both groups. Younger group developed higher power while lactate concentration was higher in the young than in the older group in response to all three sessions ($p < 0.05$). The increase in testosterone concentration was evident immediately (5 min) after the exercise in both groups in response to 3 x 60 s session and also in response to 3 x 30 s in young subjects. Sessions of 3 x 30 s and 3 x 60 s evoked larger degree of stimulated torque and MVC depression in both groups as compared to 6 x 5 s session. Old men ranked the 6 × 5 s session as the most preferred for further training, while the 3 × 30 s session was most frequently preferred by young subject.
CONCLUSION: The study confirmed that as little as 6 x 5 s all-out cycling induces not only metabolic perturbations but also depression of muscle contractile function in both young and old men. The findings also indicate that the reduced ability to exert maximally in older people may require them a larger overall duration of intense exercise to achieve the same cumulative stress and health benefits as of younger exercisers.

THE INFLUENCE OF SHORT-TERM AEROBIC CONDITIONING ON CHRONIC RESISTANCE TRAINING OUTCOMES IN HEALTHY YOUNG MEN AND WOMEN.

THOMAS, A., MCGLORY, C., PARISE, G.
MCMASTER UNIVERSITY

INTRODUCTION: Resistance exercise training is the most effective and accepted strategy for increasing skeletal muscle mass and strength. There is tremendous individual variability in the adaptive response to exercise and the source(s) contributing to this variability are largely unknown. Recent evidence in the literature supports the notion that capillaries may be a potential target for improving outcomes to chronic resistance exercise. Aerobic exercise training is a proven stimulus for eliciting angiogenesis and increasing capillary content. Therefore, we hypothesize that completing a period of aerobic training prior to resistance training will result in a greater increase in fibre cross sectional area (CSA) compared to resistance training alone.
METHODS: 14 participants (8M, 6F) completed 6-weeks of unilateral single leg aerobic training prior to undergoing 10-weeks of bilateral lower body resistance exercise training. Performance and anthropometric measures were completed at baseline, post aerobic training and post resistance training. Skeletal muscle biopsies were obtained from the vastus lateralis and immunofluorescent staining of muscle cross sections was completed to determine fibre CSA.
RESULTS: Single leg VO2 watt peak ($p<.0001$), and consumption (O2mL/min) ($p=.0032$) was significantly higher in the trained versus untrained leg following unilateral aerobic training. Both single leg VO2 watt peak ($p<.001$), and consumption (O2mL/min) ($p=.0123$) remained higher in the aerobically trained leg following resistance exercise. Resistance training resulted increases in 1 repetition maximum of both squat ($p<.0001$) and leg press ($p<.0001$). A main effect of time was observed for leg lean mass ($p<.0001$) as determined via DXA. Preliminary results (n=5) indicate that type I and type II fibre CSA was 28% and 26% greater, respectively, in the aerobically trained leg following resistance training.
CONCLUSION: Results suggest that a period of unilateral aerobic training elevates the aerobic capacity of the trained leg significantly in comparison to the non-exercising limb. Furthermore, these aerobic changes are maintained following a 10-week period of bilateral resistance training. Bilateral leg strength increased post resistance training whilst preliminary CSA results may suggest altered adaptation of an previously aerobically conditioned leg following resistance exercise training.
Preliminary results suggest that a period of aerobic preconditioning may augment the muscle's ability to respond to a hypertrophic stimulus.

HIT THE GYM BEFORE YOU HIT THE HAY? THE IMPACT OF MODERATE AEROBIC EXERCISE AND MODERATE RESISTANCE EXERCISE ON NIGHT-TIME SLEEP.

MILLER, D.J., SARGENT, C., ROACH, G.D., SCANLAN, A.T., VINCENT, G.E., LASTELLA, M.
CQUNIVERSITY

INTRODUCTION: To maintain a healthy lifestyle, humans should exercise regularly and obtain 7-9 hours of sleep per night. However, in a time-poor society, exercise and sleep may compete with each other. For those who cannot exercise in the morning, evening exercise may be the only alternative to maintain health. Traditional sleep hygiene recommendations advise against exercising in the evening because an increase in core body temperature in response to evening exercise may negatively impact sleep. However, recent epidemiological and experimental data suggest that evening exercise may have no detrimental effects on sleep. Thus, the mechanisms responsible for how evening exercise and any associated increases in core body temperature may impact subsequent sleep are unclear. Furthermore, no studies have examined the effect of the modality of exercise performed in the evening on sleep. The aim of this study was to compare the effect of single bouts of aerobic exercise and resistance exercise performed in the evening on subsequent sleep in healthy young males.
METHODS: A repeated-measures, counterbalanced, crossover design was employed to examine the effect of three conditions (control, evening aerobic exercise, and evening resistance exercise) on sleep. Twelve participants (mean ± SD; age: 27.3 ± 3.4 yr) attended a purpose-built sleep laboratory overnight on three occasions, with 1 washout day between each visit. At 20:45h on each experimental night, participants completed either no exercise, 30 minutes of aerobic exercise at 75%HRmax, or 30 minutes of resistance exercise corresponding to 75% of 10-repitition maximum. A 9-h sleep opportunity was provided in all conditions from 23:00h until 08:00h. Sleep was measured using standard polysomnography. Core body temperature was continuously measured (1-min epochs) using ingestible core body temperature capsules.

RESULTS: Core body temperature was significantly higher during aerobic exercise compared to resistance exercise and the control condition (p=0.001). Core body temperature did not differ between conditions at bedtime (p>0.05). Total sleep time, time spent in each sleep stage, sleep onset latency, wake after sleep onset and sleep efficiency did not differ between conditions (p>0.05).
CONCLUSION: In conclusion, aerobic and resistance exercise ceasing 90 min before bed did not impair the sleep of healthy young males. When performed at a moderate intensity, aerobic exercise seems to result in a marked increase in core body temperature compared to resistance exercise. Therefore, if aerobic exercise was performed closer to bedtime (e.g., <90 min before bed), it is possible that core body temperature may remain elevated and may interfere with sleep. Future research should aim to manipulate the duration/intensity/timing of exercise, all of which are factors that could change the impact of exercise on sleep.

HIGH-INTENSITY INTERVAL TRAINING AMELIORATES CEREBROVASCULAR PHENOTYPE WITHOUT IMPROVEMENTS IN CENTRAL ARTERIAL STIFFNESS: CONSEQUENCES AND POTENTIAL MECHANISMS

STREESE, L.

UNIVERSITY OF BASEL

INTRODUCTION: Screening of subclinical vascular alterations is important to evaluate the process of vascular ageing and predict the development of cardiovascular (CV) disease. High-intensity interval training (HIIT) has the potential to improve cardiorespiratory fitness and vascular health. This study aimed to investigate whether HIIT can reverse large artery stiffness and microvascular endothelial dysfunction in older patients with increased CV risk.
METHODS: Eighty-four (aged 58±6 years) patients with ≥2 CV risk factors were randomized to a 12-week walking based HIIT or physical activity recommendations as control condition. Central arterial stiffness (AST) was measured by carotid-femoral PWV (cfPWV) using the SphygmoCor CPV® device. The microvascular phenotype was assessed by analysing retinal vessel diameters as well as retinal flicker light-induced maximal arteriolar dilatation (ADmax), as marker for retinal microvascular endothelial function, using the Retinal Vessel Analyzer. In addition, anthropometric measurements, cardiorespiratory fitness as well as systemic oxidative stress were investigated before and after 12-weeks. Plasma 3-nitrotyrosine (3-NT) was measured by ELISA kits as a systemic oxidative stress marker.
RESULTS: HIIT reduced body weight, body mass index, fat mass, low-density lipoprotein and increased muscle mass and maximal oxygen uptake (VO2max). HIIT induced wider retinal arteriolar (pre: 175 ±14µm vs post: 181 ±13µm, p=0.001) and narrower venular diameters (pre: 222 ±14µm vs post: 220 ±14µm, p=0.007). ADmax (pre: 102.7±2.1% vs post: 103.0±2.2%, p=0.018) increased after HIIT compared to CC. HIIT blunted 3-NT plasma levels (pre: 5.7±5.2µg/ml vs post: 3.8±2.2µg/ml). No direct influence of classical risk factors such as reduction of body weight, BMI, fat mass, blood pressure or LDL on microvascular amelioration was observed (p>0.05 for all). Increased VO2max was significantly associated with improvement of retinal vessel diameters as well as improved microvascular endothelial function (p<0.05). cfPWV did not change after HIIT.
CONCLUSION: 12-weeks of HIIT reduced classical risk factors and improved retinal vessel diameters as well as flicker-light induced arterial dilatation with a concomitant reduction of systemic oxidative stress. Assessment of retinal microvascular function seems to be more sensitive to detect vascular effects of exercise treatment compared to large artery stiffness. Increased cardiorespiratory fitness and associated reduced oxidative stress seem to be a key mechanism for exercise-induced improvements in microvascular health.

Invited symposia

IS-MI03 Sport for athletes with disability: Classification research, smart monitoring technology

SPORT FOR ATHLETES WITH DISABILITY: CLASSIFICATION RESEARCH, SMART MONITORING TECHNOLOGY AND TRAINING OR PERFORMANCE ISSUES IN WINTER SPORTS FOR INDIVIDUALS WITH DISABILITY

VANLANDEWIJCK, Y.

KU LEUVEN

The purpose of classification in the Paralympic Movement is to minimize the impact of impairment on competition outcome and to prevent athletes from dropout. In November 2015, the General Assembly of the International Paralympic Committee (IPC) approved the revised IPC Classification Code, providing comprehensive guidelines, policies and procedures for the conduct of classification in sports governed by the IPC or its member federations. From a sport science perspective, the code is significant because it explicitly mandates the development of evidence-based classification systems (1). To support the evidence-based approach in classification, IPC recognized three Research & Development Centers for Classification, for athletes with Physical (QU Brisbane, Australia), Visual (VU Amsterdam, The Netherlands), and Intellectual (KU Leuven, Belgium) impairments.
Since 2003, KU Leuven has collaborated in an international research effort to reinstate athletes with Intellectual Impairment in the Paralympic Movement. The International Research group has established a four-step procedure to decide on the eligibility of athletes with Intellectual Impairment. After providing primary evidence of the athletes' intellectual impairment (step 1), athletes go through a generic (step 2) and a sport-specific intelligence test (step 3); finally, all athletes are observed during competition (step 4). After explaining the four-step procedure, we will provide a research state-of-the-art for each step, with examples from athletics, basketball and Nordic skiing. Conclusively, we will discuss future research to optimize the eligibility and classification process of athletes with Intellectual Impairment.

SMART SENSOR TECHNOLOGY AND MODERN MEASUREMENT TOOLS AND CONCEPTS IN WINTERSPORTS FOR ATHLETES WITH DISABILITY - OPTIONS FOR TRAINING AND RACE ANALYSES

LINDINGER, S.

UNIVERSITY OF GOTHENBURG

Introduction
Biomechanical-physiological aspects of skiers with vs. without physical impairments in Winterport are hardly examined. Knowledge about functional mechanisms or limitations are lacking (eg. group of spinal cord injury people). Efficient monitoring of impairment effects

during competition and training requires smart sensor technologies. In sit-skiing, the impact of functional limitations on performance (different functional challenges) alters over track profiles but is unknown in detail, although crucial for a correct class and race %-system assignment (Tweedy et al., 2016). Smart split-time, GPS and force systems were developed for race/training analyses. Purposes were to 1) provide a simple, magnetometer-based split-time system, 2) to establish high-standard GNSS technology and 3) to develop force systems for sit-skiing to monitor racing and training in these particular target groups.
Methods
Relevant variables were measured by: Split-times: Magnetometer systems/IMUs (Supermagnete Disc Magnets (20 & 15 mm), GER/"9DoF Razor"-IMU, Spark Fun Electronics, USA; 100 Hz); Track profiles: Leica-GNSS-Systems (Leica AG, SUI); Speed: portable GNSS receiver (AT-H-02; JAPAN); Pole forces: mini, real-time system for mechanical work (SkiSense, SWE; 400 Hz). Leg 3D-forces: force bindings (strain-gauge sensors; Univ. of Jyväskylä, FIN; 1000 Hz). Technique recognition/speed: combined IMU-GNSS system (Archinisis, CH).
Results
Paralympics data showed largest split-time effects in uphills with smaller impairment effects in flat parts (5 different sit-ski classes (10-12)): Split-time differences - uphill (LW10 vs. others; male): Diff10vs11:-21.7% (-10.5 s), Diff10vs11.5:-25.5% (-12.3 s), Diff10vs12:-26.9% (-13 s) with further decreases for Diff11vs11.5, Diff11vs12, and Diff11.5vs12 from -5.1 to -1.4%. Flat terrain: Diff10vs11:- 9.0% (-1.9 s), Diff10vs11.5:-13.2% (-2.8s), Diff10vs12:-14.0% (-3.0 s) and furthermore Diff11vs11.5, Diff11vs12 and Diff11.5vs12 from -5 to -0.8%. Sharp curves: Diff10vs11:-8.7% (-0.8s), Diff10vs11.5:-18.4% (-1.8s), Diff10vs12:-8.4% (-0.8s) with Diff11vs11.5 (-9.7%) and increases back up for Diff11vs12 (0.4%) and Diff11.5vs12 (10.1%). Speed profiles, technique change patterns and force profiles showed class-specific patterns and helped discriminating classes.
Discussion
Used technologies contributed to understand the impairment-performance relationships for skiers with physical impairment. Uphill-sections discriminated most between classes with half effects in flats. Results partly suggest that track-profiles influence time differences and the %-system could be likewise adjusted. The introduced technology is applicable repeatedly also to visual and intellectually impaired skiers. Further race analyses can bring a solution for %-systems and classification if combined with other tests.

TRAINING INTERVENTIONS AND PERFORMANCE IN DISABLED ELITE SPORTS

PERRET, C.
SWISS PARAPLEGIC CENTRE

Introduction
The number of competing nations at Paralympic Summer Games more than doubled since Athens 2004. In parallel, Paralympic sports performance tremendously improved over the past 15 years. Nowadays, often less than a 0.5% difference in performance decides on winning or losing a medal at international championships, which underlines the necessity of optimizing training interventions and equipment in order to achieve top class performances.
Methods
This presentation will focus on various interventions and adaptations in order to improve wheelchair sports performance taking the special physiological circumstances (e.g. impaired respiratory muscle function; thermoregulatory problems) of these athletes into account. Discussed interventions will include respiratory muscle training strategies, nutritional interventions using supplements, cooling interventions as well as individual equipment adaptations.
Results
Respiratory muscle training seems to enhance wheelchair endurance performance, whereas in the field of investigated supplements caffeine seems to reveal the highest ergogenic potential to increase (sprint) performance. Further, precooling interventions seem to reduce thermal stress and to improve performance in athletes with a tetraplegia. Significant impacts on performance were also found by adapting the body position in sit skiing, the configuration of basketball wheelchairs or by optimizing the aerodynamic properties when changing the handbike set-up.
Conclusions
Beside the conventional basic training process there seem to exist several intervention strategies to further enhance wheelchair sport performance of different sport disciplines. The implementation of respiratory muscle training, cooling interventions, a well-directed use of caffeine or individual equipment adaptations seem to offer promising options and may make the small difference responsible for winning or losing a medal competing at international championships.

OP-PM44 Nutrition: Carbohydrates and dietary regimens

THE EFFECT OF A LOW CARBOHYDRATE HIGH FAT DIET ON BODY COMPOSITION AND INSULIN SIGNALLING.

MCCULLOUGH, D., HARRISON, T., BODDY, L., AMIRABDOLLAHIAN, F., ENRIGHT, K., LANE, K., STEWART, C.E., DAVIES, I.G.
LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Cardiovascular diseases are the number one cause of death globally but can be prevented by modifying lifestyle factors such as, diet, obesity and physical inactivity (1). However, time constraints have been cited as a barrier to achieving the recommended physical activity levels. It may be possible to improve cardiometabolic (CM) risk via altering diet composition alone. Controlled studies have shown that low carbohydrate, high fat (LCHF) diets can reduce a variety of CM risk markers (e.g., insulin resistance) (2). However, the underlying mechanisms are yet to be elucidated. The impact of serum on insulin mediated metabolic tissue may reveal such mechanisms. It also remains to be investigated if this diet can be replicated in a 'free living' population. Therefore, the purpose of this study was to investigate the effects of an ad libitum LCHF diet on CM risk markers in adults.
METHODS: n=8 participants (44 ± 10y, 89.5 ± 14.6 kg) followed an ad libitum LCHF diet (<50g CHO) for 8 wks. Blood samples were collected at 0, 4 and 8 wks. Body composition was measured using bioimpedance (SECA mBCA 515). Four-day food diaries were recorded. Participants wore an accelerometer to measure physical activity at weeks -1, 3 & 7. Following attainment of 80% confluence, murine skeletal muscle C2C12 cells were transferred to low serum medium containing human serum (baseline (PRE) vs end of intervention (POST))

for 24 hours, prior to stimulation for 5 mins in 0nM, 10nM or 100nM insulin. Cells were fixed and processed for flow cytometry analysis after incubation with phospho-Akt (ser473) antibody.
RESULTS: Food diary analysis confirmed that participants significantly reduced their CHO consumption (42 ± 9% to 10 ± 4%, P<0.001) and increased their fat intake (34 ± 4% to 61 ± 6%, P<0.001) while also maintaining a similar energy intake throughout (1974 ± 618 kCal to 1728 ± 482 kCal, P=0.392). Participants also maintained a similar total physical activity level (218.4 ± 44.1 mins p/day to 270.8 ± 101.5 mins p/day, P=0.215). Fat mass (FM) significantly declined over 8 weeks (32.1 ± 11.6 kg to 29.1 ± 3.4 kg, P<0.001). Preliminary data for cells in 2% PRE showed reduced Akt phosphorylation when stimulated with 10nM (-13.26%) and 100nM (-3.3%) of insulin compared to 0nM. However, cells in 2% HPOST showed an increase in Akt phosphorylation when stimulated with 10nM (+3.34%) and 100nM (+38.65%) compared to 0nM.
CONCLUSION: The findings of this study demonstrate that LCHF diet can directly reduce FM without exercise, perhaps via an improvement in glucose metabolism. Preliminary data also suggest that the LCHF diet can improve insulin sensitivity at the cellular level within skeletal muscle cells. Data provide insight into the benefits of reduced carbohydrates on fat loss and improved insulin sensitivity, warranting further investigation.

EFFECTS OF A VERY LOW CARBOHYDRATE KETOGENIC DIET ON BODY COMPOSITION, MUSCLE STRENGTH, MUSCLE AREA, METABOLISM AND PERFORMANCE IN SEMI-PROFESSIONAL SOCCER PLAYERS

PAOLI, A.1, MANCIN, L.2, CAPRIO, M.3, MONTI, E.1, CENCI, L.4, MARCOLIN, G.1, GRIGOLETTO, D.1

1 UNIVERSITY OF PADOVA, 2 VITA E SALUTE UNIVERSITY, MILAN, 3 SAN RAFFAELE ROMA OPEN UNIVERSITY, ROME, 4 SAN BORTOLO HOSPITAL. VICENZA

INTRODUCTION: Very low carbohydrate ketogenic diet (VLCKD) is a nutritional approach that restricts daily carbohydrates to under 30 g/d, replacing the majority of reduced energy with fat, while maintaining moderate quantities of protein. Despite the increasing use of VLCKD on weight control and other health outcomes, there are still many concerns about the use of VLCKD on sport performance, pointing out the urge of a greater understanding of its advantage for sport purposes. Thus, the present study sought to investigate the influence of a VLCKD on body composition and muscle strength, muscle area, metabolism and performance
METHODS: Sixteen semi-professional soccer players aged (25.5±2.6) were randomly assigned to a very low carbohydrate ketogenic diet (VLCKD n=8) or to a western diet (WD n=8). Diets had the same amount of protein (1.8g/Kg/body weight/day). Carbohydrates were less than 30g/day in the VLCKD whilst carbohydrates provided about 55%, of total daily energy in the WD.
Body weight body composition and, visceral adipose tissue VAT were measured by DXA. Resting energy expenditure (REE), respiratory exchange ratio (RER) were measured by indirect calorimetry. Cross sectional area CSA of quadriceps and isometric muscle strength were also measured. Counter movement jump (CMJ) for explosive strength and yoyo intermittent recovery test were performed. Ketonemia was monitored by ketones concentration in capillary blood weekly. A 2 Way ANOVA, Time per Diet was used, in order to investigate between and within group differences.
RESULTS: Dietary energy intake was slightly higher without significant difference during VLCKD (1984±340Kcal/day) compared to WD (1752±320Kcal/day). There was a significant decrease of body fat (p=0.0359), VAT (p=0.0018), waist circumference (p=0.0185) and extracellular water (p=0.0060) in VLCKD vs WD group. Lean mass, quadriceps muscle area and maximal strength were maintained in both groups. There were no changes for absolute and relative (Kcal/Kg) REE in both groups whilst RER decreased significantly in VLCKD (p=0.0008).
Yoyo intermittent test improved significantly (p<0.0001) in both groups without differences between groups. CMJ improved significantly (p=0.0021) in VLCKD, with no change in WD.
CONCLUSION: To the best of our knowledge this is the first study investigating the effects of a VLCKD on performance in a team sport like soccer. Despite there are still many concerns about the use of VLCKD in sports, our results suggested that it could be use safely in semi professional soccer players. In our study VLCKD athletes lost fat mass without negative effects on strength, power and muscle mass. The significant greater reduction in VAT during VLCKD represents a novel and potentially clinically significant finding that deserves further investigation. When the goal is a rapid weight reduction coaches and athletes should consider the use of a VLCKD as a feasible and safe tool.

VOLUNTARY WHEEL RUNNING ACCELERATES PHGG-INDUCED GUT ENVIRONMENTAL IMPROVEMENT IN HIGH-FAT-DIET FED MICE

AOKI, T., OYANAGI, E., WATANABE, C., TERAMOTO, F., KREMENIK, M.J., YANO, H.

GURADUATE SCHOOL OF KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Partially hydrolysed guar gum (PHGG) is a water-soluble dietary fibre prepared from guar gum. Recently, dietary PHGG has been demonstrated to be beneficial in the treatment of metabolic syndrome (Yasukawa, et al. 2012, J. Clin. Biochem. Nutr.; Dall'Alba, et al. 2013, Br. J. Nutr.). PHGG, similar to other dietary fibres, is not digested in the upper gastrointestinal tract and is fermented by colonic bacteria. Accordingly, PHGG action is strongly regulated by gut microbiota diversity and its production of metabolites. On the other hand, recent studies showed that exercise training altered gut microbiota (Zuheng, et al. 2017, Front. Microbiol.; Cani et al. 2019, Nat. Metab.). The purpose of this study was to clarify the effect of PHGG intake and exercise on gut environment in high-fat-diet fed mice.
METHODS: Four-week-old male C57/BL6J mice (n=37) were randomly divided into the following 6 groups; the control-diet and sedentary control (CDC), the high-fat-diet and sedentary control (HFDC), PHGG + CDC (GCDC), PHGG + HFDC (GHFDC), PHGG + CD + wheel running (GCDW), and PHGG + HFD + W (GHFDW). The feeding period was for 10weeks, and body mass, food intake, and fresh fecal pH which is evaluated for the gut environment of mice, were measured. After the end of this experimental period, feces were collected, and then the mice were sacrificed to harvest tissues under anesthesia. The mRNA expressions from the collected tissues were analyzed by real-time qPCR.
RESULTS: Fecal pH at 6 weeks was significantly decreased by PHGG on mice. Moreover, this alteration was accelerated by voluntary exercise (GCDC vs GCDW, HFDC vs GHFDC, GHFDC vs GHFDW; p<0.05, p<0.01 and p<0.01, respectively). At 10 weeks, the fecal pH in all groups but HFDC mice was high. Cecum content of high-fat-diet mice tended to increase due to PHGG (HFD vs GHFDC, p=0.059). Exercise increased cecum content of GCD mice (p < 0.01). In the skeletal muscle of CD mice, Pgc-1• and Cox4 expressions tended to increase

with PHGG intake (CDC vs GCDC; p=0.089 and p=0.063, respectively). However, in HFD mice, the alteration of those with mRNA expressions was inhibited by PHGG intake (HFDC vs GHFDC; p=0.051 and p<0.05, respectively).
CONCLUSION: PHGG might induce different influences between skeletal muscle in CD and HFD mice via changes in the gut microbiota community. Taken together, PHGG feeding on HFD-induced obese mice with an altered gut environment. And, this alteration was might accelerated even more by exercise.

CYSTINE AND GLUTAMINE ALLEVIATES THE EXERCISE-INDUCED DISRUPTION OF GUT BARRIER FUNCTION, THROUGH SUPPRESSING INFLAMMATION

MIZUGAKI, A.1, MATSUI, Y.2, MATSUBA, K.3, NOGUSA, Y.1, INOUE, Y.1, TOYODA, T.4, KATO, H.1, MIYAKAWA, S.5
1,4:AJINOMOTO CO., INC. 2:TSUKUBA UNIVERSITY OF TECHNOLOGY 3:UNIVERSITY OF TSUKUBA HOSPITAL 5:UNIVERSITY OF TSUKUBA

INTRODUCTION: Strenuous exercise induces systemic and local inflammation which disrupt the intestinal barrier function. Exercise-induced disruption of gut barrier, which is related with gastrointestinal tract complaints such as nausea, vomiting and diarrhea, is a crucial issue necessary to be addressed for athletes. (1). Cystine (Cys2) and glutamine (Gln) are known to be anti-inflammatory nutrients. While Gln supplementation alleviated the disruption of gut barrier (2), it is unknown if Cys2 affect the disruption of gut barrier. Therefore, we aimed to examine the effect of Cys2 alone and Cys2 plus Gln (CG) on the disruption of gut barrier.
METHODS: CD2F1 mice were fed AIN93G control diet or control diet supplemented with 2% amino acids (Cys2, Gln). After 1 week of supplementation, the mice were forced to run in a wheel for 4 hours. Gut permeability was assessed by using isothiocyanate dextran (FD4). Gene expression and protein content of inflammatory cytokines and tight junction proteins in the intestine were measured by real-time PCR, western blot or ELISA. Reduced / oxidized glutathione ratio (GSH/GSSG) was analyzed by HPLC. Ten male subjects were randomly assigned to two groups: 1) CG group, which ingested the mixture of Cys2 (0.7 g) plus Gln (3.0 g), 2) Placebo group, which ingested maltodextrin (3.7 g), once a day for 5 days. On the 6th day, 30 mins after ingestion, the subjects performed endurance exercise at 70% of VO2max for 60 min using a cycle ergometer. Gut permeability was assessed by lactulose and mannitol test.
RESULTS: In mice study, 2% Cys2, or 2% Gln supplementation significantly suppressed the increase in plasma FD4 and plasma IL-6 concentration. In addition, supplementation of Cys2 significantly evoked both inhibition of Claudin2, a tight junction protein, and increase in plasma GSH/GSSG ration. In human study, supplementation of CG significantly decreased the gut permeability, compared to the placebo group.
CONCLUSION: Cys2 suppressed the exercise-induced disruption through increasing GSH/GSSG ratio which possibly suppressed systemic and local inflammation in mice model. In addition, supplementation of CG are effective for suppressing the gut barrier disruption induced by exercise in human.

TEMPERATURE EFFECTS ON RECOVERY OF MUSCLE FUNCTION

WESTERBLAD, H.
KAROLINSKA INSTITUTET, STOCKHOLM

Recovery from fatigue induced by intense exercise is of particular importance for athletes in events that require repeated exertions, such as competitions with qualifying events, and in sports that are performed over multiple days. The speed at which muscle can recover from a previous exercise bout allows for improved exercise performance in a subsequent exercise bout, which can be critical for athletic performance. Glycogen is a primary fuel for contracting skeletal muscle, and muscle glycogen depletion results in impaired contractile function. The production of reactive oxygen/nitrogen species (ROS) increases during exhaustive exercise, and ROS have been shown to have a large impact on the recovery of muscle function. Both muscle cooling and heating are used by athletes in attempts to improve recovery. Interestingly, both the restoration of glycogen stores and ROS effects are temperature sensitive. This lecture will present the mechanistic results related to temperature and ROS effects on the recovery of muscle function, with focus on complex and interacting effects.

NUTRITION TO OPTIMISE RECOVERY

WALLIS, G.
UNIVERSITY OF BIRMINGHAM

Maximising recovery of muscle glycogen content in the post-exercise period is pertinent to athletes engaging in repeated bouts of prolonged exercise with limited recovery time. Current guidelines recommend ingestion of moderate-high glycaemic index carbohydrates such as glucose-based sources in large quantities to facilitate muscle glycogen synthesis. The sugars fructose and galactose (the latter typically consumed as lactose in milk) are low glycaemic index carbohydrates, and would not typically be advised for promoting muscle glycogen restoration. However, their preferential utilisation by the liver provides the metabolic basis to support dual source sugar ingestion (i.e., combining fructose and/or galactose-containing carbohydrates with glucose-based sources; incidentally combinations typically found in chocolate milk) to maximise whole-body post-exercise body carbohydrate storage, and of most relevance potentially recovery of exercise performance. This lecture will present the latest scientific developments in this new and exciting area of sports nutrition. The talk will demonstrate how integrating nutritional science and exercise metabolism can generate translationally relevant sports science research with the potential to impact on applied practice.

SLEEP AND SPORTS PERFORMANCE

HALSON, S.

AUSTRALIAN CATHOLIC UNIVERSITY

Sleep is emerging as a key determinant of athletic performance and as such places high quality sleep in a prominent position for optimal recovery for sport. However, issues related to the accurate measurement of sleep and identification of the causal mechanisms underlying links between sleep and performance need to be delineated before evidence-based strategies can be developed to optimise sleep in athletes. While such research is paramount, there remains a pertinent need to employ pragmatic approaches to enhance sleep quality in todays athletes. This presentation draws upon experiences of sleep research conducted in elite athletic groups and in developing practical solutions to improve sleep while working at the coal-face of elite sport. Delegates will hear a unique scientist-practitioner perspective in the role of sleep and recovery of athletic performance, with research challenges and elite insights revealed. Along with a focus on sleep, the talk will help contextualise and show ways of ensuring there is relevance in the work we as sports scientists do.

IS-EX02 ECSS-JSPFSM Exchange symposium: Lactate/pyruvate metabolism in skeletal muscle

LACTATE TRANSPORTERS IN SKELETAL MUSCLE

KITAOKA, Y.

KANAGAWA UNIVERSITY

Monocarboxylate transporter MCT1 and MCT4 are believed to be the key transporters in skeletal muscle, facilitating the uptake and extrusion of lactate, respectively. These two isoforms of MCTs enable "lactate shuttle" to function during exercise in muscles. Accordingly, the expression of these MCTs may play important roles in exercise performance. Our research interest has focused on exercise-induced changes in the expression of MCT1 and MCT4 in skeletal muscle using rodents. Voluntary wheel running increased MCT1 protein level but not MCT4, whereas high-intensity interval training increased both MCT1 and MCT4 proteins. Increased MCT4 was also observed following electrical stimulation-induced resistance training. In contrast, denervation decreased MCT1 and MCT4 proteins in skeletal muscle. Thus, muscle contractile activity appears to be important for the regulation of MCTs, and high intensity is needed for up-regulating MCT4. At present, the question is how training-induced changes in MCT1 and MCT4 are regulated. AICAR-induced activation of AMPK increased MCT1 and MCT4 proteins in skeletal muscle. Treatment with ethyl 3, 4-dihydroxybenzoate, which induces Hif-1α protein accumulation, increased MCT4 expression in skeletal muscle. Further studies are needed to elucidate the underlying mechanisms regulating MCT expression.

LACTATE AS A SIGNALING MOLECULE FOR TRAINING ADAPTAION

HOSHINO, D.

THE UNIVERSITY OF ELECTRO-COMMUNICATIONS

Lactate is produced and accumulated in muscle and blood during exercise, especially high-intensity exercise. It is well-known that increases in cytochrome c concentration, which reflects mitochondrial content in skeletal muscle, occurred in an exercise-intensity-dependent manner. We reported that high-intensity interval training (HIIT) increased mitochondrial content markers in rat skeletal muscles (Hoshino et al., 2013). We focused on effects of lactate concentration on mitochondrial adaptation by HIIT. Our study showed that increases in mitochondrial enzyme activity and protein content were reduced when 4 weeks of exercise training were performed with pharmacologically lower lactate concentration during and after exercise (Hoshino et al., 2015). This result suggest that lactate accumulation during an acute exercise may be associated with mitochondrial adaptations after chronic exercise training. In addition, acute oral administration of lactate to mice increased amount of mRNA related to mitochondrial biogenesis in skeletal muscle. This suggests that lactate serves as a signal for upregulating genes related to mitochondrial biogenesis. In this presentation, it will be focused on the potential role of lactate as a signaling molecule for training adaptation of skeletal muscle uncovered by our and other studies.

EXERCISE-INDUCED PDH REGULATION IN SKELETAL MUSCLE

PILEGAARD, H.

UNIVERSITY OF COPENHAGEN

The Pyruvate Dehydrogenase (PDH) Complex (PDC) catalyzes the irreversible conversion of pyruvate to acetyl CoA. PDC has a key position in metabolism providing the only entry of carbohydrate-derived substrates into the mitochondria for oxidation, and PDC is therefore seen as a key factor in regulating the switch between lipid and carbohydrate oxidation. The presentation will show results from studies investigating exercise-induced regulation of PDHa activity and phosphorylation in human skeletal muscle and the influence of elevated fatty acids (through intralipid treatment and high fat diet), bed rest and exercise training state on exercise-induced PDH regulation. Moreover, mouse studies focusing on the impact of muscle interleukin (IL)-6 on exercise-induced skeletal muscle PDH regulation and whole body substrate utilization will be presented. In addition, fasting-induced PDH regulation in human skeletal muscle and the impact of muscle IL-6 on fasting-induced PDH regulation in mouse muscle will also be included.

EFFECT OF MATCHA GREEN TEA SUPPLEMENTATION ON METABOLIC AND PHYSIOLOGICAL RESPONSES AT MODERATE INTENSITY EXERCISE IN FEMALES

KAVIANI, M., FRY, H., BELDING, M., WILLEMS, M.

ACADIA UNIVERSITY

INTRODUCTION: There is evidence that intake of green tea extract can increase fat oxidation during exercise but there is no consistency in observations possibly due to duration and amount of intake. For example, Venables et al (2008) observed increased fat oxidation during moderate intensity cycling for 30 min with 3x daily intake of green tea extract capsules. However, to date, the effectiveness of longer intake of Matcha green tea powder on the metabolic and physiological responses during moderate intensity exercise are not known. Therefore, we examined effect of Matcha green tea supplementation on metabolic and physiological responses at moderate intensity exercise in females.
METHODS: Twelve females (age: 28±10 yr, body mass: 69±17 kg, height: 163±6 cm) voluntarily participated in the study. Participants completed an incremental walking protocol to establish baseline metabolic values indicating individualized relationship between walking speed and oxygen uptake, and determine a speed that resulted in 4- or 5-MET. A randomized cross-over design was used with participants tested between day 9 and 11 of the menstrual cycle (follicular phase). Participants consumed 2 supplements, 3 times a day, each containing 500mg of Matcha premium grade (OMGTea Ltd UK) for 21 days, and 2 supplements 90 minutes before the 30- min walk at 4- or 5-METs with metabolic responses measured during the walking test. Paired samples t-tests were conducted to compare parameter values between control and Matcha conditions.
RESULTS: Matcha resulted in lower respiratory exchange ratio (control: 0.88±0.001; Matcha: 0.84±0.001) (P = 0.018) and enhanced fat oxidation during a 30-min brisk walk (control: 0.20±0.006; Matcha: 0.26±0.003g·min-1) (P= 0.04). There was no significant difference in heart rate response between two conditions.
CONCLUSION: Overall, this data suggests that 3-week of Matcha green tea powder supplementation can enhance exercise-induced fat oxidation in healthy females. It appears that the composition of Matcha green tea powder when combined with walking at a moderate intensity could provide metabolic health benefits.

THE INFLUENCE OF 'SLEEP-LOW' CARBOHYDRATE PERIODISATION ON IRON REGULATION AND IMMUNE FUNCTION IN ELITE TRIATHLETES

MCKAY, A.1,2,3, HEIKURA, I.3,4, BURKE, L.3,4, PEELING, P.1,2, PYNE, D.5, COX, G.6,7

1UNIVERSITY OF WESTERN AUSTRALIA 2WESTERN AUSTRALIAN INSTITUTE OF SPORT 3AUSTRALIAN INSTITUTE OF SPORT 4AUSTRALIAN CATHOLIC UNIVERSITY 5UNIVERSITY OF CANBERRA 6BOND UNIVERSITY 7TRIATHLON AUSTRALIA

INTRODUCTION: The "sleep low" carbohydrate (CHO) periodisation protocol consists of overnight CHO restriction after an exercise session, followed by a second session completed with low CHO availability. Although this strategy can enhance favourable training adaptations, the impact on an athlete's health is unclear. This study quantified the effect of an acute 'sleep-low' dietary intervention on markers of iron regulation and immune function in elite athletes.
METHODS: In a randomised, crossover design, 11 elite triathletes (4 male, 7 female) completed two 4-day trials while training and recovering overnight with high CHO availability, or employing an alternate day sleep-low approach. Key training sessions were structured such that a high-intensity training (HIT) session was performed in the field on the afternoon of days 1 and 3, and a low-intensity training (LIT) session (45-60 min) on the following morning in the laboratory (days 2 and 4). Additionally, the exercise modality was manipulated to replicate the mixed mode training practices of triathletes, with cycling sessions performed on days 1 and 2 and running sessions on days 3 and 4. The ingestion of CHO (6-8 g/kg) was either divided evenly across the day (HIGH) or restricted overnight, ensuring the LIT session was performed with low CHO availability (LOW). Heart rate (HR) and respiratory exchange ratio (RER) were measured in the final 5 min of each LIT session. Venous blood and saliva samples were collected prior to and following each LIT session and analysed for interleukin-6 (IL-6), hepcidin-25 and salivary immunoglobulin-A (s-IgA).
RESULTS: Moderately lower RER (-4.2%; $p<0.001$) and higher HR (3.8%; $p=0.053$) occurred during the LOW, compared to HIGH trials. Moderate increases in HR (4.7%; $p=0.019$) and large increases in RER (8.4%; $p<0.001$) were evident during the cycling compared to running trials. Concentrations of IL-6 increased acutely after exercise ($p<0.001$), but did not differ substantially between dietary conditions or exercise modalities. Hepcidin-25 concentrations increased 3 h post-exercise ($p<0.001$), with the greatest increase evident following the LOW trial on day 2 (+2.5±0.9-fold). The s-IgA secretion rate did not change in response to exercise, however, was greatest during the LOW condition on day 4 ($p=0.046$).
CONCLUSION: The 'sleep-low' dietary intervention yielded a higher HR and lower RER during the LOW compared to HIGH trials despite external workloads remaining similar, potentially reflecting altered fuel utilisation between dietary conditions. We note that LIT cycling trials were performed at a higher intensity than LIT running trials. Nevertheless, it appears that when 'sleep low' is implemented around sessions of low intensity and short duration, immune function and iron regulation are unlikely to be compromised. In conclusion, there appears to be minimal impact on markers of athlete health when occasional and planned exposure to low CHO availability is undertaken with expert nutrition and coaching input.

PRE-MATCH MUSCLE GLYCOGEN LEVELS OF THREE MATCHES IN 1 WEEK BASED ON HIGH CARBOHYDRATE INTAKE

NAKAMURA, D.1,2,3, YASUMATSU, M.1, TOBITA, A.1, NAKAMURA, M.3, ISHI, Y.4, TANABE, Y.5, IWAYAMA, K.6, SHIOSE, K.7, ISHIBASHI, A.3, TAKAHASHI, H.3

1 RIKKYO UNIV., JAPAN 2 WEATHERNEWS INC. 3 JAPAN INSTITUTE OF SPORTS SCIENCE , JAPAN 4 KYOTO GAKUEN UNIV., JAPAN 5 UNIVERSITY OF TSUKUBA, JAPAN 6 TENRI UNIV., JAPAN 7 FUKUOKA UNIV., JAPAN

INTRODUCTION: Muscle glycogen plays an important role in the performance of football players (1, 2). In particular, the decline in the running performance towards the end of the game is thought to be linked to reductions in muscle glycogen levels (1). However, to our knowledge, there is no study examining the relationship between muscle glycogen recovery with a high carbohydrate intake in the case of three matches held in 1 week, such as Summer Olympic Games or FIFATM competitions. Thus, this study aimed to examine the effects of a high carbohydrate diet (>7 g/kg BW/d) on pre-match muscle glycogen levels in three matches a week
METHODS: Twenty male university football players participated in this study (age, 21.3 ± 1.7 years; height, 171.0 ± 5.4 cm; weight, 62.5 ± 5.0 kg). The match schedule was similar to the group league of the football events in the Summer Olympic Games. The muscle glycogen level was measured before each match (M1, M2, and M3) by a carbon magnetic resonance spectroscopy (13C-MRS), and was assessed in the right vastus lateralis. The calorific content of all meals the subjects consumed during the experiment was recorded, and each participant's diet was managed by sports nutritionists to ensure a carbohydrate intake of 7g per kilogram of body weight per day.
RESULTS: The muscle glycogen levels before each match were 77.3 ± 16.2 mM, 85.3 ± 26.6 mM and 82.6 ± 25.6 mM (M1, M2, and M3, respectively). No significant difference was found among each match. The total distances covered in M1, M2 and M3 were 10.3 ± 1.1 km, 10.4 ± 0.6 km and 10.2 ± 1.0 km, respectively.
CONCLUSION: The results of this study supported previous findings that reported the recovery of the muscle glycogen levels within 72 hours after a competitive soccer match using a high carbohydrate diet (3). Because of the lack of post muscle glycogen levels and control condition, it was not fully elucidated that whether the recovery of muscle glycogen levels due to high carbohydrate diet or not. However, our present findings and previous studies suggested that a high carbohydrate diet (>7 g/kg BW/d) appeared to sufficient replenishment of muscle glycogen levels > 72 hours after competitive soccer matches. In conclusion, the results of our study indicated that pre-match muscle glycogen levels did not change with a high carbohydrate diet in the case of three matches held in 1 week. This result may be useful in assisting recovery strategies in nutrition, where successive matches are played with only a few recovery days in between.

EFFECTS OF VOLUNTARY EXERCISE ON PLASMA AND URINARY METABOLITES AND GUT MICROBIOTA IN A HIGH-FAT-DIET FED MICE

OYANAGI, E., WATANABE, C., KOBIKI, N., AOKI, T., KREMENIK, M.J., NAGANO, T., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Regular exercise has been understood to antagonize metabolic disorders such as obesity. In addition, according to recent studies, it is possible that exercise modulates gut microbial composition and diversity. The aim of this study was to examine the effects of voluntary exercise on plasma and urinary metabolites and the changes in gut microbiota in high-fat-diet fed mice.
METHODS: Healthy male C57BL/6J mice (four-week-old, n=26) were fed a normal controlled diet (CD) and a high-fat-diet (HFD) for 10 weeks under two conditions: voluntary wheel running (W) and sedentary controlled condition (C). The metabolites in the collected plasma and urine were detected using the 1H-NMR spectroscopy technique. Also, a meta-genome analysis of microbiome on the collected feces was carried out by NGS.
RESULTS: Wheel running activity in HFDW mice was slightly higher than that in CDW mice (p=0.075). The exercise and diet significantly altered body weight, the adipocyte area, and the glucose tolerance test (GTT). Changes in plasma metabolites differed from those in urine. In plasma, amino acids such as Leu, Ile, Ala and Tyr, were the metabolites significantly increased by exercise, whereas in urine, we did not observe any significant changes in metabolites. In contrast, diet influenced the metabolites in both the plasma and urine of mice and showed significant differences in the following; in plasma, Leu, Ile, Glu, 3-HB, lactate and acetate. Whereas in urine, citrate, TMA, TMAO, taurine, hippurate and allantoin were not shown to have any differences in exercise. Furthermore, the alpha-diversity (phylogenetic diversity whole tree, observed species, and Chao1 index) of gut microbiota in HFDC mice was significantly lower than that found in HFDW mice. With regard to beta diversity, unweighted UniFrac analysis (principal coordinate analysis (PCoA)) showed that the difference between CD and HFD mice could be observed under PC1(22.61%). Although there was substantial overlap the between two conditions (C vs. W), HFD groups were positioned in slightly different areas in the C and W conditions.
CONCLUSION: In this study, we included metabolites from plasma in addition to urinary metabolites. Contrary to urine, metabolites in plasma are highly prone to exercise factors, resulting in a greater differential in the alteration of metabolites. However, it was reported that changes in the bacterial composition of the gut in mice may alter urinary metabolites. Therefore, our results suggest that testing in both plasma and urinary metabolites may prove a more reliable approach to quantitative metabolite analysis as an effect of exercise-dependence or independent alteration of gut microbiota on the host.

ISOCALORICS AND ENJOYMENT OF MODERN ENDURANCE TRAINING MODALITIES (HIT VS. SIT VS. THRESHOLD VS. LIT) IN FIT AND UNFIT

STÖGGL, T., HERTLEIN, M.

UNIVERSITY OF SALZBURG

INTRODUCTION: The question "How much energy is burnt during and following (EPOC) training" is relevant from both a public health (e.g. reduce weight) and elite (balance between energy expenditure (EE) and available energy stores) perspective. Given that "lack of time" is one of the most commonly cited barriers to regular exercise training, which endurance training type is the most time efficient is of interest. However there is inconsistency with respect to isocaloric training times between low (LIT) and high intensity training (HIT), with isocaloric

exercise time ratios ranging from 1.0 (Peak et al. 2014) up to 1.85 (Safarimosavi et al. 2018). In addition to EE, the enjoyment level of different training concepts for different levels of fitness should be considered. Therefore, the aim of this study was to compare 3 HIT protocols (5x4, 15x1, 30x30), threshold training (THR), sprint interval training (SIT) and LIT, with regard to isocaloric exercise time, EPOC and enjoyment.
METHODS: 12 males (6 fit, 6 unfit) completed an incremental test to exhaustion on a cycle ergometer to control the load on the subsequent training sessions. Participants started in randomized order with one of the three HIT sessions, which served as reference method for the subsequent isocaloric sessions (THR, SIT, LIT). The remaining sessions were completed in randomized order. For all training sessions EE during exercise and within the first 15' of the EPOC phase were measured by indirect calorimetry. Repeated measures ANOVA with factors "training" and "fitness level" were applied.
RESULTS: HIT sessions demonstrated equal EE (~525 kcal) and EPOC, and led to higher EPOC compared with SIT ($P<0.01$) and LSD ($P<0.001$) with no difference to THR. Total duration to match the EE of the HIT with the highest EE was 19% longer for SIT ($P<0.05$), 42% longer for LSD ($P<0.01$) with no difference to THR (+3.8%). Enjoyment was greatest for SIT, followed by HIT, and clearly lower values for THR and LSD ($P<0.05$). There was no main effect of "fitness level" in any variables.
CONCLUSION: No matter which HIT protocol used, EE, EPOC and enjoyment were comparable. THR is a time efficient, but not very enjoyable endurance training mode. LIT required ~41% longer exercise time compared to HIT, and had low enjoyment levels. SIT was the most joyful training with approximately 19% longer exercise time needed to be isocaloric to HIT or THR. It should be noted that only the magnitude of EPOC and aerobic EE were considered in this study. Irrespective of fitness level, all exercise modes were feasible. In conclusion, if exercise time does not matter than SIT is recommended as an enjoyable endurance training mode. HIT is most time efficient and moderately enjoyable, while THR and LIT can be placed at the low end of the enjoyment scale.

OP-PM45 Nutrition: Protein and dietary regimens

BODY COMPOSITION AND NUTRIENT INTAKE OF OLYMPIC AND ELITE RHYTHMIC GYMNASTS

KOLIMECHKOV, S., MITEVA, S., YANEV, I., PETROV, L.
NATIONAL SPORTS ACADEMY, SOFIA

INTRODUCTION: Special consideration is given to the external appearance of rhythmic gymnasts, and this demands particular adherence to their diet and body composition. The purpose of this study was to assess the body composition and nutrient intake of top-level Olympic and elite rhythmic gymnasts.
METHODS: Twenty-one elite rhythmic gymnasts from Bulgaria were divided into three groups: FNT (First National Team, 2016 Olympic bronze medallists, n=5, mean age 24.2), SNT (Second National Team, 2017 World silver medallists, n=8, mean age 17.8), and JT (Junior Team, n=8, mean age 12.6). Body fat and muscle mass were estimated by skinfold methods, VO2max was measured, and ethics approval was granted prior to the tests. The dietary intake was assessed by using a food frequency questionnaire, in addition to questionnaires concerning the nutritional behaviour, as well as weight control management.
RESULTS: The average height-for-age percentile score in the SNT was 83.0, which was significantly higher than the 50th percentile (PR) of the WHO norms. The average BMI of the FNT was at the lower normal limit (18.5 kg/cm2). The average BMI PR for the SNT and JT were significantly lower than the 50th PR of the WHO norms ('thinness', BMI < 15th PR). No significant differences between the measured weight and the target weight were found. The % body fat of the gymnasts was within the norms for athletes. The FNT had significantly higher % muscle mass (44.0%) in comparison with the SNT and JT (40.5% and 37.6%, respectively). The SNT showed the highest VO2max results (52.0 ml/kg/min, $p < 0.05$) vs the FNT (44.0 ml/kg/min) and the JT (38.6 ml/kg/min). The relative energy intake of the gymnasts did not differ significantly from the guidelines for female gymnasts, whilst the energy contribution of proteins was significantly higher in the SNT and JT (17.6% and 19.4%, respectively) than the recommended 15%. However, there was no significant difference between the relative protein intake between the groups (1.7 g/kg/24h vs 1.7 g/kg/24h vs 1.9 g/kg/24h). The energy contribution of fats was above the recommended norms in the FNT, whilst that in the other groups was within the norms. The relative fat, protein and carbohydrate intakes were within the norms. All of the rhythmic gymnasts followed the desired nutritional habits, and 17 of the 21 competitors indicated a high degree of self-control in relation to their nutritional behaviour. The methods most frequently applied by the gymnasts for weight management included a reduction of carbohydrates, fats and salt in their diet, use of sauna facilities, and additional aerobic activities.
CONCLUSION: The BMI and % body fat of all gymnasts were considerably low, but within the reported values for elite gymnasts. Olympic and elite rhythmic gymnasts maintain their target weight, while they are keeping their % body fat and nutrient intake at the lower normal limits.

EFFECTS OF 4-HOUR TIME RESTRICTED FEEDING ON BODY COMPOSITION AND PERFORMANCE

WACHSMUTH, N., VON RITTER, R., SCHMIDT, W.
INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Overweight and obesity are a serious problem in our society. To counteract this development, there are numerous diets propagating long-term weight loss. This includes intermittent fasting (IF), which has gained popularity in recent years. In addition to losing weight, this diet promises also positive health effects. One subcategory of intermittent fasting is time-restricted feeding, that means fasting every day for 14 to 20 hours, which is, however, rarely investigated. Therefore, the purpose of this pilot study was to investigate the effect of intermittent fasting using the 20/4 model (20 hours fasting, 4 hours eating ad libitum) on energy intake, movement behavior, resting energy expenditure, body composition and performance.
METHODS: In total, 12 women participated in the study. Due to one drop out, data of 11 subjects were included in the analysis (age: 22.0 ±1.9 years, body mass: 68.5 ±8.9kg, BMI: 24.2 ±1.9). The intervention was implemented for 5 weeks with an additional measurement 6 weeks thereafter. Subject were instructed to eat ad libitum between 18:00 and 22:00 oclock, and to fast subsequently for 20h. After 15 h strict fasting, they were allowed to eat 2 to 3 small high-protein snacks. They monitored energy intake before, during and after the intervention for 5 consecutive days. At the same time activity was recorded using an Actigraph (wGT3XBT). Body composition was determined

before, 4 times during and 6 weeks after the intervention. Resting metabolic rate and performance were measured before, at the end and 6 weeks after the IF period.
RESULTS: No significant change in energy intake (before: 2159 ±438kcal; 20/4: 2015 ±541kcal), movement behavior (before 500 ±228 kcal of activity /day; 20/4: 502 ±463kcal of activity /day) and resting metabolic rate (before: 1496 ±137kcal/day; 20/4: 1549 ±177kcal/day) was found. However, after IF body weight was reduced by 2.0 ±1.3kg ($p<0.001$), fat mass by 11.1 ±4.2% ($p<0.001$) and visceral fat by 13.3 ±5.3% ($p<0.001$) while lean body mass was slightly increased by 0.8 ± 0.9kg ($p<0.05$). VO2max was reduced by 92ml ($p=0.05$) and VO2max related to lean body mass was 5.1 ±4.7% ($p<0.05$) lower at the end of the intervention than before.
CONCLUSION: Time restricted feeding (20/4) produces no caloric restriction that could explain the reduction in body weight and fat mass in young women. Therefore, other mechanism like an increased fat metabolism may lead to the negative energy balance that need to be investigated. Athletes using intermittent fasting for weight management need to consider an impaired performance during fasting periods.

ASSESSMENT OF ENERGY AVAILABILITY AND ASSOCIATED RISK FACTORS IN PROFESSIONAL FEMALE SOCCER PLAYERS

MOSS, S.L.1,2, RANDELL, R.K.2, BURGESS, D.3, RIDLEY, S.3, O CAIREALLAIN, C.3, ROLLO, I.2,4

(1)UNIVERSITY OF CHESTER, UK (2)GATORADE SPORTS SCIENCE INSTITUTE, UK (3)ARSENAL FOOTBALL CLUB, UK (4)LOUGHBOROUGH UNIVERSITY, UK

INTRODUCTION: Energy availability (EA) indicates the energy available to support body functions, after subtracting the amount of energy expended during exercise, expressed relative to fat-free mass. Congested training and match schedules of professional female soccer players could place them at risk of low EA, which may have long-term health consequences. The aim of this study was to assess EA, alongside possible risk factors of low EA during a competitive season.
METHODS: Thirteen professional female soccer players (age: 23.7 ± 3.4 y, stature: 1.69 ± 0.08 m, body mass: 63.7 ± 7.0 kg) engaged in a 5-day (x2 rest days and x1 light training, heavy training and match day) monitoring period to assess EA. Energy intake was assessed via a 5-day weighed food diary, while accelerometers, global positioning devices and metabolic equivalents provided estimates of energy expenditure, with values corrected for individualised resting metabolic rate (RMR). EA was categorised as optimal (45 kcal·kg FFM-1day-1), reduced (31-44 kcal·kg FFM-1day-1) and low (30 kcal·kg FFM-1day-1). On a separate occasion, players were assessed for bone mineral density (DXA), RMR (with the ratio between measured and predicted values <0.90 indicative of low) and additional factors associated with low EA (e.g. injury, menstrual function) using the LEAF-Q.
RESULTS: For the total 5-day monitoring period, EA was optimal for 15%, reduced for 62% and low for 23% of players. There were significant differences between days in EA, which revealed higher EA on rest days (42 ± 7 kcal·kg FFM-1·day-1) compared to all others ($P<0.05$) and when the light was compared to the heavy training day (29 ± 10 cf. 35 ± 11 kcal·kg FFM-1·day-1; $P<0.001$). Although energy expenditure differed significantly between days ($P<0.05$), total energy (2124 ± 444 kcal), carbohydrate (3.31 ± 0.64 g·kg·day-1) and protein (1.83 ± 0.41 g·kg·day-1) intake remained similar ($P>0.05$), with only fat intake being higher on the heavy (24 ± 6%) compared to the light (18 ± 6%) training day ($P<0.05$). Responses to the LEAF-Q (6.2 ± 3.2) revealed 23% of players were categorised as at risk of a long-term energy deficiency (score 8), while 23% also met the criteria indicative of low RMR. All bone mineral density T-scores (2.36 ± 0.85) were normal. Significant Pearson correlations were revealed between EA and: energy intake ($r=0.87$), protein intake ($r=0.79$) and exercise energy expenditure ($r=-0.79$) (all $P=0.001$). However, non-significant relationships were apparent between EA and bone mineral density, RMR ratio, LEAF-Q, carbohydrate intake and fat intake ($r = 0.004$-0.54; all $P>0.05$).
CONCLUSION: The majority of players had sub-optimal EA during a typical 5-day in-season period. Findings suggest that players were unable to periodise their total energy intake to match the demands of exercise. Although no health implications were evident, further research is required to determine the long-term effects and risk factors associated with low EA in professional female players.

PREVALENCE OF RELATIVE ENERGY DEFICIENCY IN SPORT (RED-S) RISK AMONGST AMATEUR AND RECREATIONAL ATHLETES IN SINGAPORE

MUKHERJEE, S., SIM, H.X.A.

NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY, SINGAPORE

INTRODUCTION: Relative Energy Deficiency in Sport (RED-S) is a syndrome caused by low energy availability (LEA) and impairs physiological and psychological functions. There are no reports on the prevalence of RED-S risk amongst athletes in Singapore. Identifying athletes at RED-S risk can enable primary prevention of the condition and its consequent adverse effects on health and athletic performance. This study determined the prevalence of RED-S risk, within athlete types (amateur, recreational), and between genders.
METHODS: 318 participants (124 males; 194 females) from Singapore completed an online questionnaire including self-reported height and weight, Eating Disorder Examination Questionnaire (EDE-Q) and Hooper's Questionnaire, and a 5-item questionnaire on perceptions related to body composition and performance. BMI <18.5kg/m2 and/or a score of ≥4.0 on any of the subscales and/or the global score in the EDE-Q were considered as primary measures of RED-S risk. Hooper's Questionnaire score, bone injury history, and perceptions related to body composition and performance were considered as additional measures of RED-S risk.
RESULTS: Overall prevalence of RED-S risk was 34.3%. Risk in female athletes (44.3%) was significantly higher than males (18.5%). However, the prevalence of RED-S risk amongst amateur (34.1%) and recreational athletes (34.4%) was not significantly different. Elevated EDE-Q score was the most common risk measure (19.8%), followed by being underweight (13.5%). Amongst the at-risk participants, highest numbers with scores ≥4.0 on the EDE-Q were for the shape concern (51.4%) and weight concern (32.1%). BMI of at-risk participants (20.1) was significantly lower than not-at-risk participants (21.7). RED-S risk was negatively associated with level of competition (international) and BMI, and positively associated with shape and weight concern scores on the EDE-Q. At-risk participants reported engaging in pathogenic eating behaviours for greater number of instances over the past 28-day period than not-at-risk participants. The Hoopers Questionnaire parameters of stress and fatigue levels as well as the Hooper's Index, was significantly higher ($p<.002$) amongst the at-risk participants than not-at-risk participants.
CONCLUSION: The moderate-to-high prevalence of RED-S risk amongst athletes is a concern, from both athletic performance and public health perspective. Similar prevalence magnitude in amateur and recreational athletes suggests greater pervasiveness of LEA and RED-S risk. Our findings make a reasonable case for developing greater awareness of the condition amongst the stakeholders and formulating strategies for primary prevention of RED-S to cultivate a healthy sporting culture amongst athletes. Future research should validate proxy

measures for RED-S risk against the gold standard, REDS-CAT, to establish a simplified RED-S risk assessment tool to facilitate the screening of RED-S risk for a larger population.

PROTEIN SUPPLEMENTATION DOES NOT FURTHER AUGMENT ENDURANCE CAPACITY AND PERFORMANCE FOLLOWING PROLONGED ENDURANCE EXERCISE TRAINING: A RANDOMIZED CONTROLLED TRIAL

JONVIK, K.L., PAULUSSEN, K.J.M., DANEN, S.L., CEELEN, I.J.M., HORSTMAN, A.M.H., WARDENAAR, F.C., VAN LOON, L.J.C., VAN DIJK, J.W.

HAN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: It has recently been speculated that protein supplementation may further augment the adaptations to prolonged endurance exercise training. We assessed the impact of protein supplementation during prolonged endurance exercise training on whole-body oxidative capacity (VO2max) and endurance exercise performance.
METHODS: Sixty recreationally active males (age: 27±6 y; BMI: 23.8±2.6 kg/m2; VO2max: 47±6 mL/min/kg) were subjected to 12 weeks of triweekly endurance exercise training. After each session and each night prior to sleep, participants ingested either a protein supplement (PRO; 28.7 g casein protein) or an isocaloric carbohydrate placebo (PLA). Before and after the 12 weeks of training, VO2max and endurance performance (~10-km time-trial) were assessed on a cycle ergometer. Muscular endurance (total workload achieved during 30 reciprocal isokinetic contractions) was assessed by isokinetic dynamometry and body composition by DXA. Dietary intake was assessed at baseline and during the intervention period. Repeated measures ANOVA was applied to assess whether training adaptations were different between groups.
RESULTS: Protein intake increased in PRO (1.21±0.35 to 1.58±0.31 g/kg), but not in PLA (1.25±0.41 to 1.19±0.31 g/kg, time x treatment interaction, P<0.0001). Endurance exercise training induced an 11±6% increase in VO2max (time effect, P<0.0001), with no differences between groups (PRO: 48±6 to 53±7 mL/min/kg; PLA: 46±5 to 51±6 mL/min/kg; time x treatment interaction, P=0.50). Time to complete the time-trial was reduced by 14±7% (time effect, P<0.0001), with no differences between groups (time x treatment interaction, P=0.15). Muscular endurance increased by 6±7% (time effect, P<0.0001), with no differences between groups (time x treatment interaction, P=0.84). Leg lean mass showed an increase following endurance exercise training (P<0.0001), which tended to be greater in PRO (PRO: 0.5±0.7 kg; PLA: 0.2±0.6 kg; time x treatment interaction, P=0.073).
CONCLUSION: Protein supplementation after exercise and before sleep does not further augment the gains in whole-body oxidative capacity and endurance exercise performance following prolonged endurance exercise training in healthy young males.

EFFECTS OF POST-EXERCISE WHEY PROTEIN OR CARBOHYDRATE CONSUMPTION ON PERFORMANCE RECOVERY AND INFLAMMATORY CYTOKINES IN YOUNG COMPETITIVE SWIMMERS

MCKINLAY, B.J., THEOCHARIDIS A., ADEBERO, T., ROY, B., JOSSE, A.R., FALK, B., KLENTROU, P.

BROCK UNIVERSITY

INTRODUCTION: Numerous studies in adult athletes and non-athletes, have demonstrated that protein consumption following exercise is beneficial for optimising recovery and enhancing lean body mass. No such studies are available in youth athletes. The period of late childhood and early adolescence is characterised by a noticeable growth spurt, involving an accelerated accretion of muscle mass. Thus, protein needs of youth are greater than adults' (relative to body size). The protein needs of growing athletes are unclear. This randomised double blind, placebo-controlled study examined the effects of post-exercise consumption of whey protein (PRO) or carbohydrate (CHO) on performance recovery and cytokine responses following a high intensity interval swim (HIIS) in 10-17-year old male and female swimmers.
METHODS: Participants were randomly divided into three groups: PRO (0.3g/kg – whey protein isolate), CHO (0.3g/kg – maltodextrin) or placebo control (H2O), matched for age, sex and body mass. HIIS consisted of 15 high-intensity swimming repetitions (5x100m, 5x50m and 5x25m at maximal intensity) with a work-to-rest ratio of 1:1. Blood samples were collected pre-, 30min, 2, 6 and 24h post-HIIS and later assessed for inflammatory response (IL-6, IL-10 and TNF-α). Swim performance (200-m front crawl) was assessed pre-, 2, 6 and 24h post-HIIS. Participants consumed PRO, CHO or H2O 30 min and 2h after HIIS.
RESULTS: No statistical differences were observed at baseline in performance or inflammatory cytokine levels IL-10 and TNF-α across groups. Baseline IL-6 levels were significantly lower in PRO (0.87±0.5 pg/ml) compared with H2O (1.75±1.42 pg/ml). Cytokine responses did not significantly differ between groups. Plasma IL-10 increased overall from pre- to 30 min post HIIS (5.43±0.3 pg/ml and 6.40 ± 0.4 pg/ml, respectively, p<0.05). Likewise (although not significant), IL-6 increased from pre- to 30 min post-HIIS (1.30±0.1 pg/ml and 1.33±0.1, respectively, p>0.05). TNF-α was significantly elevated at 30 min (2.01±0.8 pg/ml) and 24h (2.01±0.1 pg/ml) post HIIS. PRO showed the greatest performance recovery (lowest time decrements) at 24h (+0.53s), followed by CHO (+1.41s) and H2O (+2.54s), although differences did not reach a level of statistical significance.
CONCLUSION: In young swimmers, consumption of PRO or CHO following HIIS does not appear to alter the cytokine response compared with H2O. The potential apparent beneficial effect of protein consumption post-exercise on performance recovery in young athletes needs to be further explored.

OP-PM52 Health and fitness: Cardiovascular

THE CHANGES OF HRV DUE TO A 6-MONTH LONG PHYSICAL ACTIVITY PROGRAM IN HEALTHY YOUNG SEDENTARY WOMEN.

ÁDÁM, Z., GARAI, K., GYEBROVSZKI, Á., WILHELM, M.

UNIVERSITY OF PÉCS

INTRODUCTION: Physical inactivity is among the four leading risk factors for the onset of cardiovascular diseases [1]. Heart rate variability (HRV) have been studied for a long time and found to be a good biomarker of the provenance of the dysfunctions associated with low level of physical activity [2]. The method is widely used in the evaluation of the status of athletes however, much less studies have focused

on the changes of HRV in healthy young individuals of regular moderate intensity exercise. None of the published articles have evaluated the HRV parameters in repeated measures study. The aim of the present work was to determine the effects of a 6 month-long training program that involved aerobic and resistance exercises as well on the functions of the autonomic nervous system.
METHODS: Untrained women (n=16; 23.57±2.41 yrs) participated in the six-month long training program (3x60 min/week). The physical activity level was determined with wrist worn accelerometer (Actigraph). The HR was monitored during pre-exercise phase (5 min sitting), during exercise (walking and jogging at 65% VO2max, for 30 min) and during the recovery phase (5 min sitting). Time domain and frequency analysis were performed on five minute segments of the recordings at baseline, 3-, and 6 months.
RESULTS: A significant elevation occurred in the first 3 months in the resting time domain parameters (mean R-R: 724.65±94.03 to 760.36±97.62; RMSSD: 27.89±11.50 to 33.16±16.38; NN50: 36.85±35.74 to 49.82±45.98) decrease in the aerobic segment (mean R-R: 450.88±30,31 to 429.72±38.16; RMSSD: 6.28±2.03 to 5.08±1.33; NN50: 0.59±1.13 to 0.142±0.27) and no significant change was observed in the recovery period. The frequency data analysis revealed a significant decrease in sympathetic activity of the resting state (increased LF/HF, decreased LF Power) and in the endurance period (increased LF/HF, decrease HFnu), while the recovery period remained unchanged ($p<0.05$).
CONCLUSION: The results of this study indicate that regular mixed moderate intensity physical activity over a 6-month period has beneficial effects on the cardiovascular system through the modulation of the autonomic nervous system which caused an overall increase of HRV even in healthy young individuals.

EFFECTS OF A 12-WEEK AEROBIC EXERCISE INTERVENTION ON CARDIOVASCULAR RISK FACTORS, CARDIORESPIRATORY FITNESS, AND PATIENT-REPORTED OUTCOMES IN WOMEN WITH SYSTEMIC LUPUS ERYTHEMATOSUS

SORIANO-MALDONADO, A.1, GAVILÁN-CARRERA, B.2, MORILLAS-DE-LAGUNO, P.2, MONTALBÁN-MÉNDEZ, C.4, ROSALES-CASTILLO, A.3, SÁEZ-URÁN, L.M.3, SABIO, J.M.3, VARGAS-HITOS, J.A.3

1 UNIVERSITY OF ALMERÍA . 2 UNIVERSITY OF GRANADA . 3 VIRGEN DE LAS NIEVES UNIVERSITY HOSPITAL, GRANADA . 4 LA MANCHA CENTRO HOSPITAL, CIUDAD REAL .

INTRODUCTION: Premature cardiovascular diseases represent a major cause of mortality in patients with systemic lupus erythematosus (SLE). Despite relevant advances in treatment options and survival rates, patient's quality of life and other patient-reported outcomes (PROs) do not seem to improve accordingly. Exercise might improve both cardiovascular risk and PROs, although information is scarce in this population. The aim of this study was to assess the effects of a 12-week aerobic exercise intervention on emerging cardiovascular risk factors (i.e. arterial stiffness and inflammation), cardiorespiratory fitness, and PROs (including fatigue, depressive symptoms, and health-related quality of life [HRQoL]) in women with SLE.
METHODS: A non-randomized clinical trial was conducted [clinicaltrials.gov identifier: NCT03107442]. A total of 58 women with SLE were assigned to either an exercise group (n=26) or a usual care control group that received healthy lifestyle recommendations (n=32). Exercise consisted of 12 weeks of aerobic treadmill exercise (2 sessions × 75 minutes per week), including continuous and interval sessions, which progressively increased from 40% to 75% of the individual's heart rate reserve. At baseline and at week 12, arterial stiffness (primary outcome) was assessed through pulse wave velocity (PWV), and inflammatory markers (i.e. high-sensitivity C-reactive protein [hsCRP], tumor necrosis factor alpha [TFN-α] and interleukin 6 [IL-6]) were obtained from fasting blood samples. Cardiorespiratory fitness was assessed through the time (in minutes) to achieve 85% of the estimated maximal heart rate in the Bruce treadmill test. Widely validated questionnaires were used to assess fatigue (Multidimensional Fatigue Inventory), depressive symptoms (Beck Depression Inventory; BDI-II) and HRQoL (36-item Short-Form Health Survey; SF-36).
RESULTS: The exercise intervention did not reduce PWV (median between-group difference: -0.034, 95% CI -0.42 to 0.36 m/s; $P = 0.860$), hsCRP, TNF-α, or IL-6 (all, $P > 0.05$). The exercise group significantly increased cardiorespiratory fitness (median between-group difference: 2.26 minutes, 95% CI 0.98 to 3.55; $P = 0.001$) and reduced general fatigue (mean difference -2.11 units; 95% CI -4.18 to -0.04; $P = 0.046$) and physical fatigue (mean difference -3.90 units; 95% CI -6.3 to -1.5; $P = 0.002$) in comparison to the control group. No effect was observed on depressive symptoms and HRQoL (all, $P > 0.05$).
CONCLUSION: The results of this study suggest that 12 weeks of progressive treadmill aerobic exercise increases cardiorespiratory fitness and reduces general and physical fatigue in women with SLE, without exacerbating arterial stiffness and inflammatory markers. No effects were observed on other relevant PROs such as depressive symptoms and HRQoL. Future clinical trials with larger sample sizes are needed to improve our understanding of how different exercise configurations might affect cardiovascular health and PROs in this population.

IMPACT OF OBESITY ON WALKING CAPACITY AND CARDIOVASCULAR FUNCTION OF PERIPHERAL ARTERY DISEASE PATIENTS: A CROSS-SECTIONAL STUDY

RITTI-DIAS, R., DOMICIANO, R., CUCATO, G.G., KANEGUSUKU, H., LONGANO, P.O.M., WOLOSKER, N., CORREIA, M.A.

UNIVERSIDADE NOVE DE JULHO

INTRODUCTION: Patients with peripheral artery disease (PAD) present high prevalence of obesity and metabolic syndrome, diseases related to cardiovascular dysfunction. However, whether obesity influence walking capacity and cardiovascular function in patients with PAD is poor known. The aim of this study was to analyze impact of obesity on walking capacity and cardiovascular parameters in patients with PAD.
METHODS: One-hundred and two patients with PAD and symptoms of intermittent claudication were recruited and divided in two groups according to their body mass index: normal weight (<25 kg/m2) and overweight/obese (≥25 kg/m2). Patients were submitted to objective (six-minute walk test) and subjective measurements of functional capacity (walking impairment questionnaire). In addition, cardiovascular and autonomic parameters [blood pressure (BP)], arterial stiffness and heart rate variability) were also obtained.
RESULTS: Speed domain of walking impairment questionnaire was lower in overweight/obese compared to normal weight group (21±16 vs. 32±20; $P<0.01$). Resting heart rate (70±12 bpm vs. 61±10 bpm, $P< 0.01$) was higher in overweight/obese patients. The remaining parameters were similar between groups.
CONCLUSION: Obesity impairs the capacity to walking fast and increases resting heart rate in patients with PAD.

THE ASSOCIATION BETWEEN CARDIORESPIRATORY FITNESS AND NAFLD IN OVERWEIGHT AND OBESE ADULTS.

SABAG, A., KEATING, S.E., WAY K.L., SULTANA, R.N., JOHNSON, N.A.
THE UNIVERSITY OF SYDNEY

INTRODUCTION: Cardiorespiratory fitness (CRF) is a known independent risk factor for morbidity and mortality (1). Furthermore, CRF and obesity have been shown to be associated with impaired fasting glucose (IFG) and type 2 diabetes (T2D) by similar magnitudes (2). Non-alcoholic fatty liver disease (NAFLD) is also associated with IFG and T2D, and increases in CRF has been shown to mitigate IFG and insulin resistance. The primary aim of this study was to explore the association between CRF and NAFLD in inactive adults with overweight and obesity. A secondary aim was to examine the possible association between CRF and NAFLD independent of known demographic and anthropometric risk factors.
METHODS: CRF, IHL, and other demographic, anthropometric and biochemical risk factors were assessed in 67 inactive, overweight and obese adults with and without diabetes. CRF was measured via a graded exercise test (Lode Corival cycle ergometer). NAFLD was assessed by grading participants' liver fat concentration via proton magnetic spectroscopy (where a liver fat score >5.5% was classified as NAFLD positive). Bivariate regression and hierarchical multiple regression analyses were performed.
RESULTS: CRF was not associated with NAFLD (p=0.49) nor liver fat concentration (p=0.09). CRF was associated with other cardiometabolic risk factors such as fasting blood glucose (p=0.02), fasting serum insulin (p=0.02) and systolic blood pressure (p=0.04), however these associations were not independent of BMI.
CONCLUSION: Our findings showed that CRF was not associated with NAFLD in inactive, overweight and obese adults, with and without diabetes. Additional studies incorporating a greater variation in CRF are needed to further explore the relationship between CRF and liver fat.

COMPARING THE EFFECTS OF TWELVE WEEKS OF HIGH-INTENSITY INTERVAL AND MODERATE-INTENSITY CONTINUOUS TRAININGS ON AFFECTIVE AND ENJOYABLE RESPONSES OF INACTIVE YOUNG WOMEN

LI, F.F., ZHANG, D., ZHU, X., LIU, Y., WANG, L., ZHANG, H.
HEBEI NORMAL UNIVERSITY

INTRODUCTION: High-intensity interval training (HIIT) is a popular solution to inactive lifestyle. The purpose of this study is to compare the effects of HIIT and moderate-intensity continuous training (MICT) on affective responses and enjoyment of 12 weeks exercises in obese women.
METHODS: Fifty-six obese and inactive young women were randomly divided into four groups, all-out sprint (SIT, 40 × 6-second sprint interspersed with 9-second rest), traditional HIIT (HIIT90: 4-minute cycling at 90% VO2max interspersed with 3-minute rest, 200 kJ/session), work-equivalent HIIT (HIIT120: 1-minute cycling at 120%VO2max interspersed with 1.5-minute rest) or MICT (60%VO2max cycling) groups. Feeling Scale (FS) during each exercise and Physical Activity Enjoyment Scale (PACES) after each exercise were recorded 1st, 4th, 8th and 12th week.
RESULTS: Differences were detected in FS ($p < 0.05$) among four groups (SIT, 1.0 ± 1.0; HIIT90, 1.9 ± 1.3; HIIT120, 0.8 ± 1.0; MICT, 1.6 ± 1.0). FS was higher in HIIT90 compared with SIT and HIIT120, and higher in MICT compared with HIIT120 group. Differences were founded in PACES ($p < 0.05$) among four groups (SIT, 88.8 ± 5.2; HIIT90, 95.5 ± 9.1; HIIT120, 92.1 ± 8.1; MICT, 80.8 ± 8.6). PACES was higher in HIIT (HIIT90, SIT and HIIT120) compared with MICT, and higher in HIIT120 compared with SIT group.
CONCLUSION: Compared with traditional MICT, higher enjoyment with HIIT at intensity 90%VO2max, but lower pleasure with HIIT at intensity 120%VO2max. Among three types HIIT, HIIT at intensity 90%VO2max is the most pleasurable.

OP-PM51 Exercise therapy

CHANGES IN CORTICAL MOTOR PLANNING FOLLOWING THERAPEUTIC EXERCISE POST-STROKE

GARLAND, S.J., PETERS, S., IVANOVA, T.D., LAKHANI, B., BOYD, L.A.
WESTERN UNIVERSITY

INTRODUCTION: After stroke, many people exhibit altered movement patterns making performance of balance and walking difficult. Therapeutic exercise has been shown to improve balance and walking ability in people after stroke; however, the extent to which motor planning improves in concert with motor performance is unknown. This pilot study examined how therapeutic exercise affects motor planning and motor performance for stepping in people post-stroke.
METHODS: Seven participants, who were enrolled in a randomized clinical trial examining two forms of therapeutic exercise post-stroke, consented to electroencephalography (EEG) and electromyography (EMG) testing on two occasions: at discharge from inpatient rehabilitation (baseline) and after 6 weeks of therapeutic exercise (post). Therapeutic exercise included either fast stepping and balancing training or usual care involving strengthening and mobility training. On each testing occasion, the participants performed three or four sets of 20 self-initiated steps whereby the foot was placed onto a 10 cm high step, totaling 60–80 steps per leg when the paretic leg was either stepping or standing (to step with the non-paretic leg). To examine motor planning processes in the cortex, the movement related cortical potential (MRCP) amplitude (cortical "effort") and duration were measured using EEG for 4s prior to step initiation. The Cz electrode was chosen for data analysis as it was the only electrode directly over the leg region in the primary sensorimotor cortices. EMG from biceps femoris (BF) and rectus femoris (RF) were measured for 150% of step duration including 50% of step duration before the step. EMG was quantified as a BF:RF co-contraction index (CCI). Clinical measures of motor impairment (Chedoke McMaster Stroke Assessment, CMSA) and balance (Community Balance & Mobility Scale, CBM) were also collected.
RESULTS: At baseline, individuals had mild to moderate leg and foot impairments, with average CMSA scores for the lower limb of 9.8 ± 0.7 (out of 14) and CBM Scores of 36.4 ± 4.9 (out of 96). After the therapeutic exercise, their clinical scores improved to 10.4 ± 0.6

and 40.9 ± 6.0, respectively. After 6 weeks of therapeutic exercise, all 7 participants showed a reduction in MRCP duration post exercise, irrespective of the type of therapeutic exercise, from 3.3 ± 0.3s to 1.1 ± 0.7s (paretic leg step, p<0.001) and 3.2 ± 0.2s to 1.4 ± 0.7s (non-paretic leg step, p<0.001). The MRCP amplitude data were more variable, with non-significant changes from 20.4 ± 13.6 mV to 17.9 ± 21.2 mV (paretic leg step) and 16.2 ± 11.0 mV to 13.0 ± 10.7mV (nonparetic leg step). Step performance improved, as evidenced by a lower CCI during the paretic step from 0.21 ± 0.12 to 0.15 ± 0.06, baseline to post, respectively.
CONCLUSION: This pilot study suggests that motor planning for initiating stepping may be improved after therapeutic exercise post-stroke through a reduction in cortical planning time without a change in the cortical "effort".

THE EFFECTS OF EXERCISE ON THE SYMPTOMS OF PERIPHERAL NEUROPATHIES – A META-ANALYSIS

STRECKMANN, F.1,2,3, TOSCANELLI, A.1, BALKE, M.4, BLOCH, W.3, LEHMANN, H.C.5, FAUDE, O.1

UNIVERSITY OF BASEL (1), UNISPITAL BASEL (2), GERMAN SPORT UNIVERSITY (3), NEUROLOGICAL DAY CLINIC , COLOGNE (4), NEUROLOGY UNIVERSITY HOSPITAL COLOGNE (5)

INTRODUCTION: Peripheral neuropathies (PNP) encompass a large group of disorders of heterogenous origin and represent a highly prevalent disease group (5-9% (Hanewinckel et al.) of the population). To date, effective treatment options are lacking and causal therapies only barely exist for inflammatory neuropathies. Promising results have been achieved with specific exercise interventions (Streckmann et al.). Our objective was therefore to conduct a systematic review with meta-analysis on specific exercise interventions tailored for neuropathic patients in order to reduce the symptoms of PNP.
METHODS: This systematic review was performed according to the PRISMA guidelines. Two independent reviewers searched electronic databases for relevant studies (until November 2018) and extracted relevant study information. We included studies in human subjects using a randomized, controlled design, conducting an exercise intervention and assessing parameters related to PNP. We calculated standardized mean changes (Hedges´g) of the training effect in the intervention relative to the control group. Data were analysed using inverse-variance models with random effects.
RESULTS: Out of 10702 search results, 36 full text studies were identified and 11 Studies (3 CIPN and 8 diabetes) fulfilled the criteria for the meta-analysis. Most studies targeted diabetic neuropathic patients. For these patients, the meta-analysis revealed beneficial effects on postural sway through balance training, Tai Chi, multimodal approaches, Frenkel, ball or plantar-stimulation (g = -0.62 [95% CI, -0.96,-0.28]). Patients in the intervention groups improved in the berg balance scale (g = -0.50 [-0.85,-0.15]) as well as in the timed-up-and-go test (g = -0.39 [-0.7,-0.07]) through balance training. Furthermore, HbA1c was reduced (g = -0.39 [-0.7,-0.07]) and nerve conduction velocity increased (N. suralis: g = -2.0 [-4.11,0.11]; N. peroneus: g = -1.17 [-2.4,0.06]) through endurance training. Data on the effects of multimodal and/or sensorimotor training in CIPN is currently insufficient.
CONCLUSION: To conclude, patients with diabetic neuropathy benefit from exercise interventions. They are able to improve balance parameters and functional mobility, mainly though sensorimotor training, while effects can be seen regarding HbA1c as well as for the nerve conduction velocity through endurance training. Regarding CIPN, data is insufficient to derive evidence-based recommendations and further high-quality studies are needed. For diabetic neuropathy, endurance and SMT target the symptoms as well as functional mobility best.

EFFECTS SPRINT INTERVAL TRAINING ON EXERCISE MOTIVATION AND AFFECTIVE RESPONSES IN PATIENTS WITH MAJOR DEPRESSIVE DISORDERS: A RANDOMIZED CONTROLLED TRIAL

DONATH, L., GERBER, M.

GERMAN SPORT UNIVERSITY

INTRODUCTION: Sprint interval training (SIT) has become increasingly popular, and is meanwhile seen as a promising exercise strategy to increase fitness in healthy people. Nevertheless, some scholars doubt whether SIT is an appropriate training protocol for largely physically inactive populations, because SIT might be too arduous, and therefore contribute to feelings of incompetence, failure, and lower self-esteem, which may undermine participants' exercise motivation. Therefore, we examined in a sample of patients with major depressive disorders (MDD) whether participation in twelve SIT sessions would lead to different changes in self-determined motivation, affective responses to exercise, cardiorespiratory fitness, physical activity, and depressive symptom severity as continuous aerobic exercise training (CAT).
METHODS: Two groups of 25 patients (39 women, 11 men) with unipolar depression were randomly assigned to the SIT and CAT condition (M=36.4 years, SD=11.3). Data was assessed at baseline and post-intervention (three weekly 35-min sessions of SIT/CAT over a 4-week period). Self-determined exercise motivation was assessed with a 12-item self-rating questionnaire, whereas affective valence was assessed in each session, prior, during, and after the exercise training using the Feeling Scale (FS). Cardiovascular fitness was measured with a maximal bicycle ergometer test, self-perceived fitness with a 1-item rating scale, physical activity with the International Physical Activity Questionnaire (IPAQ-SF), and depressive symptom severity with the Beck Depression Inventory II.
RESULTS: The SIT and CAT groups did not differ with regard to their changes in self-determined motivation from baseline to post-intervention. Participants in the SIT and CAT group showed similar (positive) affective responses during and after the training sessions. Cardiorespiratory fitness, self-perceived fitness and depressive symptom severity similarly improved in the SIT and CAT group. Finally, significant increases were observed in self-reported physical activity from baseline to post-intervention. However, these increases were larger in the CAT compared to the SIT group.
CONCLUSION: From a motivational point of view, SIT seems just as suited as CAT in the treatment of patients with MDD. This is a promising finding because from a self-determination perspective, it seems advantageous if patients' can opt between different exercise therapy regimes, and if patients' preferences with regard to exercise type and intensity are considered.

DEVELOPMENT OF A DUAL TASK MANAGING TRAINING FOR PATIENTS WITH PARKINSON'S DISEASE

RUDNIK, S.1, GULBERTI, A.2, BRAASS, H.2, PÖTTER-NERGER, M.2, WOLLESEN, B.1

1: UNIVERSITY OF HAMBURG, 2: UNIVERSITY MEDICAL CENTER HAMBURG-EPPENDORF

INTRODUCTION: Most daily activities require the simultaneous management of sensorimotor tasks while processing external information (dual-task performance, DT). Examples for daily dual-tasks represent walking on a crowded floor while avoiding bumping into people or crossing a street while observing traffic flow. Most patients with Parkinson's disease show deterioration of dual-task performance of daily

activities and particularly of gait resulting in freezing episodes and decreased mobility (Plotnik et al., 2011; Kelly et al., 2012). This study investigates the feasibility of a DT-Managing training in patients with Parkinson's disease to improve their DT walking performance.
METHODS: The DT training was performed within four training sessions with 17 Patients (3 female; 70.1 ± 7.4 years) with chronical Parkinson's disease. The exercises integrated a progression and intensity as well as task difficulty and complexity. Six different Gait conditions (single task (ST) normal and fast gait speed, DT cognitive or manual, triple task) were measured at Baseline, after every training and one week after last training with a GAITRite system (GAITRite system; CIR Systems Inc, Franklin, NJ, USA). Demographic Data and health characteristics were collected by Questionnaires (FES-I, SF 12, FOGQ, MoCA). Data analysis were done using SPSS 24.0 (IBM Corp. Released 2016. IBM SPSS Statistics for Macintosh, Version 24.0. Armonk, NY: IBM Corp.).
RESULTS: Under ST and DT cognitive conditions all gait parameters improved from baseline to the final posttest. Gait performance remained constantly among the training sessions. The Intervention improved the physical well-being of the patients ($F(1,16) = 8.166$; $p = 0.011$; $peta2 = 0.020$). The participants were able to increase the amount number of completed task progressively from an average number of 36 to 58 exercises ($F(3,12) = 19.491$; $p < 0.001$; $peta2 = 0.830$).
CONCLUSION: Patients with Parkinson's disease can pass a dual task managing Training with progressively increasing task difficulty and training volume. The training shows benefits for these Patients in daily life in kind of sanitary well-being or walking performance. Further studies should ensure the exact dose of training and progression to gain the highest impact.

Plotnik, M., Giladi, N., Dagan, Y., & Hausdorff, J. M. (2011). Postural instability and fall risk in Parkinson's disease: impaired dual tasking, pacing, and bilateral coordination of gait during the "ON" medication state. Experimental brain research, 210(3-4), 529-538.

FOSTERING AUTONOMOUS MOTIVATION, CARDIORESPIRATORY FITNESS, AND PHYSICAL ACTIVITY TO IMPROVE CARDIOVASCULAR DISEASE RISK AND WELLBEING IN RHEUMATOID ARTHRITIS: A RANDOMISED CONTROLLED TRIAL

VELDHUIJZEN VAN ZANTEN, J.J.C.S., FENTON, S.A.M., ROUSE, P.C., NTOUMANIS, N., OSAILAN A., YU, C., METSIOS, G.S., KITAS, G.D., DUDA, J.L.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Rheumatoid arthritis (RA) is an autoimmune disease, characterised by high-grade systemic inflammation, pain, and swelling of joints. RA patients are at increased risk for cardiovascular disease (CVD), and exercise is recommended to manage this risk. Less is known about effective ways to support exercise behaviour in RA. Programmes grounded in Self-Determination Theory (SDT), which aim to facilitate autonomous motivation for engagement, have been successfully used to promote exercise. In RA, autonomous motivation is associated with higher physical activity (PA) and vitality. The present study examined if a 3-month RA-tailored exercise programme with one-on-one SDT-based support for exercise, induced immediate and longer-term cardiovascular, disease- and wellbeing-related and motivational benefits when compared to the RA-exercise programme alone.
METHODS: RA patients were randomised into the experimental group (EXP, n=43, 27 women, 55 (12) years) or control group (CON, n=45, 31 women, 55 (13) years). Both groups received the same 3 month individualised gym-based exercise programme tailored for people with RA, with instructors available if needed. The experimental group also received one-on-one SDT informed consultations which aimed to foster more autonomous motivation for exercise. Cardiorespiratory fitness, self-reported PA, disease characteristics (DAS28, CRP, functional ability), CVD risk (Qrisk), wellbeing (vitality, depression, fatigue), and SDT constructs (autonomous and controlled motivation) were assessed at pre-intervention baseline, 3 months, 6 months, and 12 months follow-up. Mixed linear modelling examined within- and between participant changes in these outcomes.
RESULTS: Cardiorespiratory fitness did not change from baseline (EXP 20.1 ml/min/kg, CON 19.3 ml/min/kg) to 3-m (EXP 20.0 ml/min/kg, CON 19.1 ml/min/kg), 6-m (EXP 19.3 ml/min/kg, CON 19.6 ml/min/kg) or 12-m (EXP 19.0 ml/min/kg, CON 18.0 ml/min/kg) in either group. DAS28, CRP, vitality, depression, and fatigue did not change in either group. Significant group by time interactions revealed lower CVD risk at 6-m (11.1 vs 13.3), better functional ability at 6-m (1.58 vs 1.86) and 12-m (1.54 vs 1.73), as well as higher PA at 3-m (1577 vs 902 mins/week) in EXP compared to CON. The interaction effects revealed a worsening of functional ability and CVD risk and a decrease in PA in the control group, rather than positive changes in the experimental group. Greater increases in autonomous motivation (EXP 32% increase, CON 20% increase) and greater decreases in controlled motivation (EXP 73% decrease; CON 33% decrease) were reported in EXP compared to CON.
CONCLUSION: The SDT-based exercise intervention was successful in enhancing the quality of motivation for exercise engagement. However, no changes in cardiorespiratory fitness or other physiological or psychological outcomes were found. This suggests more intensive support is needed to facilitate sustained exercise at levels needed to achieve health benefits in RA.

ISOLATED LUMBAR EXTENSION RESISTANCE EXERCISE AS TREATMENT OPTION FOR PATIENTS WITH ADVANCED STAGES OF SPINAL DISORDERS – A CASE SERIES OF 428 PATIENTS

SPANG, C.1,2, ORT, S.2, LÖSCH, A.2, HARANDI, V.M.3, ALFEN, F.M.2

1: UMEA UNIVERSITY, SWEDEN; 2: PRIVATE ORTHOPAEDIC SPINE CENTER, GERMANY; 3: UNIVERSITY OF LUND, SWEDEN

INTRODUCTION: Isolated lumbar extension resistance exercise (ILEX) has been shown to be an effective treatment option for unspecific chronic low back pain by strengthening the paraspinal back muscles (Steele et al., 2015). Only little is known about its clinical potential for treating patients with advanced stages of spinal degeneration and disc herniations.
METHODS: In a case series of 428 consecutive patients (172 women, 273 men; mean age 51, range 17-83) with chronic low back pain and/or radiating pain into the lower extremities were selected. All patients underwent a 9-week rehabilitation program (2 sessions per week) including one set of ILEX (12-15 repetitions). Based on structural changes diagnosed by an orthopedic consultant, patients were divided into 4 different groups: (A) unspecific low back pain (n=88); (B) disc herniation (n=104); (C) degenerative/inflammatory spine disorders (n=77); (D) multiple conditions from B and C (n=159). Before and after the study isometric lumbar extension strength was tested and several Visual Analogue Scales (VAS, 0-10) were used to measure pain, psychological burden, satisfaction rates and percentage of achieved rehabilitation goal (0-100%).
RESULTS: Altogether, improvement of pain symptoms was achieved in 401/445 (90.1%) of all patients (A: 98.9%; B: 90.4%; C: 92.2%; D: 82.9%). For 283/445 patients (63.6%) no or only mild discomfort remained (A: 96.6%, B: 71.2%, C: 53.3%, D: 52.5%). Overall, pain scores (VAS) decreased from 4.6 (±2.3) to 2.7 (±2.0) ($p<0.001$). Scores on psychological burden decreased from 6.0 (±2.4) to 3.4 (±2.5) ($p<0.001$).

For most outcome measures group (A) showed better results than the other groups ($p<0.01$) and group (B) had better results than (C) and (D) ($p<0.05$). Overall, the clinical improvements of ILEX treatment decreased with the degree of degenerative features in the spine, higher pain scores prior to treatment, longer pain duration and increased age. Furthermore, there was a strong tendency of larger increase of isometric strength leading to better clinical results ($p=0.053$).
CONCLUSION: ILEX treatment can successfully improve different kinds of back pain conditions, even when advanced stages of spine degeneration are present. Thus, applying ILEX can potentially avoid spine operations for several patients. Best results were achieved for unspecific low back pain and in patients with bulging discs. Higher degrees of spine degeneration and inflammation decreased the clinical outcome and the chance of full recovery. Thus, early application of ILEX may prevent progression of spine degeneration.

ANALYSIS OF ACUTE-CHRONIC WORKLOAD RATIOS IN POPULAR MARATHON TRAINING PROGRAMS

FERLIC, M., BURNS, G.T., ZERNICKE, R.F., KOZLOFF, K.M.
UNIVERSITY OF MICHIGAN

INTRODUCTION: Monitoring of acute and chronic workload ratios (ACWR) above a critical threshold has been used in team sports to predict injury and performance (1). Despite high prevalence of injuries related to volume and intensity exposure, to date the ACWR method has not been applied to runners. Here we analyzed three popular marathon training programs detailing prescribed daily volume and intensity. The specific aim was to determine whether these programs exceeded a critical ACWR threshold when considering daily volume (external work) or volume and intensity (internal work) (2). We hypothesized that inclusion of an intensity metric will capture greater variability in the dynamic nature of marathon training. A second aim was to test different ACWR algorithms calculated through a 7:28 day simple moving average (SMA) and an exponential moving average model (EMA). We hypothesized the exponential model would be more sensitive to workload spikes and more accurately represent the time-decaying nature of fatigue.
METHODS: Three 18-week marathon training programs (i.e., Hanson, Higdon, and BAA) were compiled by training volume (kilometers) and session-RPE (sRPE) based on prescribed workout paces (i.e. MP, 10k, 5k, etc.). Paces were then mapped to a Borg-RPE scale (3). Session RPE values were calculated as the sum of interval duration (min) x RPE. Acute & chronic workloads were calculated on the daily sRPE using 7 & 28 day simple moving averages, respectively. Exponential moving averages were also computed using equivalent weighting factors.
RESULTS: None of the 3 marathon training plans exceed the critical ACWR threshold of 1.5 when analyzed by either daily volume or sRPE with both the SMA and EMA algorithms. The ACWR for all plans fell into either the low, 0.50-0.99, to moderate, 1.0-1.49, range. Across plans there was significant correlation between external workload (volume) and internal workload (sRPE) ($r2=0.991$, $p=0.0045$). For all plans, there was significant difference between the ACWR calculated using the SMA and EMA methods ($r2=0.632$, $p<0.05$).
CONCLUSION: The external & internal workloads for all 3 marathon programs remained stable over the course of the training plans and did not exhibit any danger-zone spikes. Our analysis did not support the hypothesis that session RPE would provide greater detail on workloads compared to simple external volume measures. Conversely, the EMA model did influence the calculated workloads and displayed greater correlation to daily values. These findings indicate further research may be needed for quantifying theoretical internal workloads in runners and refinement of the type of algorithm used.

EFFECT OF TWO DIFFERENT RETRAINING PROGRAMS ON POPULAR LONG-DISTANCE RUNNERS IN TERMS OF POSTURAL BALANCE.

MOLINA-MOLINA, A.1, MERCADO-PALOMINO, E.1, DELGADO-GARCÍA, G.1, LATORRE-ROMÁN, P.A.2, SOTO-HERMOSO, V.M.1
UNIVERSITY OF GRANADA

INTRODUCTION: Running is established as one of the most popular modes of exercise worldwide for general health. Unfortunately, one of the consequences of practicing running is the high rate of injuries (1). Running economy (RE) has been shown to be an important variable for the performance of long-distance runners. The increase in step frequency (ISF) during a retraining program has shown a decrease in force peak at foot strike, related to reducing injury risk factor and improving RE (2). Barefoot running has been demonstrated as useful method with the purpose of ISF (3). In addition, a different cadence retraining protocol proved the same (4). Therefore, the ways to reach an ISF could follow different protocols, but the effects on other secondary consequences such as neuromuscular or postural balance factors may not be the same. The aim of this study was to observe the effect on the postural balance of two retraining programs for 10 weeks, barefoot running versus a 15% increase in the baseline rate using sound biofeedback.
METHODS: 72 long-distance runners participated in this experimental study for 10 weeks. The sample was randomly divided into 2 experimental groups (EG1, n = 24; EG2, n = 25) and 1 control group (n = 26). EG1 carried out barefoot running periods and EG2 increased its baseline rate by 15% using a metronome in shod condition. All groups maintained their usual training programs, except for EG1 and EG2 that during the return to calm followed 2 different specific retraining programs. The retraining programs were evaluated using a total of 6 different balance tests in conditions of open and closed eyes: 2x double-support, 2x single-support left and 2x single-support right. A pressure plantar platform was used to measure the balance tests' parameters (Sensormedica, Italy). The variables of interest were 1) ellipse surface (mm2), 2) length sway (mm) and 3) average speed sway (mm/s).
RESULTS: A one way ANCOVA (groups) was performed on all data using SPSS. Significant differences were found between the barefoot group and the cadence and control groups. The variable that repeatedly shows these differences was the ellipse surface. The more difficult the balance test, the more differences were shown.
CONCLUSION: Increasing step rate is a useful method of reducing injury risk factor and improving running economy, although the way to reach this goal could be different. We have seen how retraining through barefoot running could be more effective in improving the bal-

ance abilities of popular runners than an increase in cadence through sound feedback in shod condition. Therefore, if the goal of sports professionals is to improve the postural balance of runners, in addition to other possible changes to running technique as ISF, a barefoot running retraining program could be an effective method.

ALTERATIONS IN TRAINING VOLUME AFFECT SKELETAL MUSCLE OXIDATIVE CAPACITY IN TRAINED MIDDLE-DISTANCE RUNNERS

BELLINGER, P., SABAPATHY, S., CRAVEN, J., MINAHAN, C.

GRIFFITH UNIVERSITY

INTRODUCTION: Increases in training volume improve muscle oxidative capacity in healthy, untrained individuals (Granata et al, 2016), but it is unknown if these findings translate to trained endurance athletes who already have high training volumes. Further increases in training volume in these athletes may result in acute fatigue (AF), or the development of functional overreaching (FOR). Thus, the aim of the present study was to determine if muscle oxidative capacity is influenced by alterations in training volume in trained middle-distance runners.
METHODS: Twenty-two trained middle-distance runners (n=14 male, VO2max: 73.9±4.1; n=8 female, VO2max: 63.3±3.1) completed 3 wks of normal training (NormTr), 3 wks of high-volume training (HVTr; 10% weekly increase in training volume from NormTr), and a 1-wk taper (TapTr; 55% exponential reduction in training volume from HVTr week 3). Before, and immediately after each training phase, the recovery rate of muscle oxygen consumption in the gastrocnemius medialis after short-duration (~10 s) plantar flexion exercise was measured using near infared spectroscopy and fit to an exponential curve, with the time constant (tau; s) being used as an index of muscle oxidative capacity (Ryan et al, 2012). Runners also performed a maximal incremental treadmill test to determine time to exhaustion (TTE) and VO2max. Runners who had a decreased TTE after HVTr were classified as FOR, others as AF. Differences between AF and FOR were analysed using mixed-model ANOVAs with Bonferroni pairwise comparisons.
RESULTS: Training volume was increased from NormTr (3 wk mean ± SD: 69.0±21.7 km), throughout HVTr (week 1: 75.7±22.5; week 2: 84.1±24.5; week 3: 90.6±25.9 km; all $p<0.001$) and was reduced during TapTr (42.1±12.1 km; $p<0.001$). The AF group (n=11) demonstrated an increase in TTE following HVTr (absolute difference ± 95%CI: 21 ± 18 s; $p = 0.026$) and TTE and VO2max following TapTr (37 ± 29 s; $p = 0.02$; 1.20 ± 0.66 mL·kg·min-1; $p = 0.01$), while muscle oxidative capacity improved after HVTr (-3.37 ± 2.68 s; $p = 0.009$), with no further improvement following TapTr (0.97 ± 2.43; $p=0.42$). The FOR group had a decrease in TTE (-41 ± 14 s; $p<0.001$) and VO2max (-2.30 ± 2.2 mL·kg·min-1; $p = 0.03$) following HVTr which was reversed following TapTr (67 ± 19 s; $p<0.001$; 5.30 ± 2.50 mL·kg·min-1; $p = 0.006$), while there was no change in muscle oxidative capacity at any time point ($p>0.05$). The AF group had substantially larger improvements in TTE from pre-HVTr to post-TapTr (absolute difference score: 32 ± 30 s; $p = 0.04$) compared to the FOR group.
CONCLUSION: The results from this study indicate three key points; 1) muscle oxidative capacity is increased in response to HVTr in runners who do not develop FOR but is unchanged in those who do; 2) despite improvements in running TTE following a taper period, there is not a concomitant increase in muscle oxidative capacity and; 3) runners who did not develop FOR had substantially larger performance improvements following a taper period.

UPHILL RUNNING GAIT VARIABILITY

PADULO, J.1,2, AYALON, M.3, POWELL, D.W.4, CULAR, D.2, ARDIGÒ, L.P.5, DELLO IACONO, A.6

1:UNIVERSITY ECAMPUS , 2:UNIVERSITY OF SPLIT , 3: WINGATE INSTITUTE , 4:UNIVERSITY OF MEMPHIS , 5:UNIVERSITY OF VERONA , 6: UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: Running variability (RV) has been previously investigated as a clue to profile the effect of fatigue on motor control (Fuller 2017). Accordingly, it is reasonable to hypothesize that small perturbations of whole body position (Padulo 2012a), as occurring in uphill running conditions, might influence the control of running rhythmicity that, in turn, would lead to an increase of the variability in a dissipative deterministic regimen. Therefore, we used a simple model to clarify RV role in the modulation of the motor control system leading to the increased metabolic demand during uphill running.
METHODS: Twenty-five male Ethiopian runners (age 39.5±12.0 yrs), after 10' warm-up, were tested twice (for reliability assessment) in three 10-min conditions (including 3-min passive recoveries in-between) in random order: 0%, +2%, and +2%iso. Some metabolism (HRMax% and CR10=rate of perceived exertion) and RV variables (SF=Stride frequency and SL=Stride length) were measured. 0%/+2% speed was administered as -1 km/h with respect to 10,000-m race best performance value, whereas +2%iso speed was adjusted to keep same 0% speed metabolic cost (Padulo 2012b). SF and SL were analyzed stride-by-stride in terms of coefficient of variation (CV). Univariate ANOVA with gradient as independent factor was performed and Intra-Class Correlation Coefficient was performed to assess the reliability of the measures. Significance level was set at $p<0.05$.
RESULTS: Intra-class Correlation Coefficient showed a good reliability for either HRMax%, CR10, SF, and SL (> 0.887). HRMax% and CR10 resulted different (i.e., increased) between 0% and 2% ($p<0.001$), and between 2%iso and 2% (i.e., increased; $p<0.01$). CV resulted different (i.e., increased), regarding SF and SL, between 0% and both 2%iso and 2% ($p<0.05$), whereas no difference was found between 2%iso and 2% ($p>0.05$).
CONCLUSION: Discussion
This study showed that uphill running (2%iso or 2%) had an isolated and, by specific speed choice, not cost-related increasing effect on RV. The increase of the running variability may be considered a signal of less controlled movement (Padulo 2012a), which could determine detrimental effects on performance hypothetically over long duration running. Therefore, planning some uphill running training sessions might be useful to keep motor control (Fuller 2017) counteracting increasing gait variability occurring during long distance races along hilly courses (e.g., Berlin and Boston marathons, with ~2% inclines).

DIFFERENT PSYCHOPHYSIOLOGICAL RESPONSES TO A HIGH-INTENSITY REPETITION SESSION PERFORMED ALONE OR IN A GROUP BY ELITE MIDDLE-DISTANCE RUNNERS

CASADO, A.1, JAENES, J.C.2, MORENO-PÉREZ, D.3, RENFREE, A.4

1: ISABEL I DE CASTILLA UNIVERSITY, 2: PABLO DE OLAVIDE UNIVERSITY, 3: COMILLAS PONTIFICAL UNIVERSITY, 4: UNIVERSITY OF WORCESTER

INTRODUCTION: Internal training load refers to the degree of disturbance in psychophysiological homeostasis provoked by a training session and has been traditionally measured through session-RPE, which is the product of the session Rate of Perceived Exertion (RPE) and the duration (Foster, 1998). External training load refers to the actual physical work completed, and depends on session volume, intensity, frequency and density. Drafting, which is achieved by running closely behind another runner has been demonstrated to reduce the energy cost of running at a fixed speed and to improve performance (Zouhal et al., 2015). Therefore, it is hypothesized that psychophysiological responses might reflect different levels of internal load if training is performed individually or collectively.
METHODS: 16 elite middle-distance runners performed two high-intensity training sessions consisting of 4 repetitions of 500 m separated by 3 minutes of passive recovery. Sessions were performed individually and collectively. Times for each repetition, RPE, core affect (valence and felt arousal) and blood lactate concentrations [BLa] were measured after each repetition.
RESULTS: Main time effect was significant and increased across repetitions for [BLa] and RPE ($p < 0.001$), and decreased for valence ($p = 0.001$). Main group effect was significant and values were higher when training individually for [BLa] ($p = 0.003$) and RPE ($p = 0.001$), and lower for valence ($p = 0.001$). No differential responses were found between conditions in terms of repeat time or felt arousal.
CONCLUSION: Our findings demonstrate that elite middle-distance athletes running collectively displayed a higher affective valence and lower levels of internal training load than when running alone, even when external training load was the same. According to a recently proposed model (Venhorst, Micklewright and Noakes, 2018), core affect is considered to play a primary role in performance regulation and a mediatory role in decision-making. They also consider perceived physical and mental strain to be the primary regulators of pacing behaviour. We also found that affective valence became more negative and perceived exertion increased as the session progressed. However, felt arousal remained similar throughout the session and did not differ between conditions. Although the reasons for this are not entirely clear, we suggest that the collaborative rather than the competitive nature of the exercise protocol may have had some impact on the results. A noticeable feature of this study was the high-performance level of the experimental participants, and the 'real world' scenario, whereby data were collected during training sessions of the type routinely performed during the pre-competition phase of preparation.

MOTOR ABILITY AND LOWER LIMBS KINEMATICS IN YOUNG FOOTBALL PLAYERS: AN INERTIAL SENSORS-BASED KINEMATIC EVALUATION

DI PAOLO, S., ZAFFAGNINI, S., BRAGONZONI, L.

IRCCS RIZZOLI ORTHOPEDIC INSTITUTE

INTRODUCTION: Quantitative assessment of sport performances is one of the raising domain in the human movement research. Such a research is focusing on generation of quantitative data to support a better understanding of functional improvements and prevention strategy of non-contact injury. Currently the evaluation performed in Gait Labs can be affected by bias related to the environment, either for the limited space to perform the task and for a lower automatization of the movement. Instead, performances evaluated during real training are much closer to the reality. To the date, there is still a lack of movement kinematic assessment on field.
The aims of the present work were to evaluate during ordinary training the lower limb kinematics in young football players during a pre defined training path, and to verify if the kinematics patterns are influenced by motor abilities.
METHODS: Fourteen healthy young football players (10 years ± 2 months) were enrolled in the study. Every subject was asked to perform two different activities: the Harre test, to evaluate the children motor ability, and typical movements performed in football training and matches in a pre defined path. The path consisted in 5 tasks: a lateral shuffle (LS), a vertical jump (VJ), a low skip (SK), 2 changes of direction (COD) at 90°, one right and one left, and a shot on goal (SH). Children received only few indications on how to perform the path in order to let them perform in the most natural way. For the Harre test, the time elapsed was measured. For the path, motion data were collected through a set of 7 inertial sensors (Xsens MVN) placed on feet, lower legs, upper legs, and pelvis. Kinematic data of hip, knee, ankle angles were acquired for all the tasks performed.
RESULTS: Based on the results of the Harre test, the children were divided in 2 groups ($p=0.0012$): in the Group A the ones who took more time to complete the test, which were considered less coordinate; and in the Group B the ones who took less time to complete the test, considered more coordinated. In particular, during all tasks performed the subjects of Group A presented a reduced flexion angle of all lower limb principal joints respect to Group B. For example, in the VJ the flexion angle of the Group A was 37.3° ± 12.4, 56.6° ± 16.5 and 17.7° ± 8.5 respectively (hip, knee and ankle joint) while flexion angle of the Group B was 53.5° ± 18.8, 73.5° ± 21.8 and 34.9° ± 18.2. No statistical difference was found between dominant and controlateral limbs.
CONCLUSION: The flexion angle values are slightly affected by motor abilities. The young players of the Group A adopted a "stiffer" kinematic strategy to perform the tasks compared to the ones Group B, thus resulting in more reduced movements and less performing task as reported by the trainer. Improving motor coordination could help to increase performances and avoid risky kinematic patterns during the game, like low knee flexion coupled with high ankle extra rotation, typically found in non-contact injuries.

THE EFFECT OF DIFFERENT PLAYING SURFACES ON SOCCER SKILL PERFORMANCE

ALI, A., OMEAGHER, R., OREILLY, J.

MASSEY UNIVERSITY

INTRODUCTION: Due to its popularity, football (soccer) is played on natural grass and, ever more frequently, on artificial turf. With the growing emergence of futsal, football is also played on hard surfaces as well as sprung wooden floors. Playing surfaces can impact on number of passes, shooting ability, changes in muscle forces during agility tests, repeated sprint ability and players perceived physical demands. Therefore, playing on different surfaces may impact on ball movement, traction / turning ability, and possibly influence training design and team tactics.
The aim of the present study was to examine football skill performance comparing different commonly used playing surfaces; natural grass, synthetic sand-based tennis court, 3G artificial, and hardwood gymnasium floor.
METHODS: Fourteen male players (12.7 years, with 6.2 years playing experience) from the local elite school competition volunteered to undertake the Loughborough Soccer Passing Test (LSPT; Ali et al 2007) on four different surfaces. The LSPT is a valid and reliable test of soccer skill performance, and is carried out under time pressure and incorporates passing, ball manipulation, and ball control. Following a familiarisation session, main trials were conducted with one to two weeks separating trials on each surface. Players were given two practice attempts before the mean of the next two trials were recorded as the performance score (for each surface). The overall LSPT performance time (performance time) is comprised of the time taken to complete the 16 passes (time only), plus penalty time accrued for inaccurate passing, poor ball control and/or taking too long to complete the test (penalty time).
RESULTS: There was no difference in time taken (natural grass = 46.3 ± 1.5 s; synthetic sand-based tennis court = 46.7 ± 0.8 s; 3G artificial = 46.0 ± 1.0 s; hardwood gymnasium = 46.1 ± 2.2 s; P=0.59) between the four surfaces. There was no difference in penalty time (natural grass = 9.1 ± 3.1 s; synthetic sand-based tennis court = 10.2 ± 0.9 s; 3G artificial = 10.1 ± 4.0 s; hardwood gymnasium = 7.9 ± 3.8 s; P=0.20) between trials. Finally, there was no difference in overall LSPT performance time (natural grass = 55.6 ± 4.2 s; synthetic sand-based tennis court = 56.9 ± 1.0 s; 3G artificial = 56.1 ± 4.6 s; hardwood gymnasium = 53.9 ± 5.7 s; P=0.31) between conditions.
CONCLUSION: In summary, no difference in skill performance was observed between four commonly used football playing surfaces, when using an established test of football skill. The LSPT has been used in several studies using different surfaces; these findings suggest that any differences in LSPT performance are unlikely due to playing surface.

INFLUENCE OF FATIGUE ON THE H/Q RATIO AND THE ANGLE OF MAXIMAL TORQUE IN PROFESSIONAL SOCCER PLAYERS

ZHANG, Q.S., FOURÉ, A., DEGHAIES, K., GERMAIN, A., HAUTIER, C.

UNIVERSITY CLAUDE BERNARD LYON 1

INTRODUCTION: The imbalance of torque ratio between Hamstring and Quadriceps (H/Q ratio) is considered as a major risk factor for hamstrings strains and knee injuries (1,4). Many clinicians use conventional Hconc/Qconc and functional Hexc/Qconc ratios for performance evaluation and medical screening (2). These ratios are usually measured on fresh muscles whereas injury may occur under fatigue conditions. Very few studies focused on the influence of fatigue on the muscle imbalance (4). The purpose of this study was to determine the effects of repeated maximal contractions on conventional and functional ratios as well as the angle of maximal torque in professional soccer players.
METHODS: 11 professional soccer players participated in this study. The H/Q ratios and the fatigue protocol were performed on an isokinetic dynamometer. The pre and post fatigue isokinetic assessment consisted of a set of reciprocal repeated maximal knee extension/flexion movements at 90°/s followed by a set of hamstring eccentric contraction (-30°/s). The fatigue protocol consisted of 30 maximal extension/flexion movements at 180°/s. The conventional (Hconc90/Qconc90 and Hconc180/Qconc180) and functional (Hecc30/Qconc90) ratios as well as the angle at maximal torque were compared before and after fatigue using a paired Student t tests.
RESULTS: The peak torques of knee flexors and extensors muscles were significantly reduced after fatigue whatever the velocity. The quadriceps torque loss was higher at 180°/s as compared to 90°/s. Thus, the Hconc180/Qconc180 ratio was 10% enhanced after fatigue (0.72 ± 0.14vs0.80 ± 0.17, 95% CI: -0.14 to 0.02, p-value = 0.03) whereas the Hconc90/Qconc90 was 10% lowered (0.76 ± 0.12vs0.67 ± 0.11 ,95% CI: -0.17 to -0.05, p-value = 0.04). In contrast, no significant fatigue effect on the functional Hecc30/Qconc90 ratio was observed (0.88 ± 0.05vs0.83 ± 0.29 ,95% CI: -0.15 to 0.26, p-value = 0.58). The angle at maximal torque of hamstring and quadriceps muscles were unchanged after fatigue whatever the velocity.
CONCLUSION: This study demonstrated that fatigue differently affected the hamstrings and quadriceps muscles inducing opposite conventional ratios evolution depending on the velocity - i.e. the conventional ratio increased when measured at 180°/s and decreased at 90/s whereas functional ratio kept unchanged. These results are in contradictions with previous studies (3) but may be explained by muscle typology and/or training status. Further developments will analyse EMG signal to better understand the influence of fatigue on H/Q ratios.

PHYSICAL ACTIVITY MONITORING WITH GPS AND 9-AXIS MOTION SENSOR FOR SOCCER PLAYERS

TANAKA, T.1, GOUDA, T.2, MAGOME, T.3,4, NAKATA, K.3

1: HITACHI, LTD. RESEARCH & DEVELOPMENT GROUP, 2: HITACHI, LTD., 3: OSAKA UNIVERSITY GRADUATE SCHOOL OF MEDICINE, 4: OTEMON GAKUIN UNIVERSITY

INTRODUCTION: Sports analytics using IT is introduced actively into competitive sports. For prevention of injury in daily training, real-time quantitative assessment of player's training load with measurement technologies is required [1]. In the major field sports such as soccer and rugby, many professional teams are using wearable GPS tracking systems which monitor running speed and running distance of the players. However, in order to understand plyers' training load and fatigue, monitoring physical activities such as changes of running direction and jumping is needed [2]. Therefore, our purpose is to recognize physical activities with different injury risk levels in a soccer training from only wearable sensor data.

METHODS: We developed the ultra-light (15 g, 65 mm * 35 mm * 11 mm) wearable sensor device including a GPS (YSFDMAXB, Taiyo Yuden) and a 9-axis motion sensor (MPU-9250, InvenSense) . This device has a 2.4 GHz wireless communication module (IEEE 802.15.4 standard) and can transmit sensor data to our developed receiver system set outside a soccer court. After receiving data, we extract speed, moving direction, acceleration and body direction from GPS and 9-axis motion sensor data, and recognize the basic physical activity (forward running, backward running, side stepping, change of direction, jumping and the other) which we defined with the staffs of the Japanese professional soccer team.
We performed the simulated football training of 10 college football players (age: 19 - 21) and recorded sensor data and video. After this experiment, we evaluated the reliability of our physical activity recognition by comparing with video observation.
This training is a part of the physical training in the Japanese professional football team. In this training, each player runs between the marks set at 5-meter intervals and makes a turn or jump on the marks according to our predefined pattern. We made three different moving patterns of this training. Each player performed the all pattern two times at the different intensity levels (high / middle).
RESULTS: We confirmed that our algorithm can recognize 5 types of basic physical activities from all sensor data which recorded in our simulated training. Forward running, side stepping and backward running are recognized by using the data of moving direction and body direction, and the specific pattern of acceleration indicated jumping. Moreover, the intensity level is discriminated by using the data of running speed.
CONCLUSION: Our developed system can evaluate more detailed training load of elite soccer players than the other conventional sports tracking systems. Next, we are going to apply our developed system to injury prevention of athletes with long-term monitoring.
Data were obtained according to the standards of internal review board on R&D group, Hitachi, Ltd.

PREDICTING AND INDIVIDUALIZING TRAINING LOAD USING HISTORICAL GPS DATA IN ELITE SOCCER

SIMPKIN, A., NEWELL, J., HYNES, G., MCMILLAN, K., MOORE, B.

NATIONAL UNIVERSITY OF IRELAND, GALWAY

INTRODUCTION: There is a fine balance when optimizing training load to maximize performance while minimizing injury. Accurate prediction of individual training loads for a planned training session is clearly beneficial.
In this project, annotated drills based on GPS data collected over several seasons on a professional soccer team were used to build an interactive "Drill Planner" that allows a coach to instantly predict training load metrics from a tailored session. Potential outliers (players that will find certain combinations difficult or easy) are highlighted in order to aid in injury prevention and to prescribe individualized load adjustment, crucial in a dynamic high performance environment where plans can change quickly.
METHODS: Our approach was to use linear and non-linear mixed models to create a connected statistical model that accounted for the number of drills, drill duration and rest between sets that provided reliable and robust estimates of expected training load metrics and corresponding estimates of uncertainty. Unsupervised learning techniques such as k-nearest neighbours were used to combine data between similar drills. Non-parametric regression and smoothing methods were incorporated into the mixed model framework (e.g. cubic splines, kernel smoothers) to model the correlation structure over time and to account for outcomes where the functional form was better modelled as a non-linear relationship (e.g. maximum velocity). Random effects were used to account for within player variability, player position, drill similarity (e.g. 7v7 and 8v8 small sided games) and game schedules. Suitably weighted residuals were used to identify potential outliers.
RESULTS: The performance of the final models was assessed by comparing predicted versus actual training load in test data (three soccer teams not used in the development of the Planner) across commonly used training load metrics such as total distance, high load distance, accelerations, decelerations, explosive distance and dynamic stress load. The Drill Planner achieved strong out of sample predictive performance where the model achieves correlations over 0.95 in out-of-sample testing, with median differences of below 1% of GPS outcomes.
CONCLUSION: This research is important as it demonstrates that with correctly annotated GPS data, a reliable Drill Planner can be built in order to create personalized training plans using statistical learning algorithms that are updated as more data become available. It is applicable to all sports where annotated GPS data are collected (e.g. soccer, NFL, rugby, basketball). Such a planner allows coaches to better plan, prescribe and tailor training drills in advance in order to use previous data in an objective manner to design fit for purpose individualized training sessions. The Drill Planner may also be useful as a training tool for new coaches.

THE IMPACT OF INTENSIVE SMALL SIDED GAMES ON THE DECISION-MAKING ABILITY OF SOCCER PLAYERS

MITROTASIOS, M., CHRISTOFILAKIS, O., VASILARAKIS, F., POULOS, S.

UNIVERSITY OF ATHENS

INTRODUCTION: Fatigue constitutes a major detriment for sports performance. Extensive periods of cognitive demands induce mental fatigue, which is accompanied by a decrease in cognitive functions (Boksem et al., 2006). Aim of this study was to investigate the impact of mental and physiological fatigue on the decision-making ability of soccer players during six 4vs4 plus 2 GK SSG's. We hypothesized that the intensity of these SSG's could 1) deteriorate the decision-making ability of the players and 2) the effectiveness of their execution.
METHODS: Elite U20 soccer players (n=10, aged 18,3•1 years) participated in this research. At the 1st phase of the experimental overview, players were assessed for their physiological condition. At the 2nd phase players performed 6x4vs4 plus 2 GK SSG's (duration= 4 min, rest time=3 min) at an outdoor pitch of 30x20 m with artificial grass as its surface. The two phases were conducted within a seven-day period of time. Before the SSG's players warmed – up for 20 min. During SSG's the restriction was not to pass the ball to GK. During rest periods blood lactate, heart rate and mental fatigue (VAS) were measured. The SSG's were recorded on video by 5 m distance and 3 m height. The decision - making of each player was analyzed into three phases and decisions respectively: 1) starting position and ball receive, 2) the selection of action (driving, dribbling, passing, shooting) and the direction (front – penetration, back, horizontal) and 3) the execution phase. Every phase was assessed positively (code 1) or negatively (code 0). For the statistical analysis we used descriptive statistics (f, %f, MD), the chi-square test, McNemar-test Wilcoxon-test and r - Pearson test ($p<0.05$).
RESULTS: The SSG's induced high physiological (MD heart rate: 182 bpm, MD blood lactate: 8,28 mmol/kg/min) and mental fatigue (MD mental fatigue: 77.64 AU, MD mental effort: 75.81 AU, MD motivation: 76.73 AU). Concerning the effectiveness of each of the phases of the action we found: 1) Decision A was coded positively 97.22%, Decision B was coded positively 86.49% and Decision C was coded positively 67.27%. Moreover, the outcome of the execution phase was positive 53.25%. Nevertheless, the z-scores for the comparison of

the three decisions were high too (Decision A – Decision B = .7000, Decision A – Decision C=1.1091, Decision B – Decision C=.8074) (p<0.001).
CONCLUSION: In support of our first hypothesis, mental and physiological fatigue deteriorated the decision – making ability, as several of the players' actions were not sufficiently utilized. In contrast to the second hypothesis, the rate of the positive decision on each phase of the action was high and the effectiveness of the actions executed was also remarkable.

INVESTIGATION OF THREE INDEPENDENT POPULATIONS STRENGTHENS THE HYPOTHESIS THAT GENETIC LOCI WITHIN THE PROTEOGLYCAN AND ANGIOGENESIS ASSOCIATED PATHWAYS PREDISPOSE TO ANTERIOR CRUCIATE LIGAMENT INJURY

FELDMANN, D.C., RAHIM, M., SUIJKERBUIJK, M.A.M., CIESZCZYK, P., FICEK, K., HUMINSKA-LISOWSKA, K., HÄGER, C.K., STATTIN, E., NILSSON, K.G., POSTHUMUS, M., COLLINS, M., SEPTEMBER, A.V.
UNIVERSITY OF CAPE TOWN

INTRODUCTION: Previous studies implicated polymorphisms within genes encoding proteoglycans and components of the angiogenesis-associated pathway with risk of anterior cruciate ligament (ACL) injury. The study aimed to investigate previous loci in the aggrecan (ACAN), biglycan (BGN), decorin (DCN), vascular endothelial growth factor (VEGFA) and kinase insert-domain receptor (KDR) genes with risk of ACL injury in participants from Poland and Sweden.
METHODS: The Polish cohort comprised 149 asymptomatic controls (CON) and 142 surgically confirmed ACL ruptures (ACL) of whom 127 sustained a non-contact mechanism of injury (NON). The Swedish cohort comprised 116 CON and 95 NON participants and the South African cohort included 234 CON, 227 ACL and 126 NON participants. Participants were genotyped for 11 polymorphisms:VEGFA rs699947C>A, VEGFA rs1570360G>A, VEGFA rs2010963G>C, KDR rs2071559G>A, KDR rs1870377T>A, ACAN rs1516797T>G, ACAN rs2351491C>T, ACAN rs1042631C>T, BGN rs1126499C>T, BGN rs1042103G>A, and DCN rs516115T>C. Genotype, allele frequencies and inferred haplotypes constructed were compared. Independent and combined analyses were conducted for cohorts. Statistical analyses were performed using environment R and package SNPassoc, p<0.05 was used.
RESULTS: The Polish cohort, ACAN rs1042631 TT genotype was over-represented in CON (CON vs ACL: p=0.016, OR: 0.17, 95% CI: 0.03–0.85; CON vs NON: p=0.020, OR: 0.17, 95% CI: 0.03–0.90). While the ACAN rs1042631 CT genotype was under-represented in CON (CON vs ACL: p=0.049, OR: 1.96, 95% CI: 1.00–3.84; CON vs NON: p=0.019, OR: 2.29, 95% CI: 1.14–4.60). In the Swedish population, an over-representation of VEGFA rs2010963 GG genotype and CG genotype were observed in the CON (CON vs NON: p=0.003, OR: 2.75, 95% CI: 1.39–5.45; p=0.021, OR: 0.51, 95% CI: 0.28–0.91) dominant and over-dominant models respectively. Whereas the CC genotype, recessive model, was significantly under-represented in CON (CON vs NON: p<0.001, OR: 7.98, 95% CI: 3.67-17.35). Additionally, the VEGFA rs2010963 C allele was significantly under-represented in the CON (CON: 37% vs NON: 63%; p<0.0001, OR 2.9, 95% CI: 1.91-4.42). Pooled data analyses of female participants revealed an over-representation of the KDR rs2071559 AG genotype in CON compared to NON (p=0.026, OR: 0.55, 95% CI: 0.32–0.94). Inferred A-A-G rs699947-rs1570360-rs2010963 haplotype was associated with reduced risk of ACL injury (CON vs NON: 32%, n=492 vs 26%, n=348; p=0.014, OR: 0.80, 95% CI: 0.629 – 1.021) when all participants were evaluated.
CONCLUSION: This study strengthens the hypothesis that polymorphisms within the proteoglycan and angiogenesis-associated genetic loci associate with ACL injury risk. The association of VEGFA A-A-G haplotype with reduced ACL risk further highlights angiogenesis in the aetiology.

APPLICATION OF A WHOLE EXOME SEQUENCING MODEL IDENTIFIES POLYMORPHISMS WITHIN THE TGFBR3 AND TGFBI GENES TO BE ASSOCIATED WITH SUSCEPTIBILITY TO ANTERIOR CRUCIATE LIGAMENT RUPTURES.

SEPTEMBER, A.V., LAGUETTE, M.J., BARROW, K., SAUNDERS, C.J., GAMIELDIEN, J., COLLINS, M.
UNIVERSITY OF CAPE TOWN, UNIVERSITY OF THE WESTERN CAPE

INTRODUCTION: Applying a candidate gene method, more than 80 genetic loci have been implicated in susceptibility to Achilles tendinopathy and/ or ruptures to the anterior cruciate ligament (ACL). A novel whole exome sequencing (WES) approach in conjunction with a tiered filtering strategy was applied to identify potential functional polymorphisms within the genes encoding the transforming growth factor-beta (TGF-β) family: TGFBR3 and TGFBI to be investigated in risk models for anterior cruciate ligament (ACL) ruptures.
METHODS: A case-control genetic association study was performed on participants from South Africa compromising of 210 physically active asymptomatic controls (CON; N=92 females), and 249 surgically diagnosed ACL (ACLR; N=65 females) cases of which 147 were reported to have a non-contact mechanism of injury (NON group; N=47 females). Data from WES and bioinformatics tools were used to prioritize variants of potential functional significance. Participants were genotyped for three polymorphisms: TGFBR3: rs1805113 G>A, TGFBR3 rs1805117 T>C and TGFBI rs1442 G>C genes using Taqman© SNP genotyping assays. The genotypes and allele frequencies were compared and inferred haplotypes were constructed using the genotype data. Statistical analyses were conducted using the programming environment R and package SNPassoc. A significance level of p<0.05 was set for all statistical analyses.
RESULTS: An over-representation of the TGFBR3 rs1805113 GG genotype was observed in CON (CON vs ACLR: p=0.0097, OR: 0.48, 95% CI: 0.286 - 0.848). Similarly, the G allele was over-represented in the CON when compared to ACL (p=0.014, OR: 0.72, 95% CI: 0.547 - 0.940) and NON (p=0.021, OR: 0.70, 95% CI: 0.517 - 0.950). When only females were evaluated, TGFBI rs1442 CC genotype was under-represented in CON when compared to ACLR (p=0.013; OR: 0.31, 95% CI: 0.12 - 0.77) while the G allele was over-represented when compared to ACLR (p=0.021; OR: 0.57, 95% CI: 0.352 - 0.922). The inferred A-T rs1805113-rs1805117 haplotype was associated increased risk of ACLR and found to be significantly under-represented in CON (47.9%, N=101) compared to ACLR (52.6%, N=131)(p=0.043, OR: 1.18, 95% CI: 0.866 – 1.612) when all participants were evaluated. The alternate G-C haplotype was associated with reduced risk of ACLR and

found to be significantly over-represented in CON (16.0%, n=34) compared to ACLR (9.2%, n=23) (p=0.009; OR: 0.58, 95% CI: 0.346 - 0.965).
CONCLUSION: This novel study implicates polymorphisms within TGFBR3 and TGFBI with risk susceptibility to ACL ruptures. These genes play key roles in the TGF-β signalling pathway, pivotal to the development, integrity and healing of connective tissues and therefore represent potential novel targets for therapeutic interventions for ACL

TOP ATHLETES DEMONSTRATE GENOTYPE AND PHENOTYPE SPECIFIC SPECIALIZATION OF MUSCLE COMPOSITION

FLÜCK, M., KRAMER, M., FITZE, D.P., FRANCHI, M.V., VALDIVIESO, P.

UNIVERSITY OF ZURICH

INTRODUCTION: Gene polymorphisms are associated with specifically athletic phenotypes relying on maximal or continued power production and affect the specialization of skeletal muscle composition with endurance or strength training of untrained subjects. We tested whether prominent polymorphisms in genes for angiotensin converting enzyme (ACE), tenascin-C (TNC) and actinin-3 (ACTN3) would also be associated with the differentiation of cellular hallmarks of muscle metabolism and contraction in high level athletes.
METHODS: Muscle biopsies were collected from m. vastus lateralis of three distinct phenotypes; high level competitive endurance athletes (n = 29) and power athletes (n = 17), and untrained non-athletes (n=63). Metabolism-related cellular parameters (such as capillary-to-fiber ratio, capillary length density, and volume densities of mitochondria and intramyocellular lipids) and contraction-related factors (fiber type distribution, mean cross sectional area (MCSA), volume densities of myofibrils and sarcoplasma) were analyzed by quantitative electron microscopy of the biopsies. Gene polymorphisms of ACE (rs1799752), TNC (rs2104772) and ACTN3 (rs1815739) were determined using high-resolution melting polymerase chain reaction (HRM-PCR). Genotype distribution was assessed using Chi2 tests. Genotype and phenotype effects were analyzed by univariate or multivariate analysis of variance and post-hoc test of Fisher. P-values below 0.05 were considered statistically significant.
RESULTS: The athletes demonstrated the reported specialization of metabolism- and contraction-related cellular parameters. Genotype differences in the percentage of slow fiber type were identified for all three gene polymorphisms. Further genotype effects on cellular parameters could be identified, and localized post-hoc, for rs1799752 and rs2104772 when taking the interaction with the phenotype into account. Between the endurance and power athletes this concerned effects on capillary length density for rs1799752 and rs2104772, fiber type distribution and volume densities of myofibrils (rs1799752) and MSCA (rs2104772). The major theme was that presence of the I-allele of rs1799752 was associated with 50%-higher volume densities of mitochondria and sarcoplasma, at the expense of myofibrils, in endurance athletes, when absence of the I-allele in power athletes was associated with the highest fiber MCSA.
CONCLUSION: ACE and tenascin-C gene polymorphisms influence subcellular strategies that enhance metabolic and contractile function at the muscle fiber level in specifically-trained competitive athletes. Associations of the insertion/deletion genotypes of ACE (rs1799752) with endurance- and power-type Sports appear, in part, to be explained by trainable differences in metabolism-related composition and capillarisation of muscle fibers in knee extensor muscle. By contrast, associations between ACTN3 genotypes and Sports performance appear related to genetically-determined differences in fiber type distribution.

FUNCTIONAL POLYMORPHISMS WITHIN THE INFLAMMATORY PATHWAY REGULATE EXPRESSION OF EXTRACELLULAR MATRIX COMPONENTS IN A GENETIC RISK DEPENDENT MODEL FOR ANTERIOR CRUCIATE LIGAMENT INJURIES

SUIJKERBUIJK, M.

ERASMUS MC

INTRODUCTION: Although various intrinsic and extrinsic risk factors of anterior cruciate ligament (ACL) injuries have been identified, the exact mechanism of injury is still not fully understood. Today there is mounting evidence suggesting a genetic contribution to the susceptibility of ACL injuries. Therefore, the aim of the current study is to investigate the functional effect of polymorphisms within genes of the inflammatory pathway on the expression of structural extracellular matrix components and the susceptibility to ACL injury.
METHODS: Eight healthy South African participants were genotyped for interleukin (IL)1B rs16944 C>T and IL6 rs1800795 G>C and classified in genetic risk profile groups. Differences in type I collagen (COL1A1), type V collagen (COL5A1), biglycan (BGN) and decorin (DCN) mRNA expression were measured in dermal fibroblasts either unstimulated or following IL-1β, IL-6 or tumor necrosis factor (TNF)-α treatment. Moreover, a genetic association study was conducted in two cohorts from different ancestries: (i) a Swedish cohort comprised of 116 asymptomatic controls (CON) and 79 surgically confirmed ACL ruptures and (ii) a South African cohort of 100 CONs and 98 ACLs. All participants were genotyped for COL5A1 rs12722 C>T, IL1B rs16944 C>T, IL6 rs1800795 G>C and IL6R rs2228145 G>C. Genotype data was used to create inferred allele constructs: COL5A1-IL1B-IL6 and IL6R COL5A1-IL1B-IL6R for each of the cohorts. The frequency distributions of the genotype, allele and inferred allele constructs were compared between the cases and controls.
RESULTS: Fibroblasts with an IL1B high-risk genotype profile resulted in decreased BGN (p=0.020) and COL5A1 (p=0.012) expression levels after IL-1β stimulation and expressed significantly less COL5A1 (p=0.042) in response to TNF-α compared to the controls. Similarly, unstimulated IL6 high-risk fibroblasts had significantly lower COL5A1 (p=0.012) expression levels then IL6 low-risk fibroblasts.
In the genetic association study, the COL5A1-IL1B-IL6 T-C-G combination (p=0.034, Haplo-score 2.1) and the COL5A1-IL1B-IL6R T-C-A (p=0.044, Haplo-score: 2.0) combination were associated with an increased susceptibility to sustaining a ligament injury in the Swedish cohort when only male participants were evaluated.
CONCLUSION: These novel findings provide functional evidence underpinning some of the previously implicated inflammatory genetic susceptibility loci and highlights specific ECM structural components. The findings further emphasise the involvement of the inflammatory pathway in matrix remodeling in the context of genetics susceptibility models and highlights potential therapeutic targets.

VOLUNTARY WHEEL RUNNING INFLUENCES ON DYNAMICS OF GUT MICROBIOTA F/B RATIO IN TLR5 DEFICIENT MICE

YANO, H., KOBIKI, N., WATANABE, C., KREMENIK, M.J., AOKI, T., UCHIDA, M., IEMITSU, M., OYANAGI, E.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: The gut microbiota has emerged as a key regulator of host metabolic diseases such as obesity, diabetes, insulin resistance and other cardiometabolic disorders. Especially, it has been reported that obese people have a high Firmicutes and Bacteroidetes (F/B) ratio. To clarify the relationship between Firmicutes, which relates to obesity induction, and Bacteroidetes, which is involved in leanness, it is important to investigate the preventive effect of exercise on obesity via changes in gut microbiota. In this study, we examined the changes in gut microbiota, especially Firmicutes and Bacteroidetes, by voluntary exercise habits using Toll-like receptor 5 gene knock out (Tlr5-/-) mice, which develop metabolic syndrome in a normal diet.
METHODS: Four-week-old Tlr 5-/- (KO 5) and wild type (WT) male mice (C57BL/6 strain) were used and loaded in the sedentary (Ctrl) or wheel running (WR) condition for 20 weeks. Fecal matter was collected at 4-, 8-, 14- and 24-weeks old in order to analyze gut microbiota.
RESULTS: As a result of all the obtained data, a negative correlation was shown between Firmicutes and Bacteroidetes ($r=-0.745$, $p<0.001$). Although the influence of Tlr5 gene deficiency in 4-week-old mice was not observed in the correlation between Firmicutes and Bacteroidetes, the influence has been definitive for every week of age, and at 24-weeks, different regression lines in KO5 and WT were plotted. Furthermore, the difference in correlation coefficient also was noticeable (KO5 vs. WT: $r=-0.996$ and $r=-0.506$, respectively). In addition, when comparing the relationship between Firmicutes and Bacteroidetes in the stage of 24-week-old of KO5 mice with WR and Ctrl conditions, differences in F/B ratio were indicated on the linear regression. Namely, in the WR condition, the relative abundance showed Firmicutes < Bacteroidetes, and in Ctrl condition, it was Firmicutes > Bacteroidetes.
CONCLUSION: It is an interesting finding that the relationship between Firmicutes and Bacteroidetes was simply shown by the lack of one gene. Also, it might have shown a new important function of TLR5, which recognizes bacterial flagella protein flagellin, for living organisms. In addition, it is considered that our findings are meaningful in examining the effect of exercise on the prevention of obesity via gut microbiota. These results suggest that a high correlation between gut microbe Firmicutes and Bacteroidetes of Tlr5-/- mice was revealed with or without exercise.

DIFFERENT EFFECTS OF EXERCISE INTENSITY ON GUT MICROBIOME COMPOSITION IN PATIENTS WITH TYPE 2 DIABETES

TORQUATI, L.1,2, GAJANAND, T.1, COX, E.R.1, ZAUGG, J.1, KEATING, S.E.1, COOMBES, J.S.1

THE UNIVERSITY OF QUEENSLAND

INTRODUCTION: Gut microbiome plays a crucial role in determining health and disease status, with composition being both inherited and modulated by lifestyle. Recent findings have suggested that regular exercise is associated with higher microbial diversity and health promoting taxa (1,2). However, studies so far have included only healthy or athletic populations, providing limited translation to clinical populations. We therefore aimed to compare the effects of 8 weeks of combined aerobic and resistance high intensity interval training (C-HIIT) with combined moderate intensity continuous training (C-MICT) on gut microbiome composition and abundance in adults with type 2 diabetes.
METHODS: In this sub-study of the Exercise for Type 2 Diabetes trial, 12 inactive volunteers (age 64.3±6.4 y) with confirmed type 2 diabetes (duration 7.8±6.3y; HbA1c 8.5±1.5%) were randomly allocated to either: A) combined aerobic and resistance high intensity interval training (C-HIIT, n=5), (3min 50-60%HRpeak, 1x4min 85-95% HRpeak, 8x1min at RPE 17-18, 3x/week) or B) combined aerobic and resistance moderate intensity continuous training (C-MICT, n=7), 52.5min 2x/week and 22.5min + 30min at RPE 11-13 2x/week (55-69% HRpeak). Outcome measures were taken at baseline and at 8-weeks (end of intervention), and included gut microbiome (faecal samples), anthropometric and glucose metabolism markers, and cardiorespiratory fitness. Bacterial DNA was isolated with Qiagen DNeasy Powersoil Kit and sequenced with shotgun metagenomics (Illumina MiSeq). Within-subjects differences were assessed with paired samples t-test, and between-group differences were examined via ANCOVA, adjusting for baseline. Data are presented as mean ± standard deviation.
RESULTS: There was a significant effect of time, with exercise increasing Proteobacteria (phylum), Alestipes onderdonkii and Blautia obeum (+1.0±1.5%, +0.1±0.1%, +0.1±0.2%, $p=0.04$). Proteobacteria and A. onderdonkii significantly increased (+2.4±0.8% and +0.2±0.1%, $p<0.01$) and Agathobacter significantly decreased in C-HIIT (-0.8±0.6%, $p=0.03$). Tyzzerella and species from Oscillospirales significantly changed only in C-MICT (-0.1±0.1% and +0.2±0.2%, $p=0.05$). Changes were significant between groups ($p<0.04$). VO2peak increased more in C-HIIT than in C-MICT post-intervention (+2.9±3.0 vs +1.0±1.9 ml/kg/min) but this difference was not significant. There were no significant changes in glucose metabolism markers.
CONCLUSION: Higher intensity exercise had a greater effect on gut microbiome composition, by modulating taxa associated with health outcomes.

THE EFFECT OF TRAINING AND SINGLE BOUT OF EXERCISE ON BLOOD IRISIN AND BDNF CONCENTRATION AND ENERGY STATUS OF ERYTHROCYTES

RODZIEWICZ, E., KRÓL-ZIELINSKA, M., ANTOSIEWICZ, J., FLIS, D., KAWA, M., ZIEMANN, E.

ACADEMY OF PHYSICAL EDUCATION AND SPORT IN GDAŃSK

INTRODUCTION: Irisin the exercise-induced myokine is involved in glucose homeostasis, post-exercise muscle adaptations and plays a significant role in stimulating brain-derived neurotrophic factor (BDNF) - a potent marker of cognitive abilities 1. Moreover, animal as well as human models indicated that both proteins could regulate energy metabolism in muscle and brain 1,2. No data indicated the relationship between irisin and energy status of red blood cells, presented as ATP/ADP ratio, what in particular importance due to cellular energetics and proper functioning of the erythrocyte during intense exercise. Interestingly irisin as well BDNF concentration decreased with

age 3,4. The aim of the current study was to assess the effect of a single bout of exercise and training status on irisin and BDNF concentrations and erythrocytes energy status in two age groups. In addition, differences in analyzed parameters in two age groups at the baseline have been evaluated.
METHODS: 12, highly trained males (training experience - 38 ± 6 years) took part in the study. Participants were assigned into two groups– the middle-age group (MG) and the senior group (SG). Participants performed a single bout of acute exercise to the exhaustion on a treadmill. The blood samples were collected at the baseline and 10 minutes after exercise. BDNF and irisin serum concentrations were determined by the immunoenzymatic method. The ATP, ADP, AMP in red blood cells were also assessed using high-performance liquid chromatography (HPLC).
RESULTS: We observed no differences in irisin and BDNF serum concentrations between SG and MG at the baseline. Still, only in MG significant correlation between these proteins was noted ($r=0.80$, $p<0.05$). Resting values of nucleotides (ATP, ADP, AMP) were significantly higher in MG than in SG. Among all participants serum BDNF was significantly associated with higher ratio ATP/ADP ($r=0.88$, $p<0.05$). A single bout of the exercise induced rise of BDNF only in MG group ($p<0.05$), and any changes in irisin concentration in both groups. The increase of ATP/ADP ratio was also observed in both groups ($p<0.05$). Only in SG irisin inversely correlated with ADP and AMP ($r=-0.93$, $r=-0.97$; $p<0.05$) respectively.
CONCLUSION: The concentration of BDNF and irisin correlated with nucleotides in erythrocytes among trained men. Futures studies are needed to establish if the interdependence is physiological significant or accidental. Considering that in other cell types both these proteins influence energetic metabolism it is possible that they also act on erythrocytes.

CIRCULATING MYOKINE IRISIN LEVELS MODULATED BY AN ACUTE BOUT OF AEROBIC EXERCISE ARE LINKED TO COGNITIVE FUNCTIONS AND METABOLISM IN THE ELDERLY

UKROPEC, J.1, TOMKOVÁ, M.1, SCHON, M.1,2, SLOBODOVÁ, L.1,2, LAIFEROVÁ, N.1,2, NEMEC, M.1, SUTOVSKÝ, S.3, TURCÁNI, P.3, VALKOVIC, P.4, UKROPCOVÁ, B.1,2,5

INTRODUCTION: Irisin has been recently identified as an exercise-induced myokine released to circulation by contracting skeletal muscle. Evidence from animal studies suggests that irisin could mediate some of the exercise benefits for both metabolism and cognition. Aim of this work was to evaluate effects of acute exercise bout on serum irisin.
METHODS: Serum irisin levels (ELISA, Biovendor) were assessed at baseline, immediately after and 60min after an acute bout of aerobic exercise (40-minutes cycling on a stationary cycle at 70% of VO2max) in the group of 30 (7M/23F) seniors (65.8+/-4.7yrs.). Cognitive functions were assessed by cognitive tests (DSST, computerized tests MemTrax & Cogstate). Metabolic flexibility (ΔRQ) was determined by combining euglycemic hyperinsulinemic clamp (assessment of insulin sensitivity) with indirect calorimetry (assessment of energy expenditure and metabolic substrate preference).
RESULTS: At baseline pre-exercise state, irisin was not correlated with metabolic flexibility (ΔRQ) nor with cognitive functions. However, irisin levels detected immediately after an acute aerobic exercise bout were positively associated with both metabolic flexibility ($p=0.002$) and cognitive tests` scores (Learning/working memory, $p=0.018$; DSST, $p=0.046$; MemTrax, $p=0.03$). These associations were detected despite the fact that the effect of an acute exercise bout on circulating irisin did not reach statistical significance.
CONCLUSION: Subtle dynamic changes of circulating irisin induced by acute aerobic exercise could contribute to the benefits of exercise for metabolic flexibility (health) and cognitive performance in the elderly.

EFFECTS OF WHEEL RUNNING ON BLOOD-BRAIN-BARRIER PERMEABILITY IN HIGH-FAT-DIET FED MICE

WATANABE, C., AOKI, T., KOBIKI, N., KREMENIK, J.M., OYANAGI, E., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: It has been known that obesity is associated with an increased risk of mental disorders (Zhao et al., BMC Psychiatry, 2011). Obesity-induced inflammation and immunological responses in the brain might be risk factors of mental health. Additionally, increases in the permeability of the blood-brain barrier (BBB) also are induced by high stress associated with decreases in the expression of the tight junction molecules. Although it was reported that obesity also induced BBB dysfunction, aerobic exercise limited its BBB dysfunction in obese subjects (Roh and So, J Sport Healt Sci, 2017). However, another study showed that intense exercise has the potential to increase blood–brain barrier permeability without causing structural brain damage (Bailey et al., Exp Physiol, 2011). In this study, we examined the gene expression of tight junction molecules related to BBB function in order to clarify the effect of voluntary physical exercise and a high-fat-diet.
METHODS: Eight-week-old male C57BL/6 (n=32) mice were divided into two groups: control diet (CD) and high-fat-diet (HFD). Then, each group was treated with or without voluntary wheel running (W) and sedentary control (C) for 10 weeks. After the voluntary exercise period, brain (hippocampus and cerebrum) tissues were collected, and then they were measured for the mRNA expression of the tight junction molecules (Zo-1, Occludin and Claudin5) by real-time RT-PCR.
RESULTS: Although the Claudin5 expression of the hippocampus in the HFD group was significantly lower than that of the CD group, Zo-1, Occludin and Claudin5 with W treatment were significantly lower than those with C treatment. Zo-1 of the cerebrum in the HFD group was significantly lower than that of the CD group, and the effect of wheel running was not observed in the expression of the cerebrum. On the other hand, Occludin of the cerebrum in the HFD group was significantly higher than that of the CD group, and Claudin5 with W treatment was significantly lower than those with C treatment. However, these results were not observed in the high fat diet.
CONCLUSION: Our hypothesis was that functional damage of BBB and structural failure of tight junction molecules might be induced in HFD mice. Although, in fact, Claudin5 of hippocampus and Zo-1 of cerebrum observed a decline in dependence on a high-fat-diet, Occludin of the cerebrum was found to increase in the HFD group. In addition, the expression of tight junction molecules was decreased by wheel-running. It is considered that in this study long distance running (CD:54km/wk, and HFD:62km/wk) by wheel cage might be

enough stress for the BBB function.Thus, these data reinforce the essential risk between a high-fat-diet and voluntary wheel running and suggest that excessive exercise might not always have a beneficial effect on BBB function.

HYPOXIC TRAINING IN OBESE MICE WITH METABOLIC DISORDER

RU, W.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Hypoxic training has been reported to lower obesity morbidity without clear underlying mechanisms. This purpose of this study was to investigates the effect of hypoxic training on metabolic changes, particularly liver metabolism of diet-induced obese mice.
METHODS: Thirty-two high-fat diet induced C57BL/6J mice were assigned into the following groups (n=8 each): sedentary (S), normoxia training (N), living, and training in normoxic conditions for 4 weeks, hypoxia (H) , living in normobaric hypoxic conditions for 4 weeks, and hypoxia + training (HT), living and training in normobaric hypoxic conditions for 4 weeks. Epididymal adipose tissue expression levels of leptin and leptin receptor were determined. We compared the hypoxic training group with normoxia training, hypoxic or sedentary (housed at normoxia) animals. Body weight, fat mass, glucose tolerance, liver physiology and liver metabolomics were determined after 4 weeks intervention.
RESULTS: In both hypoxic and normoxia training groups, body weight was lower than the sedentary group, with less fat mass. Insulin sensitivity and lipid accumulation in liver were improved after hypoxic training. Moreover, analysis of liver metabolomics reveals insights into the protective effect of hypoxic training on HFD-induced fatty liver.
CONCLUSION: 4 weeks hypoxic training reduced body weight, improved glucose tolerance, rescued fatty liver and changed the glucose and lipid metabolites in DIO mice. Taken together, these findings provide a molecular metabolic mechanism for hypoxic training.

QUANTIFICATION OF INTERNAL LOAD IN WHEELCHAIR RUGBY COMPETITION: A PRELIMINARY STUDY

PENA, L.G.S., SANTOS, L.G.T.F., CAMPOS, L.F.C.C., VENDITTI, J.R.R.

CENTRO UNIVERSITÁRIO CARLOS DRUMMOND

INTRODUCTION: Wheelchair Rugby (WR) is a Paralympic sport played by people with tetraplegia or a similar condition. In order to improve performance of WR players during the matches, it is necessary to know specific demands of the sport, control and organize all the training periodization.
METHODS: Eight WR players participated the study , during a Brazilian tournament, with national Division I teams. The subjects had 20 hours per week of training time, at least four years of experience in the sport. All the athletes participated of four games in a period of two days. To avoid influence of RPE values from external factors each player provided their RPE value individually in a time between 20 to 30 minutes after each match. RPE values and playing time were considered to calculate game internal load, monotony and Strain, in reference to the whole championship.
RESULTS: The athletes showed a mean value for RPE of 4,63±0,99 per game. Total mean playing time was 156±118,26 minutes, generating a total tournament load of 875,81±646,72AU. The values average referred to monotony and Strain were 1,35±1 and 1228,03±2053,02AU, respectively
CONCLUSION: From the RPE values, it indicated that the tournament total internal load is moderate. The players were not in risk of overtrainning or overreaching, because monotony and strain parameters being in acceptable values for team sports. The number of substitutions may have influenced in a lower internal load, due the reduced playing time. Results point that championship internal load was not high enough to impair athletes' physical conditions.

CARDIAC OUTPUT DETERMINANTS DURING EXERCISE IN PARALYMPIC ATHLETES (PA) WITH A LOCOMOTOR IMPAIRMENT

BERNARDI, M.1, GUERRA, E.3, RODIO, A.4, CASTELLANO, V.5, SCHENA, F.6, BHAMBHANI, Y.7

1 SAPIENZA UNIV. ROME, 2 HEALTHCARE UNIT MODENA, 3 UNIV. CASSINO - SOUTHERN LAZIO, 4 SANTA LUCIA FOUNDATION, 5 UNIV. VERONA, 6 UNIV. ALBERTA CANADA

INTRODUCTION: Aerobic fitness levels have been well documented in Paralympic Athletes (PA) with locomotor impairment (LI) [1, 2, 3], demonstrating the impact of exercise intensity and sport type on the peak oxygen uptake. Among the possible factors associated with higher peak oxygen uptake, there is a higher maximal cardiac output (CO) [4]. The latter would be determined by higher stroke volume (SV) and heart rate (HR), but previous studies have documented that SV during exercise is significantly lower in individuals with spinal cord injury (SCI) compared to those who are wheelchair dependent due to another LI [5]. Nevertheless, limited research has documented the SV responses to exercise in PA with LI. To establish possible differences in cardiovascular adjustments to exercise between PA with SCI and PA with LI determined by different health conditions and to assess long term adaptations to exercise in PA with LI, the goals of the present study were: (1) to measure CO determinants (SV and heart rate - HR) during exercise and (2) to compare relationships between peak oxygen uptake and the highest sub-maximal exercise SV in PA with LI.
METHODS: Two groups of PA with either SCI (N=19) or lower limb amputation (AMP, N=9) and post poliomyelitis (PM, N=5), competing in sports with different energy expenditure, were tested during arm cranking ergometer maximal and sub-maximal exercises. All PA completed an incremental maximal cardio-pulmonary exercise test (CPET) to assess peak responses. In different sessions CO was measured through the carbon dioxide rebreathing method at sub-maximal exercise intensities (30%, 50% and 70% of peak oxygen uptake).
RESULTS: In spite of no differences in age, anthropometry, and both peak oxygen uptake and peak blood lactate, peak heart rate measured in the CPET was lower in PA with AMP/PM (175.5+12.59 beats/min) than PA with SCI (186.1+11.04 beats/min). During sub-maximal exercise, at the intensity in which the highest SV was attained (68±9.7% in the PA with SCI and 68±10.0% in the PA with AMP/PM), PA with AMP/PM displayed significantly higher SV (154.8±17.60 ml) and lower HR (125.6+13.74 beats/min) than PA with SCI (117±24.7 ml and 142.2±15.81 beats/min, respectively). The highest values of submaximal SV correlated linearly and positively with peak oxygen uptake in both PA with SCI (R squared=0.796) and AMP/PM (R squared=0.824).

CONCLUSION: PA with SCI compensating with a higher HR the reduce exercise SV, when appropriately trained, reach, at the same oxygen uptake level, the same CO of PA with AMP/PM. Regardless health condition and type of impairment, SV is a significant determinant of peak oxygen uptake and therefore evidence of cardiac adaptation to exercise in PA with LI.

CURRENT PERFORMANCE TESTING IN ELITE PARALYMPICS AUSTRIAN ALPINE SKI RACERS

RASCHNER, C., HILDEBRANDT, C., EBENBICHLER, C., LUCHNER, R., PEREZ, A., PATTERSON, C., HÖLLRIGL, L., STEIDL-MÜLLER, L.
UNIVERSITY INNSBRUCK

INTRODUCTION: Over the last decades, the Paralympic sport has gained a considerable medial interest; however, it still represents a lack in scientific research. Alpine ski racing demands a very high level of fitness, which is true for non-disabled and disabled athletes. The aim of this project was to establish a scientifically based skiing specific test battery for Paralympics alpine ski racers to effectively monitor training programs and individual fitness.
METHODS: 16 athletes of the Paralympics Austrian ski team underwent the testing procedures twice annually. They were separated into two different groups. One testing-protocol was designed for monoski-athletes (n=7) and the other was established for skiers (n= 9) with handicaps such as amputations, visual impairment or other disabilities. The skiing specific test battery for the monoski-athletes included isometric core, upper body (bench press and pull) and hand grip strength tests and a skiing specific balance test with the monoski. The skiing specific test battery for the other disabled athletes consisted of an isometric leg extension and core strength test, power tests (CMJ, DJ), and a diverse balance test [1]. Due to the individual handicaps, the performance diagnostic values are described descriptively with comparisons to non-disabled elite ski racers.
RESULTS: The one-legged CMJ height of a lower leg amputee male athlete was 23.1cm (average jump height of non-handicapped elite ski racers is 25cm). Athletes with amputations at the upper extremities reached comparable reactive strength indexes in the DJ (up to 2.3) to non-disabled ski racers. The strongest leg amputees showed isometric leg strength values of 26-28N/kg with their intact legs (mean values of 18 to 19 year old non-disabled elite male ski racers are in the same range). The strongest athlete among the paraplegic athletes reached 14.5N/kg while bench pressing and 16.2N/kg while bench pulling; these values (relativized to body weight) are comparable with results of Ski-Cross athletes of the Austrian skiing federation, who also perform this test in their standard test battery. Due to their different levels of paralysis, the trunk strength diagnoses of sitting paraplegics are very individual. For example a monoski athlete (TH12-L1) generates an absolute strength of 885N during flexion and 1276N during extension in the core strength test in lying position.
CONCLUSION: Whether you are a disabled or non-disabled athlete, testing and analyzing the individual fitness is essential to monitor training and predict performance in ski racing. The increasing competitiveness and professionalism in handicapped sport requires an efficient and effective management of the training process. Regular testing also contributes to prevent injuries and overtraining by monitoring training adaptations [2].

DIFFERENCES IN BODY COMPOSITION IN VARIOUS WHEELCHAIR SPORTS

FLUECK, J.
SWISS PARAPLEGIC CENTRE

INTRODUCTION: It is already very well-known, that a chronic lesion of the spinal cord might lead to a significant loss of muscle mass in the paralyzed limbs and therefore generating a difference in body composition compared to healthy, able-bodied persons (Maggioni et al., 2003; Modlesky et al., 2004). On the other hand, it seems obvious, that exercise is very effective in reducing total body fat content not only in able-bodied but also in spinal cord injured persons (Gorla et al., 2016; Inukai et al., 2006). Thus, it seems very worthwhile to track body composition in wheelchair athletes in order to optimize their energy needs regarding to their training schedule as well as to optimize performance in weight-dependent sports disciplines. The aim of this study was to investigate, whether a difference in various wheelchair sports in body composition might be detected and how that difference could be interpreted.
METHODS: In total, 69 athletes (mean ± standard deviation; age 33 ± 11y; body mass 65.1 ± 14.8 kg; height 169.9 ± 14.9 cm and time since injury 228 ± 126 months) from different national teams in wheelchair sports underwent a DXA measurement to analyze their body composition. The measurement took place at the time they went to see the sports physician for a yearly medical check-up.
RESULTS: The data showed a total body fat content in all athletes of 25.2 ± 9.5 % with a fat content of 20.8 ± 10.7 % in the arms, 22.5 ± 9.5 % in the core and 35.1 ± 15.1 % in the legs. Athletes competing in wheelchair athletics seemed to have a higher total fat content in the legs compared to other sports such as wheelchair rugby and basketball. Female athletes tended to have a higher total fat content compared to male athletes as well as paraplegic athletes showed a higher fat content compared to tetraplegic athletes. Some athletes showed a very high difference in fat-free mass between left and right arm. In general, total body fat content was mainly influenced by fat-free mass and/or fat mass in the legs.
CONCLUSION: This study shows why a body composition performed by other methods such as bio-impedance analysis might lead to misinterpretation when it comes to observation of the body composition in wheelchair-dependent athletes. In addition, a DXA measurement might be a good way to track the body composition after an athlete-specific intervention (e.g. weight loss or strength training) in order to analyze different body compartments.

KINETIC AND KINEMATIC CHARACTERISTICS OF PIVOTING STRATEGIES FOR WHEELCHAIR BASKETBALL PLAYERS

RUPF, R., TAM, R.

UNIVERSITY OF TORONTO

INTRODUCTION: Wheelchair mobility is an important component to performance in wheelchair court sports such as basketball (de Witte, 2016). Further, advances with Inertial Measurement Units (IMU) have made it possible to measure rotational movements in the field. However, kinematic and kinetic descriptions of these rotational movements appear not to have been characterized, so the biomechanics and control of the pivot are not well understood. This study characterizes these basic patterns with a view to identify typical movement patterns associated with pivots.
METHODS: Wheelchair basketball athletes who play at an international level were recruited to participate in this study (N=10). Three IMU units (Shimmer) were attached to both wheel hubs, and the chair frame (van der Slikke, 2016). The wheelchair wheels were replaced with force transducers (SmartWheels) which measure force in three directions. Participants were asked to perform three pivots of 45, 90, and 135 degrees to the left and the right in random order, for a total of 24 pivots. IMU were used to derive 56 metrics for angular and linear displacement and velocity of the wheelchair and wheels, while the SmartWheels were used to calculate an additional 64 metrics describing force and impulse of the left and right wheels. Two way repeated measures ANOVA was used to compare pivot direction and angular displacement.
RESULTS: No difference in time, average and peak speed were found between left and right pivots. Pivots of 45, 90, and 135 degree pivots can be characterized to have these average times (0.55s, 0.76s, and 0.97s respectively), these average rotational speeds (92, 126, 143 degrees per second respectively). The propulsion phase was estimated to be 56% of the total turn time. The initial total force produced by the hand on the inside turning wheel was 87% higher than forces produced by the hand on the outside wheel of the pivot direction. These forces on the inner and outer wheel of the pivoting direction remained higher than the initial force until at least 50 and 90% of the total propulsion time respectively. Additionally, when pivoting to the left, the inner hand may produce higher forces up to 90% of the total propulsion time for pivots 90 degrees and less.
CONCLUSION: This study suggests that there are no differences in the kinematics of the frame that characterizes pivoting to the left and right, and provides typical ranges that practitioners can use. This study also highlights that a typical strategy used during the propulsive phase may consist of two parts. The first phase involves pulling the inside wheel. However, after around 50% of the propulsion phase, there appears to be more emphasis on pushing the outside wheel. Further, when pivoting to the left, during pivots of small rotational displacement, additional strategies may be employed.

EXPANSION OF LOWER-LIMB MUSCLE REPRESENTATIONS IN A PARALYMPIC ARCHER WITH CONGENITAL AMPUTATION OF BOTH ARMS

NAKAGAWA, K., TAKEMI, M., NAKANISHI, T., SASAKI, A., NAKAZAWA, K.

THE UNIVERSITY OF TOKYO

INTRODUCTION: Some Paralympic athletes show superior performance than able-bodied top athletes. For instance, the person who has the world record in archery farthest accurate shot is a Paralympic athlete with a congenital amputation of both arms, and he uses his feet for playing archery. We can speculate that his great motor skill stems from his reorganized neural circuits. In this study we investigated the brain reorganization by using functional magnetic resonance imaging (fMRI) and transcranial magnetic stimulation (TMS).
METHODS: In each fMRI and TMS experiment, we measured the Paralympic archer with congenital amputation of both arms and 6 control subjects without any disability. In the fMRI experiment, we recorded brain activity during unilateral rhythmic contraction of toe, ankle, knee, and hip muscles. We calculated the size of M1 activity in each task. In the TMS experiment, we performed mapping of M1 representation of lower limb muscles. We calculated the size of area in which motor evoked potentials were recorded from lower limb muscles.
RESULTS: In the fMRI experiment, we found that the M1 activation area expanded towards lateral part of the M1 (i.e, hand representation) in the Paralympic archer compared to control subjects, especially during contraction of toe and knee muscles. In the TMS experiment, map sizes were significantly larger in the Paralympic archer than control subjects for foot and lower leg muscles.
CONCLUSION: An Paralympic archer who has congenital amputation of both arms showed that 1) an expansion of lower-limb representation was observed especially in toe and knee muscles towards lateral side across the trunk representation and 2) corticospinal tract connecting to the lower-limb muscles ranged in the expanded area. His great performance of archery by his feet would be supported by these M1 reorganizations. Paralympic athletes possibly have the most dynamic nature of M1 plasticity by the combination of long-term hard motor training and compensatory M1 reorganization for missing/paralyzed body parts.

IS-SH07 Economic, sociological, pedagogical and ethical approaches to e-sports

THE RECEPTION OF ESPORTS AMONG GERMAN STUDENTS, AND PEDAGOGICAL CONSIDERATIONS

HOFMANN, A.R.

LUDWIGSBURG UNIVERSITY OF EDUCATION

On an international level the popularity of eSports is rising. In some countries they have been accepted as sports by the governing sport federations; in others, such as Germany, this is not the case. Arguments against including eSports in organized sports are, among others: commercial background through the publishers, the violent content of many games and the suppression of female players.
Although there are many studies on eSports, a pedagogical approach is lacking despite the fact that they have become part of the Lebenswelt, the everyday lives, of many children and youth in Western industrialized countries. eSports is offered by many universities as a varsity sport and in the meanwhile has become part of the curriculum of some schools, and even is being included in physical education classes in some cases.

In a first part, this paper will look at pedagogical issues of eSports and eGaming. Mainly the lack of primary experiences and the de-embodiment of sports through eGaming and eSports will be issues. Additionally, the ethics of such games for children and adolescents shall be considered. A number of eSport titles can be seen critically, since shooting and virtual killing are essential to winning a game.
The second part focuses on studies done in German schools and universities. An analysis will be made of what children and students like about eSports, and what their individual playing habits and preferred games are, e.g.: Do they see eSport as a sport? How do they train? What is their relation to analogue sports? The gender issue and the aspect of inclusion will also be touched upon.
The conclusion will include a discussion of how eSports and eGaming can and should be part of the school curriculum, especially in physical education.

E-SPORT AND DIGITALISATION AS A TOOL FOR (PHYSICAL) LEARNING IN SCANDINAVIA

RADMANN, A.

NORWEGIAN SCHOOL OF SPORT SCIENCES

SESSION ID: IS-SH07
E-sport and digitalization as a tool for (physical) learning in Scandinavia.
The paper discusses sociological and pedagogical aspects on how e-sport, e-gambling, e-activity can be used and understood in different sport and school contexts. The paper is presented into two different topics related to e-sport and digitalization; the school context, and "the-hard-to-reach group".
With examples from Norway and Sweden, from schools, professional sport clubs and cities that arrange big e-sports events like "Dreamhack", the discussion focus on possibilities and threats connected to (e-) sport, physical education and digitalization.
The school context:
96% of the boys and 63% of girls play digital games in Norway – is this a threat to the health of the young generation or can digitalized activity be part of positive input when it comes to physical and mental health among the youngsters? We know that young people use social media for various purposes and that the communication on ICT-platforms have a major impact on identity, everyday life, friendship, motivation, mental health, physical activity and inactivity. What are the consequences if the new technology, that are accused for making the youngsters adopt a sedentary lifestyle, instead are used actively in Physical Education?
The Hard-to-reach group:
Research shows that physical activity and health are connected to social class, education, gender, ethnicity, (dis) abled bodies and one of the big challenges when it comes to physical education and physical activity is how to include "the-hard-to-reach" group – those that not take part in PE in School and that have a leisure life without physical activity. Can the new technology be used to increase physical and mental health for these groups?
Some common conclusions will be discussed that will bring these two different topics together within the field of e-sport and digitalization using sociological and pedagogical theories about: generation consciousness, onstage-offstage, stigma, prod-users and contemporary media culture.

ACTORS AND INTERESTS IN THE ESPORT ECO SYSTEM

FRITZ, G., SCHUBERT, M.

HOCHSCHULE FÜR ANGEWANDTES MANAGEMENT BERLIN & JOHANNES GUTENBERG-UNIVERSITÄT MAINZ

Prof. Dr. Gerald Fritz, Hochschule für angewandtes Management, Berlin (Germany), gerald.fritz@fham.de
Dr. Mathias Schubert, Johannes Gutenberg University, Mainz (Germany), schubert.m@uni-mainz.de

During the past years, eSport has become a skyrocketing phenomenon and revenues have more than doubled from 2014 to 2016 to around 463 million USD (Newzoo, 2016). Many non-endemic actors, such as sponsors, media and sport organizations, are investing in this fast growing market. Among them, more than one hundred professional football clubs have become increasingly involved in the business since 2015. Our multidimensional research project aims to shed light into the organisation as well as market opportunities and risks which are based on an engagement in eSports. At the same time, we see the necessity to objectively examine the evolution of eSport which strongly fascinates the digital natives and want to apply guidance to the analogue sport world for a mutual and constructive dispute about the eSport phenomenon.
Based on a stakeholder analysis, key actors within the eSport EcoSystem in Germany have been identified. On basis of both quantitative (e.g. survey among eSports consumers, n=1.137; July 2016) as well as qualitative (e.g. expert interviews; 2016-2018) approaches, we intend to disclose interest and intentions of core stakeholders who all try to gain their share in this steadily professionalizing market. For the quantitative study, we were interested in finding out if there exists common interest among eSport players to be organized under the umbrella of the German club sport. A second research question focused on the feasibility as well as on the financial challenges of organizing eSports in the German club sport system. For the qualitative part of our research, semi-structured interviews have been conducted with senior officials representing club sport, experts from non-endemic organizations taking the first steps into the eSports market, and last but not least experts from endemic organizations who functioned as pioneers while developing the German eSport environment from scratch. Results of this work in progress focusing on both players and stakeholders of the emerging eSport Ecosystem in Germany will be presented at the conference.

IS-PM09 Imaging the future of elite sports with metabolic Magnetic Resonance innovations

PROTON, PHOSPHOROUS, AND CARBON MAGNETIC RESONANCE SPECTROSCOPY TECHNIQUE (MRS) FOR MONITORING OF TRAINING AND PERFORMANCE IN ATHLETES

TAKAHASHI, H.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Magnetic resonance imaging (MRI), which can image various tissues of the human body using the principle of nuclear magnetic resonance (NMR), has not only been applied to the field of medicine but also to sports science. An additional highly useful application of NMR is magnetic resonance spectroscopy (MRS). Using this technique, it is possible to noninvasively detect and quantify chemical compounds in different tissues.
METHODS: Proton (1H) MRS is the most widely used MRS technique given the highest natural abundance and the detection sensitivity of the 1H. It can be used to measure intramyocellular lipid, extramyocellular lipid, and carnosine concentrations in skeletal muscle. Using phosphorus (31P) MRS, it is possible to measure the contents of phosphorus compounds, such as phosphocreatine (PCr), adenosine triphosphate (ATP), and inorganic phosphate (Pi), and to calculate intracellular pH using the chemical shift difference between PCr and Pi. In addition, 31P MRS can be performed not only on individuals at rest but also during exercise, and allows to evaluate the aerobic capacity of the muscle by analyzing the kinetics of phosphorus compounds during exercise and recovery. Carbon (13C) MRS allows for the determination of muscle and liver glycogen (Gly) contents. However, implementation of 13C MRS is more difficult than the use of MRS with other nuclei because the natural abundance and detection sensitivity of 13C is considerably lower and there is a need for additional special hardware and software, thus limiting the sites in which it can be performed. We established a quantitative 13C MRS system and applied it to measure the Gly contents of the thigh, calf, and arm muscles in athletes.
RESULTS: Using 1H MRS, we reported that the concentration of carnosine, which plays an important role in intracellular buffering, in the vastus lateralis muscle increased with the supplementation of imidazole dipeptide in athletes. Furthermore, 1H MRS enables the evaluation of brain temperature; thus, we observed the reduction in temperature of the human brain following ice slurry ingestion. Using 31P MRS, we showed differences in the concentration of PCr and ATP of sprinters, endurance runners, and untrained subjects as well as the relationship between muscle fiber composition and relative contents of phosphorus compounds. Using 13C MRS, we evaluated how muscle Gly decreases during training, competitions/games, and weight loss, and how it increases with dietary intake during recovery.
CONCLUSION: As described above, this MRS technique provides objective data about metabolite concentrations and the metabolic capacity of the muscle, which are both closely associated with exercise performance. It is highly expected that this MRS technique will be a powerful tool for objectively evaluating the current state or condition of athletes and will provide useful data for planning training and nutritional strategies to enhance athletic performance.

NON-INVASIVE ASSESSMENT OF MUSCLE FIBER TYPOLOGY BY PROTON MAGNETIC RESONANCE SPECTROSCOPY IN ELITE ATHLETES

DERAVE, W.

GHENT UNIVERSITY

Magnetic Resonance Imaging (MRI) scanners become more and more affordable and they become widely available in sport science settings worldwide, such as in team sport clubs, national training centers, etc. Their potential applications reach way further than imaging of injuries alone. Non-invasive assessment of skeletal muscle metabolites has shown tremendous promise for application, but the techniques have long been limited to the use as mere research tools. Their actual application in real sport scientific support and guidance of elite athletes is emerging.
This lecture discusses the recent development, documentation and application spectrum of one such technique, the Muscle Talent Scan. We observed that non-invasive quantification of the muscle metabolite carnosine through proton MRS, can accurately estimate the muscle fiber type composition (i.e. the variable mixture of fast/white and slow/red fibers) without invasive muscle biopsies. This was validated through biopsy comparison, as well as through benchmarking in numerous elite athletes from various sport disciplines. The interindividual variation in both muscle carnosine and muscle fiber type composition is large and seems to be mainly genetically determined. The high intra-individual stability is documented through twin studies and longitudinal follow-up studies. It is anticipated that the ongoing research and valorization effort in this domain will soon lead to the adoption of these useful new methodologies in sport science practice.

THE APPLICATION OF MRS-BASED MEASUREMENTS FROM THE LAB TO THE POOL, TRACK, AND FIELD

MINAHAN, C.

GRIFFITH UNIVERSITY

Scientists have long been intrigued with measuring the muscle fiber composition of athletes to explain performance. Success has been achieved in identifying differences in muscle fiber composition between athletes and non-athletes, as well as between athletes competing in endurance- and sprint-type events. Nonetheless, differences in muscle fiber composition that distinguish the most elite athletes (i.e., world-class) from other elite performers in the same event are less clear, possibly due to the scarce number of world-class athletes for which muscle fiber composition has been determined (1,2,3). Magnetic Resonance Spectroscopy (MRS) provides a non-invasive method to determine muscle fiber type (4) and the opportunity to determine the degree of homogeneity in muscle fiber composition in a large number of elite and world-class athletes within and between events/sports. Furthermore, this novel method of determining muscle fiber composition has permitted various investigations into the relationship between the associated contractile/metabolic properties of specific muscle fiber types and fundamental determinants of performance. This presentation will explore a series of ideas that use the application of MRS to understand the relationship of muscle fiber type with four determinants of performance: Participation (e.g., retention rates), Prediction (e.g., talent identification), Prevention (e.g., injury and illness risk), and Prescription (e.g., optimal training and recovery pro-

grams). Current projects will be presented including the muscle fiber type characterization of elite and world-class swimmers, the responses of well-trained middle-distance runners with heterogeneous muscle fiber types to varying training volumes, as well as the potential relationships between muscle fiber type and the injury risk profiles of elite Rugby League players. It is envisaged that the provision of individualized muscle fiber composition data to coaches and sports scientists will facilitate improved talent identification, personalized training and recovery programs, and injury prevention.

IS-PM10 The masters athlete: Performance, recovery and health considerations [Applied track]

PHYSICAL PERFORMANCE OF MASTERS ATHLETES

LEPERS, R.

UNIVERSITÉ OF BOURGOGNE

Over the past three decades, there has been a continual increase in the number of masters athletes (i.e. > 40 years old) continuing to train and compete at high levels. This increased participation of master in sporting events over the past few decades has been accompanied by an improvement in their performances at a much faster rate than their younger counterparts.
Ageing does however result in a decrease in overall performance. Such age-related declines in performance depend upon the modes of locomotion, event duration and gender of the participant. For example, smaller age-related declines in cycling performance than in running and swimming have been documented. Research investigating masters athletes enables the differentiation between the effects of aging and, the effects of training status and physical activity levels by comparing younger and older cohorts of similar training status. For example, previous studies have shown that masters athletes undertaking continued systematic physical training exhibit the ability to slow the age-related declines in both physical and physiological capacities commonly observed in an age-matched sedentary population (Borges et al., 2016; Lepers et al., 2016).
Peak endurance performance has been suggested to be maintained until approximately the age of 35 years after which it declines slowly until the age of 50-60 years after which there is an increased rate of decline due primarily to a decrease in maximal oxygen consumption. Among the main physiological determinants of endurance performance, the maximal oxygen consumption (VO2max) appears to be the parameter that is most altered by age. Exercise economy and the exercise intensity at which a high fraction of VO2max can be sustained (i.e. lactate threshold), seem to decline to a lesser extent with advancing age.
Decreases in strength and power have also been observed in an ageing athletic population by Korhonen et al., (2006) who reported that both type II muscle fibre size and maximal voluntary contraction (MVC) were significantly lower in 75 male masters sprint runners aged 40-87 years old compared to 16 younger adult male sprinters aged 18-33 years. However, when compared with age-matched or younger sedentary groups, muscle integrity was well preserved in the masters sprinters group. This finding strongly suggests that systematic sprint training into older age may attenuate the suggested age-related loss of type II muscle fibre size.
The ability to maintain a high exercise-training stimulus with advancing age is emerging as the single most important means of limiting the rate of decline in performance. The current research strongly suggests that although physical performance decrements occur with age in both sedentary and athletic populations, specific systematic training in older individuals leads to significant physical adaptations that can attenuate the age-related declines in capacities that effect physical performance.

POST-EXERCISE RECOVERY IN MASTERS ATHLETES

BORGES, N.

UNIVERSITY OF NEWCASTLE

Post-exercise recovery is a complex process involving physiological and psychological components (Borges et al., 2017). The importance of post-exercise recovery in an athletic population is widely acknowledged with improved rates of recovery linked to a reduced risk of overtraining, a more rapid return to training and greater training quality (Kreher & Schwartz, 2012; Nédélec et al., 2012). In older untrained adults there are marked decreases in exercise capacity and also a reduced capacity to recover from a given exercise stimulus (Roth et al., 1999; Simoes et al., 2013). However, it remains to be elucidated whether this age-related delay in the post-exercise recovery is due to a natural aging process or due to increasing levels of sedentary behaviour in a normal aging population. Limited research has empirically compared post-exercise recovery rates of masters and younger athletes with current findings reporting context-specific results. For example, some studies have shown that masters athletes maintain post-exercise recovery rates following endurance, high-intensity interval and resistance training compared to younger athletes (Bieuzen et al., 2010; Borges et al., 2018). However, masters athletes have also demonstrated that despite similar performance recovery, masters athletes may still subjectively perceive to take longer to recover from endurance and high-intensity interval training compared to younger athletes (Fell et al., 2008; Borges et al., 2018). This perceived delay in recovery may have a negative influence on training adherence and long-term adaptation in masters athletes. Additionally, studies that employed exercise protocols that elicited exercise-induced muscle damage, such as trail or downhill running, have demonstrated that masters athletes can show a delay in both performance recovery (Easthope et al., 2010) and remodelling of skeletal muscle (Doering et al., 2016). Therefore, there is evidence to suggest that age may have context-specific influence on post-exercise recovery in masters athletes, where muscle-damaging exercise such as trail or downhill running in contrast to cycling, may lead to longer recovery times compared to younger athletes. The delayed remodelling of skeletal muscle following exercise-induced muscle damage also suggests that anabolic resistance, commonly seen in untrained older adults, may also occur in masters athletes and that further insight may be required when considering nutritional guidelines for performance and recovery in masters athletes. Therefore, further investigation into the recovery rates of masters athletes is warranted to elucidate i) the extent that training can maintain recovery into older age ii) the influence of different exercise modalities and intensities on post-exercise exercise recovery and iii) how to tailor individualised recovery strategies for masters athletes specific to the exercise stress to maximise recovery and performance.

HEALTH BENEFITS AND CONSIDERATIONS FOR MASTERS ATHLETES

PIACENTINI, M.F.

UNIVERSITY OF ROME-FORO ITALICO

The increasing ageing population has resulted in increased research interest into successful aging as a public health priority and stimulated a surge in research aimed at understanding and promoting the successful aging concept (Cosco & Kuh, 2016). In 2007, the White Paper on Sport was issued by the European Commission as a policy document addressing sport with the aim to decrease the sedentary lifestyle of EU citizens which may become a major health concern. Both physical activity (Baker et al., 2009) and higher physical fitness (Lin et al. 2016) have been previously shown to promote successful ageing. In addition, exercise and sport participation have been shown to have a neuroprotective effect in individuals who were active during their middle age years (Rovio et al., 2010). Although the negative effects of inactivity are mostly eliminated when engaging in regular competitive sports, it remains difficult to assess whether the increasing amount of training registered for competitive masters athletes will necessarily increase health more than if exercising only to counteract the effects of inactivity (Lazarus & Harridge, 2017). Within the past generation, the number of older athletes (or master athletes: i.e above the age of 40) who train and compete regularly has significantly increased. These athletes have been used as a paradigm of successful ageing. Nevertheless, a recent review on sports participation and health outcomes (Oja et al. 2015) highlighted that these health benefits need to be considered with possible health risks involved (such as sports injuries, overreaching or cardiovascular risks), enforcing these athletes to rest, which itself may lead to a drop in fitness levels, as well as increased medical costs and or absence from work (Van der Worp 2015).
Competitive masters athletes engage in structured training programs balancing work, family and social life and, contrary to elite or younger athletes, they have to insert training in already very busy schedules. For some individuals balancing all these aspects brings to a condition of non-functional overreaching or overtraining (Piacentini & Meeusen, 2015), while under some circumstances individuals become addictive to exercise (Landolfi, 2013). Therefore, engagement in masters sport may not always promote successful aging and: can too much exercise be harmful? Screening for this population is not similar in all countries, specifically regarding medical supervision with only a few nations requiring pre-event participation medical clearance (Corrado et al. 2005). More research and consensus statements are required to ensure that the benefits of systematic training into older age are not hindered by the risks associated with high levels of physical training

HIGH-DOSE LEUCINE SUPPLEMENTATION DOES NOT ATTENUATE FUNCTIONAL AND METABOLIC DECLINES FOLLOWING 7-DAYS OF UNILATERAL KNEE IMMOBILISATION IN YOUNG HEALTHY MALES

EDWARDS, S., SMEUNINX, B., MCKENDRY, J., NISHIMURA, Y., LUO, D., PERKINS, M., RAMSEY, J., JOANISSE, S., PHILP, A., BREEN, L.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Disuse events lead to muscle atrophy and functional decline. Impairments in basal and post-prandial myofibrillar protein synthesis (MyoPS) rates underpin disuse-induced muscle atrophy and likely stem from a suppression of anabolic signalling processes and alterations in oxidative metabolism. Leucine robustly enhances integrated MyoPS in anti-catabolic conditions [1]. However, the effectiveness of leucine supplementation during disuse on mitochondrial protein synthesis (MitoPS) is unknown and findings in MyoPS are conflicting [2,3]. Accordingly, we aimed to determine the effectiveness of high-dose leucine supplementation on muscle mass, strength, morphology and myofibrillar and mitochondrial proteostasis following 7-days of unilateral knee immobilisation.
METHODS: Sixteen, healthy, recreationally active males (23±1yrs) underwent 7-days of unilateral knee immobilisation, with (LEU; n=8) or without (PLA; n=8) thrice daily leucine supplementation (15g/d). Prior to and following immobilisation muscle strength and compartmental tissue composition were assessed. Immediately following immobilisation, a primed continuous infusion of L-[ring]-13C6 phenylalanine with serial muscle biopsies was used to determine muscle fibre morphology, basal and postprandial MyoPS and MitoPS, as well as key indicators of muscle proteostasis and mitochondrial function between the control (CTL) and immobilised (IMB) leg.
RESULTS: Immobilisation reduced leg fat-free mass (P=0.03) and increased leg fat percentage (P=0.02) similarly in the LEU and PLA groups (P>0.05), with no such alterations noted in the CTL leg. Isometric knee extensor strength declined following immobilisation (P<0.01), with a significantly greater (P=0.03) decline in the IMB vs. CTL leg that was similar between supplementation conditions (P=0.52). A significant group*leg interaction was identified for mitochondrial complex I phosphorylating respiration (Pi; P=0.04). However, differences did not reach statistical significance in the post-hoc analysis for Pi in the IMB vs. CTL limb in either the PLA (FC=1.20±0.19, P=0.06) or LEU (FC=0.87±0.27, P=0.87) group. Analysis of muscle fibre morphology and muscle proteostasis are ongoing and will be available at the time of presentation.
CONCLUSION: Optimising nutritional interventions to offset muscle disuse atrophy during injury (i.e. lower-limb breaks) is important to not only mitigate acute metabolic dysregulations and reduce the risk of re-injury, but to also preserve musculoskeletal health across the lifespan. Thrice daily leucine supplementation (15g/d) does not appear to attenuate declines in leg fat-free mass, strength or mitochondrial respiration following 7-days of unilateral knee immobilisation in young healthy males. Further analysis will determine the role of supplemental leucine on MitoPS and MyoPS.

DOES HABITUATION TO A HIGH PROTEIN DIET INFLUENCE WHOLE BODY PROTEIN KINETICS IN A FASTED AND POST-PRANDIAL STATE?

HØJFELDT, G., BÜLOW, J., AGERGAARD, J., ASMAR, A., SCHJERLING, P., RØRDAM, L., BÜLOW J., VAN HALL, G., HOLM, L.
INSTITUTE OF SPORTS MEDICINE COPENHAGEN, BISPEBJERG HOSPITAL, COPENHAGEN, DENMARK

INTRODUCTION: The stimulatory effect of exercise on muscle protein synthesis is attenuated by protein intake and vice versa, making exercise and protein intake potent factors in combating age related loss of muscle mass. This study focuses on the nutritional aspect, looking at the increased tendency to advice older individuals to ingest more protein than the recommended daily allowance (RDA). A tendency based on both long term follow up studies, as well as acute studies, showing positive effects of high vs. low protein intakes. We aim at elucidating those findings by investigating the basal state and acute postprandial response to a standardized meal after habituation to the RDA vs. higher protein intake.
METHODS: 12 males (65-70 years) were included in a double-blinded cross-over intervention study, consisting of a 20-day habituation period to RDA or high-protein intake (1.1 g/kg lean body mass (LBM) or >2.1 g/kg LBM), each followed by an experimental trial with primed, constant infusions of D8-Phe and D2-Tyr. Arterial and hepatic venous blood samples and m. vastus lateralis muscle biopsies were obtained in the overnight fasted state and repeatedly 4 hours after a standardized meal including intrinsically labeled D5-Phe-whey protein concentrate and 15N-Phe-calcium-caseinate proteins. Blood and muscle was analyzed for amino acid concentrations and Phe/Tyr tracer enrichments on LCMS/MS. Intervention groups' response to feeding over time were compared using Two way ANOVA with repeated measures, and the fasting samples were compared using a paired t-test.
RESULTS: Being habituated to high protein, enhanced whole body (WB) protein synthesis rate (Rd,Endo) in the fasted state (0.68 vs. 0.62 µmol phe/kg LBM/min, N=8, P=0.04), where as the relative increase in the postprandial response (Time: P<0.0001) tended to be lower (intervention: P=0.06). Independent of habituation period, the WB protein breakdown rate (Ra,Endo) is decreased in the postprandial state (N=11, time: P<0.0001, intervention: P=0.8). Postprandial blood essential amino acid (EAA) concentrations are higher following habituation to RDA of protein (N=11, Time: P<0.0001, intervention: P=0.01), while there is no difference in the postprandial muscle free EAA concentrations (n=10, time: P=0.01, intervention: P=0.1). The appearance of phe from whey was more rapid than from caseinate, Ra,Exo, with no differences between interventions.
CONCLUSION: Habituation to high protein compared to RDA levels for 20 days elicits increased protein synthesis in the fasted state. In the postprandial state, the two interventions show an even Ra,Exo of phe, with lower levels of circulating levels of EAA following habituation to high protein intake, a combination indicating an enhanced removal of EAA from the circulation following habituation to high protein.

EFFECTS OF WHEY PROTEIN SUPPLEMENTATION AND RESISTANCE EXERCISE ON 24-H ENERGY EXPENDITURE AND SUBSTRATE OXIDATION IN HEALTHY OLDER MEN

GRIFFEN, C., RENSHAW, D., DUNCAN, M., WEICKERT, M.O, HATTERSLEY, J.
COVENTRY UNIVERSITY AND UNIVERSITY HOSPITALS COVENTRY AND WARWICKSHIRE NHS TRUST

INTRODUCTION: Ageing is associated with a decline in all components of total energy expenditure (EE) (Manini 2010). The age-related decline in the largest component of total EE, resting metabolic rate (RMR), can be partly explained (50-70% variance) by loss of fat-free mass (FFM) with age (Geisler and Müller 2017). To prevent age-related loss of FFM, increased dietary protein intake and resistance-type exercise are recommended; however data on the effects of these interventions on 24-h EE and substrate oxidation in older adults is scarce.
METHODS: We conducted an interim analysis on 28 healthy, non-resistance trained older men (age = 67 ± 4 y) who had completed a 12 wk randomised controlled trial. Participants were randomised to one of four groups: resistance exercise + whey protein supplement (n = 8, EX+PRO); resistance exercise + control supplement (n = 7, EX+CON); whey protein supplement only (n = 6, PRO); or control supplement only (n = 7, CON). The PRO supplement consisted of 22.75 g whey protein isolate and the isocaloric CON supplement consisted of 23.75 g maltodextrin. Supplements were consumed twice daily. Whole-body resistance exercise was performed twice weekly and consisted of 2 sets of 8 repetitions and 1 set to volitional failure at 80% one repetition maximum on 6 exercise machines. Twenty-four-hour EE and substrate oxidation were measured at baseline and wk 12 by indirect calorimetry in a respiration chamber.
RESULTS: Sleeping metabolic rate (SMR) and RMR significantly increased in the EX+PRO group (SMR, 44 ± 7 kcal/d, P < 0.01; RMR, 34 ± 9 kcal/d, P = 0.031), whereas no significant differences occurred in the EX+CON, PRO or CON groups (group x time interaction: SMR, P = 0.019; RMR, P = 0.148). When normalised to FFM, differences in SMR and RMR no longer occurred in the EX+PRO group (SMR, P = 0.088; RMR, P = 0.448). Non-exercise activity thermogenesis (NEAT) significantly decreased in the EX+PRO group (-136 ± 47 kcal/d, P = 0.024), but did not significantly change in the EX+CON, PRO or CON groups (group x time interaction: P = 0.201). Movement within the chamber did not significantly change between groups (P = 0.397). The observed change in 24-h RMR was significantly negatively correlated with change in NEAT (r = -0.938, P < 0.01). Twenty-four-hour EE and carbohydrate, fat and protein oxidation did not differ between groups (group x time interaction: P > 0.05 for all).
CONCLUSION: In healthy older men, whey protein supplementation combined with resistance exercise for 12 wks increases SMR and RMR, but not total EE. This data demonstrates that older men adaptively reduce NEAT to compensate for increased EE from RMR and SMR due to increased FFM.

INFLUENCE OF RESISTANCE TRAINING AND COLLAGEN PEPTIDE SUPPLEMENTATION ON BODY COMPOSITION AND MUSCLE STRENGTH IN PREMENOPAUSAL WOMEN

DRESSLER, P., CENTNER, C., ZDZIEBLIK, D., GOLLHOFER, A., KÖNIG, D.
UNIVERSITY OF FREIBURG

INTRODUCTION: The aim was to investigate the effects of resistance exercise combined with supplementation of specific collagen peptides (SCP) on body composition and muscle strength in premenopausal women.
METHODS: N = 77 participants completed a 12-week resistance training (3d/week) and ingested 15 g of SCP or placebo (silicea) on a daily basis. Changes in body composition were determined by bioelectrical impedance analysis (BIA) and muscular strength by isometric strength testing.

RESULTS: The treatment group (TG) significantly increased ($p < 0.001$) their percentage fat-free mass. Although the control group (CG) also showed a significant ($p < 0.01$) gain in fat-free mass from pre- to post-training, the increase in the TG was significantly higher ($p < 0.05$). Regarding the change in percentage body fat, a significant decline was observed in both TG ($p < 0.001$) and CG ($p < 0.01$), with significantly higher reductions in TG ($p < 0.05$). Subjects receiving 15 g of collagen peptides daily also underwent a significantly higher gain in hand-grip strength ($p < 0.05$) than those performing resistance training only ($p < 0.01$). In both groups the gain in leg strength (TG = $p < 0.001$; CG = $p < 0.01$) was statistically significant after 12 weeks with a more pronounced effect in the treatment group.
CONCLUSION: In conclusion, resistance training in combination with supplementation of specific collagen peptides induced a significantly higher increase in fat-free mass and hand-grip strength than resistance training and placebo supplementation. In addition, there was a trend for a higher loss in fat mass and a more pronounced increase in leg strength in the treatment group in comparison to the control group.

PROTEIN DIGESTION AND AMINO ACID ABSORPTION ARE COMPROMISED IN OLDER COMPARED WITH YOUNG ADULTS

GORISSEN, S.H.M., VERDIJK, L.B., SENDEN, J.M.G., DE GROOT, L.C.P.G.M., VAN LOON, L.J.C.

TOP INSTITUTE FOOD & NUTRITION, WAGENINGEN, THE NETHERLANDS; MAASTRICHT UNIVERSITY MEDICAL CENTRE+, MAASTRICHT, THE NETHERLANDS

INTRODUCTION: Age-related anabolic resistance to protein intake is considered one of the key mechanisms responsible for the loss of muscle mass with aging. The factors underlying anabolic resistance are unclear but may involve impaired dietary protein digestion and amino acid absorption, increased splanchnic amino acid retention, and an attenuated postprandial release of dietary protein-derived amino acids in the circulation. We assessed the impact of protein type, protein dose, and age on protein digestion and amino acid absorption kinetics and the subsequent postprandial release of dietary protein-derived amino acids in the circulation in vivo in humans.
METHODS: We included data from 18 RCTs with 602 participants in total who consumed intrinsically L-[1-13C]-phenylalanine-labeled labeled whey (n=137), casein (n=393), or milk (n=72) protein. The consumption of intrinsically L-[1-13C]-phenylalanine-labeled protein in combination with intravenous infusion of L-[ring-2H5]-phenylalanine allowed us to assess protein digestion and amino acid absorption kinetics and the postprandial release of dietary protein-derived phenylalanine in the circulation. The effect of aging on these processes was assessed in a subset of 82 young (22±3 y) and 83 older (71±5 y) individuals.
RESULTS: The complete dataset showed that 50±1% of dietary protein-derived phenylalanine appeared in the circulation during a 5 h postprandial period. Protein type modulated plasma amino acid availability, with 57±10%, 45±11%, and 65±13% of dietary protein-derived phenylalanine appearing in the circulation following the ingestion of whey, casein, and milk protein, respectively ($P<0.001$). Protein digestion and amino acid absorption was attenuated in older when compared with young individuals, with 45±10 vs 51±14% of dietary protein-derived phenylalanine appearing in the circulation, respectively ($P=0.001$).
CONCLUSION: Older age is accompanied by changes in dietary protein digestion and amino acid absorption kinetics, resulting in an attenuated postprandial release of dietary protein-derived amino acids in the circulation. The attenuated release of dietary protein-derived amino acids in the circulation may represent one of the factors that contribute to anabolic resistance of aging.

EFFECTS OF LOW OR HIGH AMOUNTS OF DIETARY PROTEIN AND RESISTANCE TRAINING ON MUSCLE QUALITY OF OLDER ADULTS: A RANDOMIZED CONTROLLED TRIAL

UNTERBERGER, S., FIORNOVELLI, G., FRANZKE, B., ZOEHRER, P., DRAXLER, A., TSCHAN, H., WAGNER, K.H., WESSNER, B.

UNIVERSITY OF VIENNA, VIENNA

INTRODUCTION: It is well known that older individuals with high muscle quality (MQ, muscle strength relative to muscle mass) have a lower risk of functional impairment [1]. In order to maintain muscle mass and function, resistance training and a sufficiently high protein intake are suggested [2]. There is evidence that for healthy older people the diet should provide at least 1.0-1.2 g protein/kg BW/day combined with progressive resistance exercise [3]. However, it is unclear whether an increase of protein intake would lead to further benefits. Therefore, the aim of this study was to evaluate the effects of resistance training combined with two different goals of nutritional protein intake on MQ of community-dwelling older adults.
METHODS: Participants (n=137, 54% females, 72.9±4.8 y) were randomly distributed to one of the three intervention groups: Low Protein (LP), and low or high protein plus resistance training (LP+T, HP+T). Dietary nutrition was controlled for six weeks, and then the two training groups started with resistance training (2x/week) for eight weeks. Measurements (muscle mass [BIA], handgrip strength, 30s chair stand test, and isometric quadriceps peak torque) were determined at baseline (T1), before (T2) and after the training period (T3). MQ_upper body and MQ_lower body were calculated from these parameters. Main time and group effects as well as time x group interactions were determined using a factorial repeated measured ANOVA with Bonferroni-corrected post-hoc tests.
RESULTS: At baseline the three groups did not differ in any of the measured parameters ($p>0.05$). Furthermore, no group, time or interaction effects were detected for MQ_upper body ($p>0.05$), while MQ_lower body changed significantly over time ($F(2,202)=24.76$, $p<0.001$, partial $\eta^2=0.197$). Post hoc analyses confirmed the increase between T1 and T2 (0.23±0.57 Nm/kg, $p<0.001$) as well as between T2 and T3 (0.19±0.58 Nm/kg, $p=0.005$). No group or interaction effects were detected ($p>0.05$).
CONCLUSION: The findings of this study suggest that eight weeks of resistance training even when combined with high protein intake were not sufficient to improve MQ of older adults. Interestingly, the MQ of the lower limbs increased over time in all intervention groups. As the participants were familiarized to the tests a learning effect is unlikely. Therefore, a factor inherent to the general physical activity behaviour (which is subject to further analyses) could explain the findings.

OP-PM47 Cardiovascular physiology II

ACTIVE AND PASSIVE HEAT ACCLIMATION, IN AIR OR WATER, PROVIDE SIMILAR SHORT-TERM HEAT ADAPTATION

KISSLING, L.S., AKERMAN, A.P., CAMPBELL, H.A., PROUT, J.R., GIBBONS, T.D., THOMAS, K.N., COTTER, J.D.

UNIVERSITY OF OTAGO

INTRODUCTION: Heat acclimation can improve exercise performance in the heat, cardiovascular function, and longevity. However, the most effective mode of heat stress is unresolved; different forms induce different profiles of strain, and thus potentially different adaptations. The aim of this study was to investigate the adaptive responses (e.g., plasma volume expansion (PVE) and reduced rectal core temperature (Tre)) to different short-term acclimation regimes matched for change in Tre; exercise in the heat (ExH), passive hot-water immersion (HWI) or Sauna. We hypothesised that ExH would induce the largest PVE owing to a greater overall strain profile when compared to passive modes of heating.
METHODS: In a crossover design, 13 physically-active participants (5 female) undertook the three heat acclimations, and a control (thermoneutral water immersion; TWI) for 60 min/d for 5 d, in randomised order, separated by a minimum of 4 wks. Tre was clamped at neutrality (36 ˚C water; TWI) or clamped at +1.5 ˚C in HWI (40 ˚C), Sauna (55 ˚C; 55% relative humidity (RH)), or ExH (40 ˚C; 50% RH). Data were analysed using linear mixed model analysis.
RESULTS: The resting PVE was 7.2 ± 4.7% by day 6 in ExH; this was not significantly larger than in HWI, TWI or Sauna (p=0.07). By day 6, resting Tre was reduced by 0.2 ± 0.1˚C; this was similar between acclimations (p≥0.153) but more than in TWI (p=0.013). By day 6, resting systolic blood pressure (SBP) was reduced by 4 mm Hg (95%CI: 1 to 8; p=0.001), which was similar between all conditions (p=0.494). However, during acute exposure, heart rate and SBP were higher in ExH, than in Sauna and HWI (p<0.001), and the volume of heat strain (area under the curve, Tre) was larger in ExH and HWI than in Sauna (p<0.001). The initial (24-h) PVE was weakly correlated to the blood pressure response during recovery from the preceding/first bout of heat (r=0.290). Two-thirds of the 6-d PVE occurred within 24 h, regardless of condition (r=0.790; slope differences between conditions: p=0.499). Plasma aldosterone concentrations did not differ reliably between acclimations (p≥0.406) but were above baseline in ExH and Sauna (p≤0.009). Albumin content was elevated by 24 h (p=0.019), and remained so at day 5, but was comparable between conditions (p≥0.559).
CONCLUSION: Short-term heat acclimation elicited the typical PVE, as well as reductions in Tre and SBP, but these outcomes did not differ reliably between modes of acclimation. The strain profiles differed between type of acclimation, but substantial thermal and cardiovascular strain was maintained over 5 d in all acclimations; presumably aiding the maintenance of PVE. Therefore, the mode of (short-term) heat acclimation may be less important than individual requirements (e.g., limiting training interruption) or equipment availability.

A COMPARISON OF NEXFIN HD MONITOR AND IMPEDANCE CARDIOGRAPHY TO ASSESS STROKE VOLUME AFTER EXERCISE

MULLIRI, G., SAINAS, G., MAGNANI, S., PALAZZOLO, G., CRISAFULLI, A.

UNIVERSITY OF CAGLIARI

INTRODUCTION: Stroke volume (SV) is a valuable measure for clinical and research purposes. Since direct SV measurement implies invasive procedures, different indirect measures have been proposed in the past decades. Recently, it has been described (1) a pulse contour method which derives SV measurements from non-invasive blood pressure (BP) real-time tracings recorded using a volume-clamp apparatus applied to a hand finger as first described by Penaz (2) and developed by Wesseling (3). This method has been implemented into the Nexfin HD monitor, a device that allows continuous BP monitoring. Numerous works have been published on Nexfin showing mixed results on its reliability as a measurement tool in different contexts. The aim of our study was to compare Nexfin SV measurements to impedance cardiography in a particular haemodynamic scenario: recovery after dynamic exercise.
METHODS: 12 male subjects underwent two rectangular 5 min leg-cycling exercise sessions at different workloads in separate days: 70% and 130% of their First Ventilatory Thershold – VT1. Each test was followed by 3 minutes of active recovery and 7 minutes of passive recovery. SV was studied by means of impedance cardiography and by the Nexfin HD monitor. Measurements were averaged over 1 minute and data at 1st , 3rd, 7th, 10th minute of recovery after exercise were considered for statistical analysis, which was conducted using linear regression, Pearsons correlation coefficient, paired sample T-test, typical error of the Estimate (TEE), coefficient of variation (CV) and Bland and Altman plot.
RESULTS: Pearsons correlation coefficients were -0.14, 0.22, 0.33 and 0.61 at 1st, 3rd, 7th, and 10th minute of recovery after the 70% of VT1 test, and -0.16, -0.18, 0.15, and 0.30 at 1st, 3rd, 7th, and 10th minute of recovery after the 130% of VT1 test respectively. T–test yielded significant differences between methods in all sessions, with the exception of the 7th and 10th minute of recovery after at 70% of VT1 test. TEEs at 1st, 3rd, 7th, and 10th minute of recovery were 54.28, 18.41, 19.07, and 22.85 ml after the 70% of VT1 test, and 58.54, 40.62, 28.58, and 23.32 after the at 130% VT1 test. CVs at 1st, 3rd, 7th, and 10th minute of recovery were X / ÷ 1.41, 1.29, 1.27, and 1.35 after 70% of VT1 test, and X / ÷ 1.42, 1.30, 1.32, and 1.30 after the 130% VT1 test.
CONCLUSION: Results show poor correlation between Nexfin and impedance cardiography in SV measuring during recovery after dynamic exercise. We consider these outcomes as the consequence of the vasoconstrictor effect of Central Command and Exercise Pressor reflex on peripheral arteries during exercise, which is only partly compensated by a shift of baroreflex sensitivity towards a lower blood pressure level during recovery. Thus, caution should be used when measuring SV with Nexfin after dynamic leg exercise.

NO SIGNIFICANT DIFFERENCE BETWEEN VO2MAX DETERMINED DURING AN INCREMENTAL OR A MAXIMAL 2K TEST

GAM, S.

UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: The most important physiological determinant of rowing performance is the maximal oxygen uptake (VO2max, L·min-1) [1]. VO2max can be measured directly during a maximal exercise test on a rowing ergometer (typical a 2k all-out test) or during a conventional step test to exhaustion. In a group of moderately and highly trained club rowers, we measured VO2max during a 2 k test and in a step test using 2 min at each step and where the increase per step was individually adjusted to the rowers fitness level [2] The aim of this study was 1) to compare VO2max measured in a 2k test and in a continuous incremental test using 2min stages with individual adjusted step increase; 2) to determine the correlation between VO2max and average power in a 2k test (Wavg) and maximal power output (MPO) measured in a continuous incremental test using 2min stages and VO2max.
METHODS: Twenty male rowers (age 24 +/- 3 years, height 1.83 +/- 0.06 m, mass 86,1 +/- 8.0 kg, fat free mass 68,9 +/- 6,32 kg, rowing experience 3.8 +/- 3.3 years), comprising fourteen university rowers and six elite national rowers. On two separate days, participants performed a 2000m all out time trail (2K) and a submaximal 7x2min incremental step test (INCR), respectively. All exercise tests were performed in the same rowing ergometer (Concept II model E, with a PM 5 computer module). Oxygen uptake was measured using an AMIS Sport (Innovision ApS, Glamsbjerg, Denmark) based on a dynamic mixing chamber system from where samples of expired air could be measured for O2 and CO2 concentrations. Criteria for obtaining VO2max was Blood lactate concentration above 8.0, RER above 1.10, HR > 90% of the aged predicted HRmax and RPE above 18
RESULTS: No significant difference was found between VO2max determined during the incremental or the maximal 2k test (P>0.05). BLmax and PRE were significant lower after the INCR compared to the 2K (p<0.05). A correlation coefficient of r=0.93 was found between Wavg and VO2max while a slightly higher correlation coefficient of r=0.96 was found between MPO and VO2max.
CONCLUSION: In conclusion, we have shown that VO2max can be measured based on in both a 2k all out test and an individual adjusted INCR test as proposed and that the individually adjusted INCL affects the rowers physical load less and have a slightly better predictive power in this group of moderately and highly trained club rowers.

OXYGEN UPTAKE KINETICS ANALYSIS REVEALS REDUCED VENOUS RETURN AND SLOW MUSCLE AEROBIC METABOLISM IN PATIENTS WITH VENOUS OBSTRUCTION AND PATIENTS WITH PERIPHERAL ARTERIAL OBSTRUCTION

REUVENY, R., WILKERSON, D., LUBOSHITZ, J., BAR-DAYAN, A., DIMENNA, F., JONES, A.M., SEGEL, M.J.

HEALTH SCIENCES AND PHYSICAL THERAPHY DEPARTMENT, UNIVERSITY OF HAIFA., PULMONARY INSTITUTE, SHEBA MEDICAL CENTER, ISRAEL., SPORT AND HEALTH SCIENCE DEPARTMENT, EXETER, ENGLAND

INTRODUCTION: Oxygen uptake (V'O2) kinetics during steady state exercise may provide insights into abnormalities in the oxygen transport pathway. The venous component of the cardiovascular response to exercise has received little attention. We sought to elucidate the pathophysiological mechanism of exercise limitation of patients with chronic ilio-femoral vein obstruction (IFVO) by measuring V'O2 kinetics. We studied phase I and II V'O2 kinetics in patients with IFVO, and compare them to patients with peripheral arterial disease (PAD) and with healthy subjects.
METHODS: Eight patients with IFVO (age= 38 yrs. (22-65)), 3 patients with PAD (54 yrs. (44-59)) and 7 healthy individuals (37 yrs. (28-58)) were studied. All subjects performed an incremental symptom-limited cardiopulmonary exercise testing using a cycle ergometer; and 4 tests at a constant work-rate of 90% of the gas exchange threshold, for analysing V'O2 kinetics. Physiological response between groups were compared by ANOVA (post-hoc Bonferroni). Results are given as median (range).
RESULTS: Peak VO2 was reduced in IFVO (74 % predicted (45-83%)) and PAD (60%, (59-71%)) compare to controls (92% predicted (78-120%); p=0.004 and p=0.009, respectively). Phase I VO2 amplitude in the constant work-rate tests, expressed as the percent increase over the resting VO2, was lower in IFVO (49% (38-60%)) and PAD (44% (38-56%)) compared to controls (64% (48-92%); p=0.013 and p=0.034, respectively). The time constant (tau) of mono-exponential fits of phase II was longer in IFVO (43 sec (36-55 sec)) and PAD (38 sec (38-40 sec)) compared to control (27 sec (22-31 sec); p<0.0001 and p=0.006, respectively). There was no difference in these parameters between IFVO and PAD groups.
CONCLUSION: Low amplitude phase I V'O2 in IFVO suggests a damped cardio-dynamic phase, consistent with reduced venous return from the abnormal veins. Intriguingly, phase I amplitude was reduced in PAD as well, suggesting peripheral arterial obstruction may also reduce venous return in the cardio-dynamic phase of exercise onset. Slow phase II V'O2 kinetics reflect a slow onset of muscular aerobic metabolism in both IFVO and PAD. These abnormalities of V'O2 kinetic may contribute to exercise intolerance in IFVO and PAD.

CENTRAL AND PERIPHERAL BLOOD PRESSURE (BP) AFTER A ACUTE BOUT OF HIGH INTENSITY INTERVAL TRAINING (HIIT) AND MODERATE INTENSITY CONTINUOUS TRAINING (MICT) IN YOUNG WOMEN WITH OBESITY

OKAWA, R.T.P., HORTMANN, K., LOCATELI, J.C., SIMÕES, C.F., OLIVEIRA, G.H., MENDES, V.H.S., LOPES, W.A.

STATE UNIVERSITY OF MARINGA

INTRODUCTION: HIIT has been considered a time efficient exercise intervention to increase cardiorrespiratory fitness and improve endotelial function. Also, HIIT has been shown to improve resting BP similar to MICT (1). However, less is known about the acute effects of HIIT compared to MICT on central blood pressure. Thus, we investigated the acute effects of HIIT versus MICT on central and peripheral BP in young obese women.
METHODS: Fifteen obese women (25.2±4.8 years) underwent high-intensity interval training (HIIT) (85-95% of HRmax), moderate intensity continuous training (MICT)(65-75% of FCmax) and control condition (CON) (rest at sitting position). Central and peripheral BP were measured at baseline, and 1 min, 30 min and 60 min after sessions, by SphygmoCor Xcel system (AtCor Medical, Sydney, Australia). The data were analyzed by ANOVA for repeated measures.
RESULTS: There was a significant reduction in central systolic blood pressure (108.7±11.5 mmHg to 103.7±10.4 mmHg, p=0.032) at 60 minutes after HIIT. Peripheral systolic BP (p=0.119) and diastolic BP (p=0.232) remained unchanged after exercise in both conditions in young obese women.
CONCLUSION: Central rather than peripheral blood pressure has been suggested as an important predictor of cardiovascular risk (2). Although few studies have investigated the role of exercise on central arterial pressure, it appears that acute aerobic exercise is able to

promote acute reduction (3). This study indicates that HIIT is superior to MICT in reducing central blood pressure in young women with obesity. These results have important clinical implications since minimal reduction in central blood pressure could decrease myocardial work and force imposed on the aorta during the ejection phase, decreasing the chance of ventricular hypertrophy and cardiac remodeling (3).

OP-PM55 Health and fitness: Sedentary lifestyle

LONGITUDINAL ASSOCIATION OF SEDENTARY TIME AND PHYSICAL ACTIVITY WITH QUALITY OF LIFE IN WOMEN WITH FIBROMYALGIA: THE AL-ÁNDALUS PROJECT

GAVILÁN-CARRERA, B.1, SEGURA-JIMÉNEZ, V.2, ACOSTA-MANZANO, P.1, BORGES-COSIC, M.1, ESTÉVEZ-LÓPEZ, F.1, ÁLVAREZ-GALLARDO, I.C.1,2, DELGADO-FERNÁNDEZ, M.1

1: UNIVERSITY OF GRANADA , 2: UNIVERSITY OF CÁDIZ

INTRODUCTION: Non-pharmacological modalities focused on the improvement of quality of life (QoL) are currently recommended in the management of fibromyalgia [1]. Sedentary time (ST) and physical activity (PA) are modifiable behaviors that are potentially related with QoL in this population [2], yet previous evidence is mainly based on cross-sectional data. This study aimed to examine the relationship over time (2- and 5-year follow-up) of ST and PA with QoL in women with fibromyalgia.
METHODS: In this prospective cohort study, women diagnosed with fibromyalgia (age:51.4±7.6 years) with compete data were included at baseline (n=407), at 2-year follow-up (n=217) and at 5-year follow-up (n=210). We assessed ST and PA (light and moderate-to-vigorous [MVPA] intensity levels) using triaxial accelerometers that were worn during 7 consecutive days. The percentage of time spent in different behaviors was calculated (e.g.:(ST/accelerometer wear time) × 100). The eight dimensions plus the physical and mental component summaries of the SF-36 questionnaire were used to assess QoL. Linear regression analyses were performed to estimate the association between QoL at 2- and 5-year follow-up (dependent variable) and changes in ST and PA over time (independent variables) while considering age and baseline QoL. Additional analyses were performed including fat percentage, analgesic and antidepressant consumption as confounders.
RESULTS: Changes from baseline in ST were not associated with quality of life at 2-year follow-up (all, P>0.05), while they were associated with physical function (β=-0.18) and physical role (β=-0.13) at 5-years follow-up (all, P<0.05). Changes from baseline in light PA were not associated with quality of life at 2-year follow-up (all, P>0.05), while they were associated with physical function (β=0.16), and physical role (β=0.13) at 5 year-follow-up (all, P<0.05). Changes from baseline in MVPA were associated with physical role (β=0.15) at 2-year follow up, and physical component summary scores at 2-year (β=0.16) and 5-year follow-up (β=0.13; all, P<0.05). The results were maintained when considering additional covariates, except for the association between light PA and physical function (P>0.05), and between MVPA and physical component summary scores at the 5-year follow-up (P>0.05).
CONCLUSION: Increasing levels of ST (negatively) and light PA (positively) is associated with physical function and physical role at 5-year follow up. Increasing levels of MVPA is positively related to physical function and physical component summary scores at 2-year follow-up. Moving towards a less sedentary and more active lifestyle over time is positively related with certain physical domains of QoL in fibromyalgia.

CHANGES IN SEDENTARY TIME AND PHYSICAL ACTIVITY OVER 2- AND 5-YEAR FOLLOW-UP ARE ASSOCIATED WITH BODY COMPOSITION PARAMETERS IN WOMEN WITH FIBROMYALGIA: THE AL-ÁNDALUS PROJECT

SEGURA-JIMÉNEZ, V.1, GAVILÁN-CARRERA, B.2, ACOSTA-MANZANO, P.2, BORGES-COSIC, M.2, SORIANO-MALDONADO, A.3, APARICIO, V.A.2, DELGADO-FERNÁNDEZ, M.2

1: UNIVERSITY OF CÁDIZ , 2: UNIVERSITY OF GRANADA , 3: UNIVERSITY OF ALMERÍA

INTRODUCTION: High prevalence of overweight and obesity has been previously reported in fibromyalgia population (1). Furthermore, it has been suggested that weight status might be associated with fibromyalgia symptomatology (2). Reducing sedentary time (ST) and increasing time spent in physical activity (PA) might be a potential strategy to improve body composition in this population. The aim of the current study was to test the association of changes in ST and PA intensity levels over 2- and 5-year follow-up with body mass index (BMI), body fat percentage, and waist circumference at 2- and 5-year follow-up in women with fibromyalgia.
METHODS: Women diagnosed with fibromyalgia aged 51.5±7.6 years who completed all the assessments were included in the analyses at baseline (n=449), at 2-year (n=243) and at 5-year (n=231) follow-up. Seven continuous days of triaxial accelerometry (GT3X+) data were collected to estimate ST and PA (light and moderate-to-vigorous [MVPA] intensity levels). The percentage of time spent in ST and PA behaviors was calculated [e.g. (MPVA/accelerometer wear time) × 100]. Body mass index (kg/m2) was calculated, and waist circumference (cm) and body fat percentage were assessed with a Harpenden anthropometric tape and by bio-electrical impedance (InBody R20), respectively. Multiple linear regression analyses were used to check the association between changes in ST and PA over time (from baseline to 2 and 5-years follow-up) on body composition parameters at the different time points in separate models, including age and baseline body composition as covariates.
RESULTS: Increasing ST over time was associated with greater BMI (β=0.042, P=0.045) and fat percentage (β=0.067, P=0.048) at 2-year follow-up. Greater light PA over time was associated with lower BMI (β=-0.043, P=0.038) and fat percentage (β=-0.073, P=0.031) at 2-year follow-up. Greater ST over time was associated with greater BMI (β=0.168, P<0.001), fat percentage (β=0.153, P<0.001), and waist circumference (β=0.151, P<0.001) at 5-year follow-up. Greater light PA over time was associated with lower BMI (β=-0.156, P<0.001), fat percentage (β=-0.137, P=0.001), and wait circumference (β=-0.143, P<0.001) at 5-year follow-up. Additionally, greater MVPA over time

was associated with lower BMI (β=-0.097, P=0.004), fat percentage (β=-0.097, P=0.025), and wait circumference (β=-0.080, P=0.038) at 5-year follow-up.
CONCLUSION: Increasing ST and decreasing light or MVPA over time is associated with less favorable body composition parameters in women with fibromyalgia. The results suggest that simply substituting ST with greater PA levels might be a powerful action plan in this population to improve weight status and body fat, especially in the long term.

RELATIVE HANDGRIP STRENGTH IS INVERSELY ASSOCIATED WITH MORTALITY IN AN URBAN KOREAN POPULATION: FINDINGS FROM THE KOREAN GENOME AND EPIDEMIOLOGY STUDY (KOGES)

PARK, S.H., SUNG, B.J., KO, B.G., KIM, K.J., PARK, S., YOON, E.S.
KOREA INSTITUE SPORTS OF SCIENCE

INTRODUCTION: Decreased muscle strength is emerging as important public health concerns in both developed and developing countries. Handgrip strength test using simple and quick has been a known risk-stratifying method to assess the risk of death, particularly in individuals who develop non-community diseases. Muscular strength is related with body weight, therefore, a relative handgrip strength (RHS) adjusted for BMI has been recommended to minimize the confounding effect of body size. However, there is a lack of evidence for the association between RHS and mortality. We investigated the association between relative handgrip strength (RHS) and mortality in a longitudinal Korean study.
METHODS: A total of 76,085 adults (25,871 men and 50,214) who participated handgrip strength testing were drawn from 39 community health examination centers located in 14 urban areas in Korea between 2004 and 2013. The RHS was calculated by dividing maximal handgrip strength (AHS) by body mass index. Mortality was followed until the end of 2015 from National Statistical Office. Cox proportional hazard models were used to assess the independent association between RHS and mortality after adjusting for potentially confounding factors.
RESULTS: During a mean follow-up of 5.0±2.5 years, 852 (1.1%) of 76,085 participants died. Multivariable Cox regression hazard ratios were 1.0 (reference), 0.82 (95% CI : 0.70-0.97) and 0.55 (95% CI : 0.46-0.67) across incremental thirds of RHS in all-cause mortality. The participants with highest RHS had significant 30% lower risk of cancer mortality (HR 0.7, 95% CI : 0.54-0.92), compared with the those with the lowest RHS. RHS was inversely associated with all-cause mortality (hazard ratio per 0.1 kg/BMI gain in RHS 0.53, 95%CI 0.40-0.69), and cancer mortality (0.62, 0.42-0.93; p<0.021), independent of age, sex, cigarette smoking, alcohol intake, education, marital status, hypertension, diabetes, metabolic syndrome, chronic disease family history.
CONCLUSION: The current finding suggested that RHS reduction was additive to increased premature death from all causes and cancer.

RELATIONSHIPS BETWEEN PHYSICAL ACTIVITY AND SEDENTARY TIME AND DEPRESSIVE SYMPTOM IN WORKERS: A 4-YEAR PROSPECTIVE STUDY

LIU, N.1, CHEN, T.2, KUMAGAI, S.1,2
KYUSHU UNIVERSITY

INTRODUCTION: Considerable evidence shows moderate-to-vigorous physical activity (MVPA) is negatively associated with the risk of developing depression. There is also emerging evidence linking higher level of sedentary time with increased risk of depression. However, most studies measured MVPA and sedentary time using questionnaires which are subject to recall bias
Therefore, this prospective study investigated the associations of accelerometer-assessed MVPA and sedentary time with risk of depressive symptom among Japanese working adults.
METHODS: Data from two prospective cohorts of Japanese workers was used in this study. Baseline examination was conducted between 2009 and 2010A total of 504 participants without depressive symptoms were followed up until 2014. Sedentary time and MVPA were assessed using a tri-axial accelerometer (Active style Pro HJA 350-IT; Omron Healthcare Co., Ltd., Kyoto, Japan). Days with at least 600 min of wear time were considered as valid. Participants with at least four valid days were included in the analysis. We considered each minute that the activity intensity was≦1.5 METs as sedentary time. MVPA was defined as activities of ≧3 METs. Depression symptom was evaluated by Japanese version of the Center for Epidemiologic Studies Depression Scale (CES-D). A CES-D score≥16 was used as the cutoff for depressive symptom. Age, sex, education, obesity, drinking and wearing time of acceleromter were included as confounding variables.
RESULTS: Over the 4-year follow, 80 participants developed depressive symptoms. In either basic model (adjusting for sex, age, wearing time) or final model (additionally adjusting for education, obesity, and drinking habit), there were no significant associations between baseline MVPA or sedentary time with the depressive symptom at follow up. Compared to the lowest quartile group of MVPA, the adjusted odds ratio were Q2 0.99(0.48-2.07),Q3 1.17(0.57-2.40),Q4 1.44(0.70-2.94) for those in the highest three quartile. Compared to the lowest quartile group of sedentary time, the adjusted odds ratio for those in the highest quartile group of sedentary time were Q2 0.95(0.48-1.86), Q3 0.84(0.41-1.72), Q4 0.65(0.31-1.36) respectively.
CONCLUSION: No significant associations of baseline MVPA and sedentary time with follow-up depressive symptom were observed in this 4-year longitudinal study.

SMART MOVING: SITTING BEHAVIOUR AND HABITUAL PHYSICAL ACTIVITY LEVEL OF UNIVERSITY STUDENTS IN GERMANY

HOFFMANN, S.W., HORTER, J., TITTLBACH, S.
UNIVERSITY OF BAYREUTH

Introduction
High sitting time and physical inactivity are widespread in the society and are associated with negative health outcomes. Initial studies in university settings show that lack of exercise and sedentary behavior is also present in university students, and data from university settings are rare. The study "Smart Moving" aims to investigate (a) daily physical activity level and sitting time in the university context, (b)

personal barriers and requirements, and (c) the efficiency and sustainability of participatory interventions of two German universities with a pre-post-design.
Methods
In 2018, the pre-tests involved in total 812 (480 women) university students who reported to a standardized questionnaire. The present study analyses data of physical activity (PA) and sitting time from a sub-sample of students during a typical week within the lecture period. This sample consist of 54 (38 women) students aged 18-29 years old. Participants wore the ActiGraph wGT3X-BT accelerometer for seven consecutive days. Sitting time in the university setting, total time spent sedentary, total steps, total activity calories, and time spent in light and moderate to vigorous activity were recorded.
Results
The two-way MANOVA revealed that gender (p-value = 0.005; η2 = 0.540; medium effect) and university location (p-value = 0.041; η2 = .440; medium effect) had significant effects on the outcome variables. Results for university 1 showed that male (female) students had mean sitting time of 33.4 ± 24.5 hours (35.3 ± 14.3 hours) in the university setting and total sedentary time of 74.4 ± 10.5 hours (65.2 ± 13.8 hours). Total step counts were 68086 ± 20024 (51757 ± 14808), and total activity calories were 4836.5 ± 1627.3 kcal (2420.5 ± 896.1 kcal). Males spent less time in light 124.6 ± 11.9 hours (130.3 ± 12.4 hours) and more time in moderate to vigorous activity 10.2 ± 3.8 hours (7.1 ± 2.5 hours) than females.
Results for university 2 showed that male (female) students had mean sitting time of 46.2 ± 19.1 hours (38.8 ± 20.1 hours) in the university setting and total sedentary time of 70.4 ± 12.0 hours (67.5 ± 11.1 hours). Total step counts were 57961 ± 18255 (61417 ± 17346), and total activity calories were 2897.5 ± 1204.5 kcal (2818.9 ± 1060.5 kcal). Males spent less time in light 138.2 ± 6.6 hours (138.9 ± 5.3 hours) and moderate to vigorous activity 8.0 ± 2.7 hours (8.9 ± 2.4 hours) than females.
Conclusion
In summary, this study showed a high incidence of sitting time in the university context and high sedentary time in general which differed from gender and university location. Moreover, university students did not achieve the recommended 10,000 steps/day on average during a normal university week. In contrast, the students meet the current recommendations for PA levels of at least 150 min of moderate intensity activity. Location and gender-based strategies must be addressed to reduce sitting time and promote PA in this population.

OP-PM56 Hypoxia II

EXERCISE-INDUCED HYPOXEMIA EXHIBITED BY ATHLETES AT SEA LEVEL LEADS TO SPECIFIC ADAPTATIONS IN MUSCLE AND CEREBRAL OXYGENATION DURING EXERCISE IN NORMOXIC AND HYPOXIC CONDITIONS

RABERIN, A.1, MERIC, H.1, MUCCI, P.2, LOPEZ AYERBE, J.3, DURAND, F.1

(1) UNIVERSITÉ DE PERPIGNAN. (2) UNIVERSITÉ DE LILLE. (3) HOPITAL GERMANS TRIAS I PUJOL

INTRODUCTION: It is well established that about 70% of endurance trained athletes exhibited a fall in O2 saturation during exercise at sea level (1). This phenomenon called exercise-induced hypoxemia (EIH) may have an impact on exercise adaptation in environmental hypoxia. Indeed, environmental hypoxia might potentiate the effect of EIH on SaO2 and the putative combined effect on tissue oxygenation has yet to be characterized. Thus, the aim of this study was to access the influence of EIH exhibited by elite athletes on muscle and cerebral oxygenation adaptations during maximal exercise under normoxia and acute moderate hypoxia.
METHODS: Twenty-five endurance-trained athletes performed two incremental treadmill tests to assess maximal oxygen consumption (VO2max); one was performed under normoxia, and the other simulated moderate hypoxia (inspired O2 fraction: 15.28%). Oxygenation of the vastus lateralis muscle and the left prefrontal cortex of the brain were monitored using near-infrared spectroscopy.
RESULTS: During the normoxic VO2max test, fifteen athletes exhibited EIH while ten don't (noEIH). EIH athletes displayed a lower muscle oxyhemoglobin (ΔO2Hb) (p=0.04) and greater changes in cerebral deoxyhemoglobin (ΔHHb) compared to noEIH (p=0.02). During the hypoxic VO2max test, the EIH group had a lower mean muscle ΔO2Hb than the noEIH group (p=0.03). At VO2max, hypoxia was associated with a low cerebral ΔO2Hb (relative to normoxia) in both groups and a high cerebral ΔHHb in the noEIH group only (p=0.02); no intergroup differences in muscle oxygenation were observed. The EIH severity was negatively correlated with muscle ΔO2Hb and changes in muscle total hemoglobin during both the normoxic and hypoxic VO2max test, and was positively correlated with cerebral ΔHHb during the normoxic test (p=0.02).
CONCLUSION: We observed two new effects of EIH during maximal exercise. Firstly, EIH athletes displayed exacerbated cerebral deoxygenation and a low muscle limb blood volume under normoxia; these results were accentuated by the EIH severity, which also conditioned the response to exercise under hypoxia. Cerebral deoxygenation is probably due to the increase in oxygen demand associated with cerebral activity. Muscle limb blood volume suggests that EIH could improve vasoconstrictor nerve traffic or lead to a metaboreflex triggering by respiratory muscle fatigue and thus restrict muscle blood volume. Secondly, when adaptations to exercise in normoxia versus hypoxia were compared, EIH athletes showed no changes in muscle and cerebral oxygenation during exercise, contrary to noEIH athletes. Thus, EIH phenomenon clearly leads to specific adaptations in muscle and cerebral oxygenation during exercise in normoxia and acute hypoxia. Further investigations are needed to understand the involved mechanisms.

FIVE-DAY INTERMITTENT HYPOXIC TRAINING IMPROVES RUNNING ECONOMY AND PERFORMANCE IN WELL-TRAINED DISTANCE RUNNERS

TANJI, F., ONUMA, H., ANDO, R., NAITO, T., HARAMURA, M., SUZUKI, Y.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Hypoxic condition training has been used for a long time for better training results than those under normoxic conditions. A Living-High Training-Low model, a typical hypoxic training model, needs to be applied for a long time (6–8 weeks) to be effective, and there have been reports of non-responders. On the other hand, it has been recently investigated the effect of a hypoxic condition exposure only during exercise. A short-term training regimen that combines sprinting and endurance exercise under hypoxic conditions reportedly improves the lactic energy metabolism and sprint performance (Oriishi et al., 2018). We aimed therefore to investigate whether

this combined training is effective for distance running performance, and to clarify what energy metabolism capacities are improved in the present study.
METHODS: Fifteen well-trained male distance runners participated in a 5-day (1–5 days) training program under hypoxic (FIO2: 14.5%; n = 7) or normoxic (FIO2: 20.9%; n = 8) conditions. They performed sprint training in the morning and endurance training in the afternoon every day. Moreover, they performed a multi-incremental running test and time to exhaustion test at 100% of the maximal oxygen uptake (VO2max) intensity on a treadmill at day 0 (pre), day 7 (post 0wk), and day 14 (post 1wk).
RESULTS: There was significant interaction for time to exhaustion ($P < 0.01$); 46.1% ± 51.1% of enhancement was observed at p1wk in the hypoxia group (267 ± 56 s to 374 ± 83 s; $P < 0.05$); however, there was no change in the normoxia group (432 ± 91 s to 392 ± 100 s). There was no significant interaction in the VO2max, lactate threshold, and maximal blood lactate concentration; however, the running economy (RE) showed significant interaction ($P < 0.05$); there was significant improvement at p1wk in the hypoxia group (0.99 ± 0.05 to 0.95 ± 0.06 kcal/kg/min).
CONCLUSION: Our main finding was enhancement in running performance (time to exhaustion) in well-trained distance runners after a 5-day training program that combined sprint and endurance exercise under hypoxia. Moreover, RE, important ability for distance running performance, also improved. The median power frequency of surface electromyography during running increased more under hypoxia than under normoxia (Torres-Peralta et al., 2014). This may be because more type II muscle fibres are recruited under hypoxia. Thus, intermittent hypoxic training may cause adaptation to the recruitment of the type II muscle fibres and improve RE, thereby enhancing running performance.

EFFECT OF INTERMITTENT HYPOXIC RESISTANCE TRAINING (IHRT) ON MORPHOLOGICAL AND STRENGTH ADAPTATIONS AND ACUTE RESPONSES – A SINGLE-BLIND RANDOMIZED CONTROLLED TRIAL

SCHÄFER, R., KIRMSE, M., OERTZEN-HAGEMANN, V., PLATEN, P.
RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Metabolic stress could be the key moderator in Intermittent Hypoxic Resistance Training (IHRT) (1). Accumulation of lactate and hydrogen ions was shown to stimulate anabolic hormone secretion which possibly lead to an increased protein synthesis. Therefore, it might have beneficial effects on morphology and strength (2). This study aimed at determining the effects of a whole-body barbell workout under systemic hypoxic and normoxic conditions using an athlete-like exercise protocol on dynamic and static strength, muscle thickness and blood parameters.
METHODS: N=23 healthy male athletes (23.9 ± 3.1 years, 182.6 ± 6.8 cm, 79.7 ± 7.5 kg) performed a whole-body barbell intervention under hypoxic and normoxic conditions (1. Hypoxic group (HG), N=13, FIO2= 14%, 2. Normoxic Group (NG), N=10, 3. Control group (CG), N=10). HG and NG exercised 2 times a week for 8 ½ weeks with 3 sets (70% of 1RM) on each exercise with an inter-set rest period of 1 min.
Before and after the time of intervention, HG, NG and CG performed 1RM in Squats (SQ), Deadlifts (DL), Bench Press (BP) and front-bended rowing (R), and maximum voluntary isometric contraction for 30s (MVC30) during Squats. Muscle Thickness (MT) in M. quadriceps femoris was measured using ultrasound images. Furthermore, a blood gas analysis (BGA) was performed to measure acute responses between the 4th and 6th session of intervention (n=28) to evaluate lactate, pH, bicarbonate, carbon dioxide partial pressure (pCO2), oxygen partial pressure (pO2), oxygen saturation (cSO2) and hematocrit (Hct) concentrations. Perceived Exertion data was collected on CR10-Scale.
Statistics are based on the smallest worthwhile change (SWC) as a small standardized effect (d=0,2). Probabilities are based on unpaired t-test for unequal variances.
RESULTS: Results between HG and NG adjusted to baseline showed trivial effect sizes ($d<0.2$) with an unclear outcome for SQ, DL, BP, MVC30 and MT, and a small effect in R (d=0.3) in favor of NG. BGA showed no substantial difference in lactate, pH, bicarbonate, pCO2 and Hct between groups. cSO2 and pO2 were substantially lower in HG (d=0.74, d=0.99 respectively) although RPE was higher in HG (8.4±0.8 to 7.6±0.5) throughout intervention.
CONCLUSION: Our data suggests that there is no additive benefit of hypoxia in a high metabolic demanding individually monitored high-intensity resistance workout. Nevertheless, there may be methodologically confounding and conflicting results in literary sources suggesting that there may possibly be a small effect of hypoxia on resistance exercise under certain circumstances (2).

PSYCHO-PHYSIOLOGICAL RESPONSES TO PERCEPTUALLY-REGULATED INTERVAL RUNS IN HYPOXIA AND NORMOXIA

HOBBINS, L., GAOUA, N., HUNTER, S., GIRARD, O.
LONDON SOUTH BANK UNIVERSITY, MURDOCH UNIVERSITY

INTRODUCTION: High-intensity interval running (HIIR) is a time-efficient exercise. HIIR performed at an absolute, fixed-intensity in hypoxia exaggerates acute physiological stress compared to normoxia, whilst perceptual responses are negatively affected. We investigated whether perceptually-regulated (self-paced exercise model) HIIR in hypoxia is associated with slower running velocities vs. normoxia, yet with comparable physiological and perceptual responses.
METHODS: Nineteen experienced runners completed a HIIR protocol (4 × 4-min intervals at a clamped rating of perceived exertion of 16 on the 6-20 Borg scale, 3-min passive recoveries) in hypoxic (HYP; FiO2 15.0%) and normoxic (NOR; FiO2 20.9%) conditions. Treadmill velocity, heart rate, arterial oxygen saturation, and vastus lateralis oxygenation were recorded during HIIR. Perceived recovery and motivation to exercise were assessed prior to each interval, whilst breathlessness, limb discomfort and pleasure were evaluated immediately after.
RESULTS: Participants adjusted to a progressively slower running velocity from interval 1 to 4 (-7.0%), and more so in HYP vs. NOR for intervals 2, 3 and 4 (-4.6%, -6.4% and -7.9%, respectively; all $p < 0.01$). Heart rate increased from interval 1 to 4 (+4.8%; $p < 0.01$), independently of condition. Arterial oxygen saturation was lower in HYP vs. NOR (86.0% vs. 94.8%; $p < 0.01$). Oxyhemoglobin (-23.7%) and

total hemoglobin (-77.0%) decreased, whilst deoxyhemoglobin increased (+44.9%) from interval 1 to 4 (all $p < 0.01$), independently of condition. Perceived recovery (-41.6%) and motivation (-21.8%) decreased progressively from interval 1 to 4, and more so in HYP vs. NOR for intervals 2, 3 and 4 (recovery: -8.8%, -24.2% and -29.3%; motivation: -5.3%, -20.3% and -22.4%, respectively; all $p < 0.01$). Perceived breathlessness (+18.6%), limb discomfort (+44.0%) and pleasure (-32.2%) changed from interval 1 to 4, with significant differences (+21.8%, +11.3% and -31.3%, respectively) after HYP vs. NOR (all $p < 0.01$). End-exercise blood lactate concentration values were higher in HYP vs. NOR (13.1 ± 3.8 vs. 10.1 ± 3.9 mmol/L-1; $p < 0.01$).
CONCLUSION: Slower interval treadmill running velocities in hypoxia achieve similar heart rate and muscle oxygenation responses to those observed in normoxia when perceptually-regulated, yet at the expense of less favourable perceptual responses. Practically, self-paced HIIR in hypoxia can be carried out at a lower external load in reference to normoxia, whilst producing a similar internal load. This strategy may be effective for athletes preparing for surgery/returning from injury and clinical populations. However, other studies are needed to develop HIIR protocols that would optimise perceptual responses and increase adherence.

Invited symposia

IS-BN06 (Im)balance of muscle and tendon adaptation in high level sports

TENDON RESPONSE TO LOADING

MAGNUSSON, P.
BISPEBJERG HOSPITAL

A tendon transfers force from the contracting muscle to the skeletal system to produce movement and is therefore a crucial component of the entire muscle-tendon complex and its function. However, research focus on tendon has for some time centered on mechanical properties without any major appreciation for its potential for cellular and molecular changes.
The overall turnover of the tendon in humans seems to be taking place primarily within the first 17 years of life, indicating that the basic structure remains relatively unchanged through adult life. Nevertheless, mechanical loading of adult human tendon results in tendon cells responses by producing growth factors and some support for loading-induced increase in tendon collagen synthesis. Similarly, methodological developments have permitted determination of mechanical properties of human tendons, in vivo, which was previously not possible. Mechanical loading of adult human tendon results in release of tendon tissue stimulating factors, whereas inactivity down regulates phenotypic tendon characteristics. Adjustment of the tendon mechanical properties in the form of increased stiffness after strength training, and the reverse after period of immobilization occurs relatively fast and is potentially coupled to molecular changes

IMBALANCED MUSCLE AND TENDON ADAPTATION IN YOUTH ATHLETES

MERSMANN, F.
HUMBOLDT-UNIVERSITÄT ZU BERLIN

Few information is available on the interaction of maturation and mechanical loading on the development of muscle and tendon, although there is reason to believe that adolescent athletes, especially from sports that feature a high frequency of jumps, could be at an increased risk for musculotendinous imbalances. Therefore, we examined the development of the morphological and mechanical properties of the knee extensors and patellar tendon in adolescent elite volleyball athletes by means of magnetic resonance imaging, ultrasound and dynamometry.
We found that mid-adolescent athletes show deficits of radial tendon growth compared to the muscle morphological and functional development and, as a consequence, increased levels of tendon stress and strain. This is in part compensated by a marked hypertrophy of the tendon until late adolescent, yet high fluctuations of muscle strength and a non-uniformity of muscle and tendon adaptation during a competitive season episodically and chronically increased the mechanical demand placed upon the tendon. A recent study on adolescent basketball athletes indicates that high levels of strain are associated with impairments of the structural integrity of the tendinous tissue. Therefore, an imbalance of muscle strength and tendon stiffness might contribute to the predisposition for the development of tendon overuse injury in these groups, which are known to be at high risk of developing tendinopathy. However, data obtained from athletes from different sports from preadolescence until adulthood suggest that musculotendinous imbalances occur in other sports disciplines as well and increase in frequency with age. We currently investigate the potential of promoting tendon stiffness by means of a specific training intervention to prevent imbalanced adaptation and reduce the incidence of tendinopathy in adolescent athletes.

DISCORDANCE IN MUSCLE AND TENDON ADAPTATION IN ELITE TRACK AND FIELD ATHLETES: A LONGITUDINAL INVESTIGATION OVER FOUR YEARS

KARAMANIDIS, K., KÖNIG, M., SCHADE, F., EPRO, G.
LONDON SOUTH BANK UNIVERSITY

Muscles and tendons are mechanosensitive, showing adaptive changes in response to mechanical loading (1). However, differences in the time course of muscle and tendon adaptation to mechanical loading and asymmetric habitual loading patterns while performing activities of daily living and sports may affect the intra- and inter-limb uniformity of the muscle-tendon unit (MTU). For instance, the lower vascularisation and metabolism of tendinous tissue may lead to differences in the temporal dynamics of muscle and tendon adaptation during training, which may potentially affect the muscle-tendon interaction during movement or cause tendon overloading (2). In this work we regularly monitored the training-induced alterations in mechanical properties of the triceps surae (TS) MTU of both legs in young adult elite sprinters (100m, 200m and 400m) and jumpers (long jump, triple jump, high jump, pole vault) over four years of training and competition, in order to detect potential discordance within the TS MTU. The first results of this ongoing longitudinal investigation indicated inter-limb asymmetries in both TS muscle strength and tendon stiffness in elite jumpers (but not sprinters), with higher values for both analysed parameters for the take-off compared to the swing leg. However, the between-leg asymmetries in TS muscle strength and tendon stiffness were comparable with about 8%, indicating that habitual athletics training in jumpers does not cause any functional meaningful inter-limb inconsistencies for AT stiffness and TS muscle strength. Furthermore, monitoring of the athletes over one season revealed similar patterns in the relative changes of TS muscle strength and AT stiffness (CVs on average10%), indicating concurrent adaptation of muscle and tendon for both legs. However, in one case of an injured athlete after AT rupture and reconstruction, the affected leg

had lower muscle strength and similar tendon stiffness to the non-affected leg, and no changes in MTU properties were observed in the affected leg over the three-year period of observation. Thus AT rupture and reconstruction may lead to an irreversible discordance within the TS MTU, suggesting that maximum contractile force may not be the sole determinant of tendon adaptation. The complete results of our ongoing longitudinal investigation with adult elite athletes, as well as the plasticity of the TS MTU in recreational and master athletes will be discussed.

OP-BN25 Sports physiotherapy: Backpain

BENEFITS OF A 4-WEEK FUNCTIONAL RESTORATION PROGRAM IN CHRONIC LOW BACK PAIN PATIENTS: FOCUS ON THE AEROBIC METABOLISM RESPONSES DURING TRUNK EXTENSION EXERCISE

ANTHIERENS, A., OLIVIER, N., THEVENON, A., MUCCI, P.

UNIV. LILLE, UNIV. ARTOIS, UNIV. LITTORAL CÔTE D'OPALE, EA 7369 - UREPSSS - UNITÉ DE RECHERCHE PLURIDISCIPLINAIRE SPORT SANTÉ SOCIÉTÉ, F-59000 LILLE, FRANCE

INTRODUCTION: Chronic low back pain is a current society problem associated to pain sensations and high level of paraspinal muscle fatigability to exercise, which can be improved following a 4-week functional restoration program. These These symptoms could be related to an alteration in aerobic metabolism responses in regard of paraspinal muscles. The aim of this study was to evaluate the aerobic metabolism responses in regard of paraspinal muscles before and after a 4-week functional restoration program in chronic low back pain patients.
METHODS: Twenty-two chronic low back pain patients were evaluated before and after a 4-week functional restoration program (11 men and 11 women; 41.6±1.8 years; 73.7±3.1 kg; 1.74±0.02 m). During both testing sessions, they performed the Sorensen test to evaluate paraspinal muscle fatigability. On another day, they performed a 5-minutes submaximal trunk extension exercise on an isokinetic dynamometer. A gas exchange analyzer and near infrared spectroscopy technique were used continuously to evaluate the on-set VO2 kinetics, the mechanical efficiency and the muscle oxygenation and blood volume to exercise. Before and after this exercise, pain sensations in the low back were evaluated using a visual analog scale.
RESULTS: The holding time during the Sorensen Test was increased following the program ($P<0.001$).
During the submaximal exercise the on-set VO2 kinetics was accelerated, the mechanical efficiency, the levels of muscle deoxygenation and blood volume were greater ($P<0.05$).
Before the program, the 5-minute exercise induced an increase in low back pain sensations ($P<0.05$), whereas at the end of the program, the exercise did not induce an increase in pain sensations anymore ($P<0.05$). In addition, pain sensations were lower at the end of the program compared to before ($P<0.05$)
CONCLUSION: The aerobic metabolism responses to specific exercise soliciting trunk extensor muscles were improved following a 4-week functional restoration program. It could permit to reduce the paraspinal muscle fatigability and the low back pain sensations induced by exercise.

THE EFFECTS OF WHOLE BODY ELEKTROMYOSTIMULATION (WB-EMS) TRAINING IN COMPARISON TO A MULTIMODAL LOW BACK PAIN CONCEPT – A CLINICAL INTERVENTION TRIAL IN PATIENTS WITH CHRONIC BACK PAIN

KONRAD, K.L.1,2, BAEYENS, J.P.2, BIRKENMAIER, C.1, LEUKERT, J.1, KRAFT, E.1, JANSSON, V.1, WEGENER, B.1,2

1 LUDWIG-MAXIMILIANS- UNIVERSITY MUNICH , GERMANY; 2 VRIJE UNIVERSITEIT BRUSSEL , BELGIUM

INTRODUCTION: Chronic non-specific back pain (NSCBP) is the worldwide leading chronic disease, it is the number one cause for years lived with disability (disability-adjusted life-years) (1). According to present guidelines, active exercise is the preferred treatment of NSCBP. Because of lag of time and bodily limitations, the lifestyle of NSCBP patients mostly does not include exercise. Whole body electromyostimulation (WB-EMS) is a safe, joint-friendly, and time-effective training method, that may be effective for NSCBP-patients (2). In this clinical prospective, controlled study, two different therapeutic approaches were compared on back pain patients. One group received a 20 minutes WB-EMS once a week. A active control group (ACG) received a multimodal low back pain program. A passive control group (PCG) included healthy subjects without back pain
METHODS: Pain and disability scores were set as primary outcome. Therefore in all groups, the following measurements were performed: North American Spine Society Instrument (NASS), Numeric Rating Scale (NRS) and Oswestry Disability Index (ODI). As secondary outcome biomechanical measurements, depression score and quality of life scores were assessed: MFT S3 check; Leonardo Stair (SC); Leonardo force plate with Trunk Rise test (TRT), single 2 leg jump (s2lJ) and the chair rising test (CRT), SF 36 survey and Hospital Anxiety and Depression Scale (HADS). In the intervention group measurements have been carried out at the following times: T0: baseline; T1: after 6 weeks; T2: after 12 weeks and T3: 24 weeks after the start. In the therapeutic control group T0 was carried out before beginning and T1: after 4 weeks.
RESULTS: 162 Subjects were includes to the study: 128 patients NSCBP, 85 allocated in the WB-EMS group and 43 in the ACG. 34 Subjects enrolled in the passive healthy control group (PCG). The average age was 58,6 years (18-86 years). In EMS group the NRS (1-10) improved statistically and clinically significant by 2 points, The ODI achieved 19,7 points reduction in disability. The NASS and all but the social role functioning score of the SF 36 improved significantly. In the ACG only the total relative force of TRT, the CRT and relative and average power of SC improved.
CONCLUSION: The WB-EMS-program showed a considerable reduction of the backpain induced disability and clinical significant reduction of pain Intensity. Therefore WB-EMS may be seen as effective and, with a training time of 20 min./week, very time-efficient alternative to established multimodal treatment.

CLINICAL OUTCOME OF ISOLATED CERVICAL EXTENSION RESISTANCE EXERCISE FOR PATIENTS WITH CHRONIC NECK PAIN AND SPINE DEGENERATION

LÖSCH, A.1, HARANDI, V.M.2, ALFEN, F.M.2, SPANG, C.1,3

1: PRIVATE ORTHOPAEDIC SPINE CENTER, GERMANY; 2: UNIVERSITY OF LUND, SWEDEN 3: UMEA UNIVERSITY, SWEDEN

INTRODUCTION: Isolated cervical extension resistance exercise (ICEX) has shown promising clinical outcomes in patients with chronic neck pain (Bronford et al., 2001). However, there is a lack of knowledge on its potential use for patients with advances stages of cervical spinal disorders and those with chronic headache.
METHODS: In this study 67 patients (35 men, 32 women; mean age 44.3 years) with chronic pain conditions in the neck region underwent a 9-week rehabilitation program including one set of machine based ICEX (2x sessions per week). Based on their symptoms and clinical diagnoses patients were sub-grouped into (A) "bulging disc" (n=23), (B) "bulging disc and spinal degeneration/inflammation" (n=23), (C) "chronic headache" (n=21). Before and after the program isometric cervical extension strength was tested. Via Visual Analogue Scales (VAS, 0-10) pain, psychological burden and satisfaction rates were measured. Furthermore, percentage of achieved rehabilitation goal was rated (0-100%).
RESULTS: Overall, 62/67 (92.5%) of patients reported a decrease of pain symptoms after the rehabilitation program. In 46 patients (68.7%) no or only a mild discomfort remained (A: 87.0%, B: 60.9%, C: 57.1%). Pain scores (VAS) decreased on average from 4.8 (±2.3) to 2.6 (±1.7) ($p<0.001$). Scores on psychological burden decreased from 6.2 (±2.4) to 3.0 (±2.2 ($p<0.001$). In all groups scores for psychological burden were on average rated higher than those for pain ($p<0.01$). There were no significant differences in outcome measures between the groups. However, for most measures patients with bulging discs seemed to have superior results than those from the other groups.
CONCLUSION: ICEX treatment is a promising treatment option for rehabilitating patients with chronic pain conditions in the neck region. The results of this study show that even patients with advanced spine degeneration and those with chronic headache can be treated.

SAGITTAL TRUNK-PELVIC POSITION COMPARISON BETWEEN RELAXED-STANDING, ACTIVE STRAIGHT-STANDING, AND ACTIVE-KNEELING POSTURES IN ACROBATIC ATHLETES

MCNEAL, J.R., SANDS, W.A.

EASTERN WASHINGTON UNIVERSITY; U.S. SKI AND SNOWBOARD CENTER OF EXCELLENCE

INTRODUCTION: Assessment of standing posture in clinical and athletic populations typically utilizes a relaxed or habitual standing posture. However, in some sports like diving and gymnastics, a linear, straight-body position is an aesthetic and technical goal, and may be a more applicable posture to assess in this population. It is not known to what degree these athletes can intentionally alter their posture. This study sought to compare sagittal trunk and pelvis positions in relaxed-standing, active straight-standing, and kneeling postures in acrobatic athletes.
METHODS: Sagittal plane video recordings of twenty-five male and female divers and gymnasts were analyzed for trunk and pelvis segment angular positions in three postures: relaxed-standing (RS), and two intentionally-straight postures (standing – SS, and kneeling - SKN, both with arms overhead). Thirteen reflective markers were placed on spinal, pelvic, sternal, and upper and lower limb anatomical landmarks. Lumbar lordosis, backward lean of the trunk, and the angle of the sternum relative to vertical were calculated based on the digitized, two-dimensional coordinates of the markers. Two measures of pelvic tilt [ASIS-greater trochanter relative to vertical (PTV), Perry et al., 2008; PSIS-ASIS relative to horizontal, (PTH) Crowell et al., 1994] were also calculated. Repeated measures one-way ANOVAs followed by post-hoc tests with Bonferroni correction were used to determine differences between postures.
RESULTS: Anterior PTV decreased from RS (43.3°± 6.8) to SS (39.6°± 5.9, $p<0.0001$), and SS to SKN (38.0°± 6.2, $p<0.0001$). Anterior PTH also decreased from RS (9.86°± 5.0) to SS (6.69°± 6.0, $p=0.004$), but increased again in the kneeling posture (9.39°± 6.3 $p<0.0001$). Backward trunk lean was greater in SS (13.05°±3.2, $p<0.001$) and SKN (13.62°±3.2, $p<0.001$) compared to RS (11.03°±3.1). Lumbar lordosis decreased between RS (158.30°±9.2) and SS (163.23°±10.2, $p=0.001$) but was not different from kneeling (161.33°±9.5). Finally, sternal angle increased from RS (18.76°±4.2) to SS (23.10°±5.3, $p<0.001$), and further increased in SKN (24.45°±4.8, $p<0.001$).
CONCLUSION: Athletes in acrobatic sports in which specific training is undertaken to achieve straight-body positions demonstrate the ability to improve the linear alignment of their trunk and pelvis in active straight-standing relative to relaxed standing. Kneeling induced alterations to the trunk and pelvis that deviated from the straight-body position. The assessment of a straight-standing posture is sport-specific in this population, and may be preferred over traditional relaxed-standing postures.

DYNAMIC FACTORS OF THE LUMBAR JOINT FORCE DURING GOLF SWING

TAKAGI, T.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Low back pain is the most common injury in golf, which accounts for more than 50% of all injuries (1). Although there have been a lot of studies investigating the factors of low back pain in golf swing, there have been no studies investigating the dynamic factors determining the force acting on the lumbar joint (lumbar joint force) which is the direct cause of low back pain. Joint forces can be affected by not only the joint torques but also the motions of the body segments, namely, the motion-dependent forces (2). The purpose of this study was to reveal the dynamic factors determining the force acting on the lumbar joint during golf swing.
METHODS: Sixteen right-handed skilled golfers (handicap, 3.5 ± 1.7) participated in the experiment. The participants hit four to seven shots into a net with their own driver. Reflective markers were attached to each participant's body and driver. The marker trajectories were collected using a three-dimensional motion capture system (VICON MX) consisting of 20 cameras operated at 500 Hz. The ground reaction forces on the both feet were measured using two force platforms (Kistler) operated at 1000 Hz. The three-dimensional coordinate data of the club and body markers were smoothed using a zero-lag fourth-order low-pass Butterworth digital filter. Referencing previous methodology (3), the lumbar joint force was described as a function of the terms of the joint torques, gravities, motion-dependent forces,

and inertia force acting on the lumbar joint. The time events were defined: the transition point where the pelvis stops backward rotation and begins rotating toward the target (i.e., top of the backswing, TOB), and the time point of maximum downswing rotation velocity of the pelvis about its longitudinal axis (MDR).
RESULTS: The lumbar joint force increased after TOB, peaked around MDR. In this phase, the lumbar joint force was caused mainly by the joint torques of the lower body rather than the joint torques of the upper body. Especially, the right hip extensor torque and left hip knee extensor torque were the main contributors to the lumbar joint force in each participant (183 ± 42% and 88 ± 32% of the magnitude of the lumbar joint force, respectively).
CONCLUSION: The present study revealed that the main contributors of the lumber joint force. The right hip extensor torque as well as left hip knee extensor torque patterns (both magnitudes and their generation timings) might be key elements to investigate the factors of low back pain.

CROSS SECTIONAL AREA OF THE PARASPINAL MUSCLES, MUSCLE STRENGTH AND LOW BACK PAIN AMONG FIGHTER PILOTS: A 5-YEAR FOLLOW-UP

HONKANEN, T.

UNIVERSITY OF JYVASKYLA

INTRODUCTION: A small cross-sectional area (CSA) of the paraspinal muscles may be related to low back pain (LBP) among military aviators but previous studies have mainly concentrated on spinal disc degeneration. The primary aim of the study was to investigate the changes in muscle CSA and composition of the psoas and paraspinal muscles during a 5-year follow up among Finnish Air Force (FINAF) fighter pilots during their early flight career and, thus, to find out whether muscle CSA and composition could have a predictive role for LBP. In addition, the secondary aim was to examine a possible relationship between the overall isometric strength test results and muscle CSA at the baseline.
METHODS: Study population consisted of 26 volunteered FINAF fighter pilots. The magnetic resonance imaging (MRI) examinations were collected at baseline and after 5 years of follow-up. CSA and composition of the paraspinal and psoas muscles were obtained at the levels of 3-4 and 4-5 lumbar spine. Maximal isometric strength tests for trunk and lower limb muscles were performed only at the time with the baseline MRI.
RESULTS: The follow-up comparisons indicated that there was a statistically significant ($p < 0.01$) increase in CSA of the paraspinal muscles during the 5-year period. The mean CSA of the paraspinal muscles increased by 8% at L3-4 level and 7% at L4-5 level. There was no change in muscle composition during the follow-up period. The paraspinal and psoas muscles' CSA was related to overall maximal isometric strength at the baseline. There was no association with muscle CSA or composition and LBP.
CONCLUSION: The paraspinal muscles' CSA increased among FINAF fighter pilots during the first 5 years of service. This might be explained by physically demanding work and regular exercise. However, no associations between muscle composition or CSA and LBP experienced were observed after the five-year follow-up. Nevertheless, the LBP occurrence was low among the study population, and, therefore, we recommend future studies to investigate this association with longer follow-up periods.

OP-MI14 Ageing II

THE EFFECTS OF EXERCISE TRAINING INTERVENTION ON FUNCTIONAL CAPACITY IN OLDER COMMUNITY-DWELLING MEN AND WOMEN USING INTELLIGENT TECHNOLOGY CONCEPT

HAUTALA, A.J.1,2, ILVONEN, K.3, MYLLYNEN, A.M.3, PIETILÄ, M.3, KUJALA, T.3, SAIKKONEN, N.2, JAAKKOLA, J.2

1: OULU UNIVERSITY HOSPITAL, UNIVERSITY OF OULU, FINLAND, 2: HUR OY, KOKKOLA, FINLAND, 3: OULUNKYLÄ REHABILITATION HOSPITAL, HELSINKI, FINLAND

INTRODUCTION: Populations are getting older facing societies to develop effective strategies to promote and improve older people's functional capacity and engagement in active daily living. One of the most important factors related to improved functional capacity is ability to walk safely and independently in one's environment. (Satariano et al. 2012, Sipilä et al. 2018). We hypothesized that an exercise training intervention using new intelligent technology concept will increase functional capacity especially among those aged individuals who report gait difficulties at baseline.
METHODS: In a two months intervention, volunteer individuals (14 females and 6 males, aged 73±7 years, BMI 29±5 kg/m2) completed strength (nine major muscle groups) and balance training sessions two times weekly by using intelligent gym (HUR Oy, Kokkola, Finland). The developed exercise training concept was computerized and automated to individualize outcome measures, training loads and volumes, and progression of training. One repetition maximum (1 RM) for leg and chest press were used to assess changes in maximal muscle strength for lower and upper body, and short physical performance battery (SPPB) was performed as a measure for changes in functional capacity.
RESULTS: All individuals completed all 16 training sessions (average duration 49±7 min). 1 RM in leg press improved 15% (from 66±15 to 73±14 kg, $p<0.0001$) and in chest press 12% (from 20±7 to 22±9 kg, $p<0.0001$). SPPB showed 5% improvement in functional capacity (from 10.4±1.3 to 10.9±1.2, $p=0.016$). We analyzed separately individuals who reported gait difficulties at baseline (GD, n=7) and those without reported gait difficulties (NGD, n=13). The GD was older than the NGD (77±6 vs. 69±6 years, $p=0.011$). 1 RM in leg press increased 25% for the GD and 10% for the NGD ($p=0.054$ for main effect). Accordingly, 1 RM in chest press changed 15% for the GD and 11% for the NGD ($p=0.517$ for main effect). SPPB improved 12% for the GD and 1% for the NGD ($p=0.001$ for main effect). The groups differed at baseline in SPPB (GD 9.4±1.2 vs. 11.2±0.5, $p<0.0001$), but no longer after the two months physical training intervention (GD 10.6±1.5 vs. 11.2±0.6, $p=0.199$) i.e. the GD was at same SPPB level than the NGD at the end of intervention.
CONCLUSION: Exercise training intervention using automated intelligent technology is effective to increase functional capacity expressed as short physical performance battery especially in aged individuals who report gait difficulties at baseline. New physical activity promoting concepts using modern technology may be potential individual motivators promoting safe walking, improved functional capacity and better quality of life in aging adults.

ORTHOPAEDIC SUPPORTS WITH HEATING ELEMENTS INCREASE THE THRESHOLD SENSITIVITY OF REFLEX EXCITABILITY IN YOUNG AND OLD POPULATION

BRAZAITIS, M., PAULAUSKAS, H., BARANAUSKIENE, N., MIKUCIONIENE, D.

LITHUANIAN SPORTS UNIVERSITY

INTRODUCTION: It has been proposed that attenuated neural excitability associated with a weaker electrically induced torque development potentially contributes to a postural instability with advanced age (1). Evidence indicates that in older men increase in whole-body temperature induces decrease in latency for spinal and supraspinal excitability in the transmission of neural drive (2). However, the effects of locally knee heating while wearing specialized orthopaedic supports on reflex excitability remain unknown.
METHODS: Young (n=10; aged 22±3 years) and older (n=10; aged 69±5 years) subjects of both sexes participated in 2 randomised trials. On arrival at the laboratory, orthopaedic supports with heating elements were placed on the knee. The participant was positioned in the dynamometer chair, stimulating electrodes were placed over the tibial nerve, EMG electrodes were placed over the SOL of the right leg, and the reflexes were assessed throughout acute knee heating (contact temperature, 45oC) procedure (experimental trial) or no heating (control trial).
RESULTS: The results of the present study revealed no age effect on H-reflex and M-wave amplitude and latency difference between control and experimental trail (P>0.05). Compared to control trial, acute knee heating was sufficient to decrease the amplitude of H-reflex and to increase the amplitude of M-wave in both groups of subjects (P<0.01). No effect was found for reflex latency (P>0.05). Acute knee heating by using orthopaedic supports with heating elements have shifted the reflex current excitation threshold to the left (i.e. increased excitation sensitivity) in both groups of subjects (P<0.01).
CONCLUSION: The main finding of the present study is that, acute knee heating by using orthopaedic supports with heating elements is a sufficient intervention to modulate reflex (spinal and sarcolemmal) excitation in young and older subjects. From a functional point of view, the potentiated neural excitability may be regarded as a way to increase the ability to maintain an upright posture during sudden balance perturbation in aged people (1,2).

THE TIME COURSE OF TENDON AND MUSCLE ADAPTATIONS TO MODERATE-LOAD ECCENTRIC VS CONCENTRIC RESISTANCE EXERCISE IN YOUNG AND OLDER MALES.

QUINLAN, J.I., FRANCHI, M.V., GHARAHDAGHI, N., BADIALI, F., PHILLIPS, B.E., GREENHAFF, P., SZEWCZYK, N., ATHERTON, P.J., SMITH, K., MAGANARIS, C.N., NARICI, M.V.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Muscle and tendon biomechanical properties change in response to resistance exercise (RE) (1,2). In this context, it has been suggested that eccentric (ECC) RE may afford greater musculoskeletal adaptations than concentric (CON) RE (1). An effective muscle-tendon unit requires both muscle and tendon to adapt at a similar rate. However, studies on human tendon adaptability typically investigate pre/post values; thus, the time course of tendon adaptation remains unknown. We therefore studied the vastus lateralis (VL) and the in-series patellar tendon (PT) to establish the time course of adaptation in response to submaximal CON and ECC RE in young and older males.
METHODS: 19 young (24.2±5yrs) and 16 older (68.2±2yrs) recreationally active, males were recruited for 8 wks of RE, involving 4 x 12 CON or ECC repetitions at 60% 1-RM, 3/wk. Groups were young CON (YC, n=10), young ECC (YE, n=9), old CON (OC, n=8) and old ECC (OE, n=8). PT Young's modulus (YM) and VL muscle architecture was obtained via ultrasound every 2 wks. Data are mean ± SEM; between groups differences were analysed via repeated-measures 2-way ANOVA with Bonferroni correction.
RESULTS: No differences in PT YM were found between YC and OC, or between YE and OE at wk0. YM significantly increased from wk0 to wk4 in YC (+29.2%±9.5, P<.001), YE (+37.7±9.4%, P<.0001), OC (+34.5±4.0%, P<.05) and OE (+44.1±10.5%, P<.05). No within age group differences were found at any timepoint. The increase at wk8 in OC (+75.9±9.7% vs +30.5±8.1%, P<.001) and OE (+88.1±19.4% vs +39.9±7.3%, P<.01) was greater than their younger counter parts. No differences in VL fascicle length (LF) or pennation angle (PA) were found between YC and YE or between OC and OE at wk0. VL LF increased in YE (+4.7±0.5%, P<.0001) and OE (+2.2±0.3%, P<.001) by wk2; but was unchanged in YC and OC at any time point. VL PA increased in YC (+3.0±0.4%, P<.0001) and OC (+2.8±0.6%, P<.0001) by wk2; but not until wk8 in YE (+2.0±0.4%, P<.05) and wk4 in OE (+2.0±0.6%, P<.05).
CONCLUSION: The present study is, to our knowledge, the first to report the time course of PT biomechanical adaptations to RE. The data suggests that PT adaptations require a longer period in the elderly than in the young; albeit capacity for adaptation appeared similar. PT adaptations occurred comparably in CON and ECC; whereas, LF and PA changes appeared to be contraction specific. Notably, both tissues appeared to adapt in a coordinated fashion, presumably to maintain an effective muscle-tendon unit.

COMPARISON OF AGILITY VERSUS TRADITIONAL STRENGTH AND BALANCE TRAINING FOR SENIORS: A RANDOMIZED CONTROLLED TRIAL

LICHTENSTEIN, E., FAUDE, O., GRILLO, J., FLURY, S., ROTH, R., ZAHNER, L., DONATH, L.

UNIVERSITY OF BASEL

INTRODUCTION: In addition to generally high levels of physical activity, multi-component exercise training is currently recommended for general maintenance of health in the elderly, including the prevention of falls and frailty. This training often encompasses serial sequencing of balance, strength, endurance and other types of exercise. Exercise training featuring integrative training of these components (=agility training) has been called for, as it more likely reflects real life challenges like stop-and-go patterns, cutting manoeuvres, turns and decision-making. In this study, such a program's efficacy is compared to the traditional strength and balance training approach in regard to risk factors for falls and frailty.

METHODS: Twenty-seven community-dwelling healthy seniors (16m; 11f; age: 69.5 ± 5.3 y; BMI: 26.4 ± 3.7 kg/m2) were trained for 8 weeks in a group setting with 3 sessions per week lasting 45 to 60 minutes. They were randomized into either the agility-training group (AGI; n=12), that used the integrative multi-component training, or the traditional group (TSB; n=15) which performed balance, and strength exercises separately, albeit within the same session. Both groups' training was progressively increased in difficulty. Outcomes were static and dynamic balance (single leg eyes open stand, Y-balance, reactive balance), lower limb (plantar flexion and dorsal extension) and trunk flexion and extension maximum strength (MS) and rate of torque development (RTD). In addition, cardio-circulatory capacity (CCC) was tested by six minute walking test. Group differences in change scores were estimated with linear regression controlled for baseline and gender. Effect sizes (ES) with 90% confidence intervals are reported.
RESULTS: Both groups improved with small ES in CCC (ES>0.45[0.24;0.80]), dorsal extension MS (ES>0.23[-0.10;0.84]) and dynamic balance (ES>0.28[-0.02;0.58]). Only AGI improved notably in plantar flexion parameters (ES>0.25[-0.02;1.24]) as well as trunk extension RTD (ES=0.28[0.01;0.55]). Small ES in favour of AGI were found for CCC (ES=0.22[-0.05;0.50]), plantar flexion parameters (ES>0.21[-0.10;1.15]) and RTD (ES>0.54[-0.06;1.15]) as well as trunk extension RTD (ES=0.45[0.09;0.80]). Compliance was high in booth groups (AGI: 90 ± 8 % of sessions; TSB: 91 ± 7 % of sessions).
CONCLUSION: Agility based exercise training seems at least as efficacious as traditional balance and strength training in affecting fall risk factors among community-dwelling healthy seniors. Especially lower limb and trunk extension power seem to benefit from the agility training. Unfortunately, neither exercise intensity nor neuromuscular load was monitored. No adverse events were recorded as a result of the agility training.

RECREATIONAL TEAM HANDBALL FOR MIDDLE-AGED AND OLDER SEDENTARY MEN IS A HIGH-DEMANDING EXERCISE MODE REGARDLESS OF THE GAME FORMAT – SMALL-SIDED OR FORMAL

CARNEIRO, I.1, KRUSTRUP, P.2, PEREIRA, R.3, COELHO, E.4, SANTOS, R.3,5,6, CASTAGNA, C.7,8, PÓVOAS, S.1,9

1:ISMAI,2:SHSC-SDU,3:CIAFEL,4:PORTOSMEDCENTER,5:ESRI,SE,FSS,UW,6:U.LUSÓF.,7:ST-FIGC,8:UTV,9:CIDESD

INTRODUCTION: Though physical activity (PA) and exercise have important wide-range health benefits (1), a third of the adults worldwide do not reach the recommended PA guidelines (2) and inactivity shows an age-related increase (3). In fact, middle-aged and older men show high levels of physical inactivity and lack of motivation is the second main reason underlying this problem (4). Therefore, new types of exercise, assuring this population interests while meeting the PA guidelines, are warranted. Recreational team handball has shown to be effective in improving health and physical fitness of previously trained adult men (5). However, this has not been yet studied for untrained middle-aged and older men, neither which game format should be recommended. This study aims to analyse the physical and physiological demands of different recreational team handball game formats in middle-aged and older sedentary men.
METHODS: Nine recreational team handball matches were performed as 45-min 5v5, 6v6 and 7v7 game formats (80m2/player in a 40x20m pitch) by 17 participants (age 67.4±3.7 years, VO2max 26.5±3.5 ml·kg-1·min-1, body mass 70.0±20.2 kg, height 168.8±6.7 cm). Distance covered, heart rate (HR), blood lactate, rating of perceived exertion (RPE) and fun were evaluated.
RESULTS: Mean distances covered during the 45-min 5v5, 6v6 and 7v7 matches were 2971±525, 3708±627 and 3326±452m, respectively, with no significant differences between game formats (p≥0.05). During 5v5, 6v6 and 7v7 matches, average HRs were 82, 81 and 81%HRmax and peak HRs were 94, 95 and 96%HRmax (p=0.025, 5v5 vs. 7v7), respectively. Time spent with HRs >80%HRmax was 45% (20±8min), 38% (17±7min) and 38% (16±10min), respectively (p>0.05). Average blood lactate values were 3.9±1.3, 3.3±1.0 and 3.1±0.7mM (p≤0.05, 5v5 vs. 7v7), and peak values were 5.3±2.0, 4.2±1.4 and 4.4±1.1mM, for 5v5, 6v6 and 7v7, respectively (p≥0.05 between game formats). RPE (8.2±1.2, 7.9±1.2 and 7.9±1.2, AU) and fun (8.7±2.4, 9.9±0.2 and 8.8±2.2, AU) values did not differ between game formats (p≥0.05), 5v5, 6v6 and 7v7, respectively.
CONCLUSION: Recreational team handball, played either as small-sided (5v5, 6v6) or formal games (7v7), is an intermittent high-intensity exercise mode for middle-aged and older men, with demands within the range described to induce health and physical fitness enhancement. No differences between game formats were observed in the cardiovascular strain, distance covered, rating of perceived exertion and fun.

OP-BN26 Sport technology IV

THE MECHANICAL PROPERTIES OF TREADMILLS DO NOT REPRESENT THOSE OF OTHER SURFACES TYPICALLY USED FOR SPORTS PRACTICE.

COLINO, E., FELIPE, J.L., HERNÁNDEZ-MARTÍN, A., GALLARDO, L., GARCÍA-UNANUE, J.

UNIVERSITY OF CASTILLA-LA MANCHA

INTRODUCTION: Mechanical properties (MPs) of sport surfaces such as Shock Absorption (SA) and Vertical Deformation (VD) are relevant for the safety and the integrity of performance of all athletes. Besides, they have the potential to independently influence physiological variables and energy cost of running. Thus, most international sport federations and other regulatory bodies such as the European Committee for Standardization (CEN) have set standards and procedures to assess surface properties and ensure safe sports practice. However, there is one particular surface whose MPs have gone unnoticed up till now. Despite being one the most commonly used sport surfaces worldwide, the MPs of the treadmills (TR) remain not only unregulated but also unknown. The main regulation concerning these surfaces, the European Standard EN 957-6+A1, does not include the need to assess their MPs nor even mention them. Moreover, the SA,

VD and other properties of TR surfaces have never been reported before. Therefore, the objective of this study was to assess SA and VD of TR surfaces and compare them with those of other overground (OG) surfaces typically used in sports.
METHODS: 13 TR from a fitness centre, 15 tartan tracks (TA), 15 artificial turf pitches (TU), and 15 asphalt (AS) samples were analysed. SA and VD were measured in all surfaces using an Advanced Artificial Athlete and following the same test method, only varying the number of test points per sample. TA and TU were tested in accordance with their international regulations. AS samples were chosen randomly, one test point per sample. TR were tested at three different points along their longitudinal axis. Mean SA and VD were obtained for each sample. A one-way Anova was used to compare SA and VD between surfaces. Where differences were identified, post-hoc pairwise comparisons were performed using Bonferroni tests. Effect sizes (ESs) were also calculated. The criterion level for statistical significance was set at p≤.01.
RESULTS: SA and VD differ significantly among all surfaces (p<.01). SA was significantly higher on TR than on TA (+29.0%; ES>1.0; p<.01), TU (+3.9%; ES>1.0; p<.01), and AS (+61.2%; ES>1.0; p<.01). VD of TR was significantly higher than that of TA (+4.2 mm; ES>1.0; p<.01) and AS (+6.4 mm; ES>1.0; p<.01), but lower that TU (-1.1 mm; ES>1.0; p<.01)
CONCLUSION: TR from fitness centres do not reproduce the MPs of other OG surfaces used for sports practice, their SA ability being significantly higher than any other surface analysed. All studies comparing TR and OG locomotion might have overlooked differences induced by the MPs of TR surfaces. Future research should assess whether these MPs vary according to model, brand, age, km covered and different structural components of the TR. Also, international standards concerning these machines should be reviewed and updated including test methods and expected ranges of variation in MPs of TR surfaces.

INDIVIDUAL FLEXION STIFFNESS VERSUS MANUFACTURERS' FLEX INDEX OF SKI BOOTS

IMMLER, L., SCHINDELWIG, K., HEINRICH, D., NACHBAUER, W.

UNIVERSITY INNSBRUCK

INTRODUCTION: The flexion stiffness (FS) of ski boots is determined by the torque-angle relation around the flexion axis of the boot. Boot manufacturers use in-house prosthetic measurement devices and in-house stiffness parameters to describe FS. These parameters are called nominal flex indices (NFI) which range from 50 (soft) to 150 (stiff). The FS is influenced by individual factors like foot and lower leg shape or buckle closure. Therefore the purpose of this study was to measure the individual flexion stiffness (IFS) of ski boots worn by skiers and to compare IFS with NFI of the manufacturers.
METHODS: The torque-angle relation of 135 skiers was measured on ski slopes by an in-house developed test device. From the torque-angle relation the slope between 5 and 10 degrees in forward direction originating from the neutral ski boot angle was taken as parameter for the individual flexion stiffness (IFS5_10°). Spearman´s correlation coefficient rs was calculated to determine the association between IFS5_10° and NFI. ANOVA with post hoc analysis was used to assess differences between IFS5_10° and NFI (80, 90, 100, 110 and 130).
RESULTS: The correlation between IFS5_10° and NFI was moderate with rs = 0.64 (p < 0.001). The ANOVA revealed a high significant difference of IFS5_10° (p < 0.001) across the NFI. In post hoc analysis no statistical difference were found between NFI 80 and 90 (p = 0.29) and NFI 100 and 110 (p = 0.60). Between NFI 90 and 100 and NFI 110 and 130 significant differences of IFS5_10° were found (p < 0.001).
CONCLUSION: There is a moderate positive correlation between NFI of the boot manufacturers and the IFS. However, comparing IFS across the NFI revealed that higher NFI do not necessarily show higher IFS. The source for the considerable differences between NFI and IFS may be the individual shape of foot and lower leg, individual buckle closure, and soft tissue deformation.
Footnote: The study was accepted for publication in Journal of Science and Medicine in Sport, https://doi.org/10.1016/j.jsams.2019.01.015.

THE INTERPLAY BETWEEN FOOTWEAR TYPES AND EXERCISE-INDUCED FATIGUE DO NOT ALTER RUNNING ECONOMY

BASSET, F., BLAIR, J., ADEBAYO, A., SAAD, M., BYRNE, J.M.

MEMORIAL UNIVERSITY

INTRODUCTION: Of the many factors known to influence running economy (RE), footwear certainly plays a role. Although minimalist footwear is believed to enhance RE and thereby endurance performance, conclusive research reports are scarce. Indeed, debates remain as to which footwear characteristics most alter RE. The purposes of this study were, therefore, two-fold: (a) to determine whether wearing minimalist shoes results in better RE compared to shod; (b) to determine whether changes in RE with minimalist shoes are still evident following a fatiguing bout of exercise.
METHODS: Well-trained male distance runners (n=10; 29.0±7.5 yrs; 71.0±4.8 kg; 176.3±6.5 cm) partook first in a maximal oxygen uptake determination test (Maximal oxygen uptake = 61.6±7.3 ml/min/kg) 7 days prior to the experimental sessions. Second, in a fully randomized fashion, a RE test consisting of three 8-min treadmill runs in shod and minimalist footwear were performed prior to and following exercise induced fatigue (EIF). The minimalist and shod conditions were tested with a minimum of 7-day wash-out period between conditions. The RE bouts, interspaced by 2-min rest periods, were run at 2.79, 3.33, and 3.89 m/s with a 1% grade. EIF consisted of 7 times 1000 m at 94-97%9'O2max interspaced with 3-min recovery. Cardiorespiratory, electromyography (EMG), kinematics, rate of perceived exertion (RPE) and blood lactate were measured throughout the experimental sessions.
RESULTS: A significant main speed effect on RE (p=0.001) and stride frequency (SF) (p=0.001) was observed. The pairwise comparisons showed that running at 2.79 m/s was less economic compared to 3.33, and 3.89 m/s (3.56±0.38, 3.41±0.45, 3.40±0.45 ml O2/kg/km; respectively) and that SF increased as a function of speed (79±5, 82±5, 84±5 strides/min). Further, EMG analyses revealed that root mean square EMG significantly increased as a function of speed for all muscles (Biceps femoris, Gluteus maximus, Gastrocnemius, Tibialis anterior, Vastus lateralis). During EIF, the statistical analysis revealed a significant main effect of time on lactate production (from 2.7±5.7 to 11.2±6.2 mmol/L), RPE scores (from 7.6±4.0 to 18.4±2.7) and peak HR (from 171±30 to 181±20 bpm), except for the recovery period. Surprisingly, a significant main footwear effect was observed on running speed during intervals (p=0.041). Participants ran faster with minimalist shoes compared to shod (3:24±0:44 min [95%CI: 3:14-3:34] vs. 3:30±0:47 min [95%CI: 3:19-3:41]).
CONCLUSION: Although EIF altered lactate production and RPE scores, no other effect was noticeable on RE, EMG, and SF pre- and post-EIF, except for the expected speed effect. The significant footwear effect on running speed during EIF was unforeseen but could be due to shoe mass and/or heel-toe-drop differences. We also cannot discard the effect of speed on foot-strike pattern and thereof running performance.

EFFECTS OF COMPRESSION GARMENT POSITION ON HEALTHY ADULTS' KNEE JOINT PROPRIOCEPTION

ZHANG, L.Y., NÉGYESI, J., OKUYAMA, T., TANAKA, M., HORTOBÁGYI, T., NAGATOMI, R.

GRADUATE SCHOOL OF MEDICINE, TOHOKU UNIVERSITY

INTRODUCTION: Athletes use compression garments (CGs) with the assumption that the mechanical support and tissue compression under CGs enhance joint position sense (JPS) by reducing muscle fatigue and/or by stretching the skin (1). However, paralleling the inconsistencies of these physiological mechanisms, the results are contradictory concerning how and if at all tissue compression under CGs affect knee JPS. While some authors contend the benefits of CGs on muscle performance and/or proprioception are related to the magnitude and uniformity of tissue compression (2), others suggest the beneficial effects are independent of tissue pressure created by CGs (3). Our recent study showed an above-knee CG did not improve proprioception as measured by a passive target-matching task. Compared with passive repositioning test , in active test, muscle spindles appear to play a role in the conscious perception of limb movement by detecting changes in muscle length (3). The purpose of the present study is to determine if the position of a CG around the knee affects healthy adults' knee joint proprioception measured by an active repositioning task.
METHODS: In a counterbalanced, single-blinded, crossover trial, 16 healthy young adults (8 female) with a mean age of 25.5 ± 2.57 years performed an active knee position-matching task by an isokinetic dynamometer using each leg separately with and without compression. Participants were randomly allocated to wear below-knee (BK), above-knee (AK), or whole-knee (WK) CG in a randomized order on the dominant (CompDom), or the non-dominant leg (CompNon-Dom). Repositioning errors were normalized with the pressure under the garment in each conditions and target angles. We also determined the magnitude of compression by measuring anatomical thigh cross sectional area (CSA) in standing using magnetic resonance imaging.
RESULTS: rANOVA showed a placement x group interaction ($F_{2, 13} = 3.988$; $p = 0.045$; $\eta p2 = 0.380$) and main effect of placement ($F_{2, 13} = 5.380$; $p = 0.020$; $\eta p2 = 0.453$). Participants performed active repositioning more accurately in BK condition compared with WK condition ($p = 0.023$). Furthermore, the magnitude of compression produced by the CG in BK condition negatively correlated with the position sense errors ($r = -0.757$, $p = 0.002$). Finally, MRI data revealed that the garment reduced thigh CSA by 4.5cm2 or 3% ($p < 0.001$, Cohen's $d = 0.27$) and calf CSA by 1.3cm2 or 1% ($p = 0.016$, Cohen's $d = 0.13$).
CONCLUSION: In conclusion, although the significant but minimal level of compression by the garment used in our study seems to be ineffective to enhance knee joint proprioceptive acuity in healthy adults, the present study revealed that active target matching was more accurate when CG compressed the calf compared with when the CG was placed on the knee joint.

NON-MOTORIZED TREADMILL SPRINTING POWER IS RELATED TO OVER-GROUND SPRINTING PERFORMANCE IN ELITE TEAM SPORTS ATHLETES

SCHARNER, M., HAIDER, P., NUSSTHALER, T., TRISKA, C., TSCHAN, H.

UNIVERSITY OF VIENNA - CENTRE FOR SPORT SCIENCE AND UNIVERSITY SPORTS

INTRODUCTION: A considerable amount of literature has used non-motorized treadmills to record kinetic parameters during sprinting to assess acceleration. The reliability of these measurements is considered acceptable with prior familarization. However, to-date there is little published data assessing the validity of kinetic parameters in non-motorized treadmill sprinting, particularly in elite sports (1). The aim of this study is therefore to assess the relationship between non-motorized treadmill sprinting performance and over-ground sprinting performance in elite team sport athletes.
METHODS: Eight elite team sport athletes (f=7, m=1; age = 25.4±4.3 yrs) participating in Austrian first league handball, fistball, softball, and baseball clubs performed 3x20 m maximum effort sprints interspersed by 4 min in a sports hall from a standing start 50 cm before the first timing gates. Double-beam infrared timing gates (WittyGATE, Microgate, IT) were used to measure sprinting times. After a passive rest of 30 min, participants performed 3x6 s maximum effort sprints interspersed by 4 min on a non-motorized treadmill (Woodway Force 3.0, Woodway Inc., USA). The following parameters were analyzed: highest power measured in non-motorized treadmill sprinting (PPO), average power in non-motorized treadmill sprinting (MPO), 0-5 m sprint time (T5), 5-20 m sprint time (T15) and 0-20 m sprint time (T20). The correlation coefficient according to Pearson was calculated to determine relationships. Statistical analysis was conducted using SPSS (version 24, IBM Analytics, USA).
RESULTS: There was a significant relationship between MPO and T5, T15, and T20 ($p<.001$, $r=-.946$; $p=.003$, $r=-.893$; $p=.001$, $r=-.915$, for T5, T15, and T20, respectively). PPO also correlated significantly with T5, T15, and T20 ($p<.001$, $r=-.965$; $p=.001$, $r=-.931$; $p<.001$, $r=-.947$, for T5, T15, and T20, respectively).
CONCLUSION: The novel finding of this work was that analysis of physical power in non-motorized treadmill sprinting is a valid method to assess sprinting performance in elite team-sports. Recent research has shown that there is a moderate relationship between non-motorized treadmill sprinting and over-ground sprinting in non-elite team sport athletes. In contrast to the present study recent research analyzed the time needed for different distances during non-motorized treadmill sprinting and compared these values to field derived times (2). The present study proved that MPO and PPO during non-motorized treadmill sprinting is highly related to short distance sprinting times. In summary physical power in non-motorized treadmill sprinting can be a useful parameter to predict over-ground sprinting performance in elite team sport athletes.

TESTING OF A 3D VIDEO ENVIRONMENT FOR VOLLEYBALL COACHES

LOMBARD, G., DEJONG, B., CLOES, M.

UNIVERSITY OF LIEGE

INTRODUCTION: Over the years the use of new technologies in sport has become more and more important. As an example the virtual reality (VR) has been used for the players' making decision training in some sports like rugby (1) or handball (2). Nevertheless the VR and 3D video haven't been widely used for the analyse of coaching leaving a gap in the literature. The present study focus on the testing of a 3D video environment for volleyball coaches to know if it could recreate the same feelings as a real championship game.

METHODS: First of all we recorded 2 simulated games involving the most important characteristics of a true competition (referee, score, atmosphere…) with a 3D camera (Nikon Keymission 360). That device was located near the bench where trainers are usually coaching. Second of all we prepared movies to create a part of game database. Finaly 17 volleyball coaches of several levels agreed to be immersed in our 3D environment with a RV headset (Oculus Rift) during 3 periods of 10-15 minutes. At the end of that experience they fulfiled a validated perception questionnaire for RV (3).
RESULTS: The mean scores (/10) of the items for 3D video were : immersion = 6.35 +/- 2.85, flow = 5.83 +/- 2.75, positive feelings= 5.24 +/- 2.69, negative feelings = 3.03 +/- 2.18, judgement = 7.70 +/- 1.82, consequences = 3.40 +/- 2.88. These scores were globaly close to values obtained with a RV headset. Through open-ended questions coaches underlined a less of interaction with the environment and a lowest quality of the video on the other side of the field. These elements could partly explain the reason why the scores were not better.
CONCLUSION: The results seemed to indicate that coaches feelings were close to the reality during the experience despite of the less of interaction and video quality. That encouraging finding provides some support to the use of the environment for the analyse and training of coaches behaviours during a game.

IS THERE A FUNCTIONAL RELATIONSHIP BETWEEN THE POLYMORPHISMS GENOTYPES OF THE MITOCHONDRIAL BIOGENESIS PATHWAY AND MTDNA COPY NUMBERS IN HIGH LEVEL PHYSICAL CAPACITY MEN? A PILOT STUDY.

SÁNCHEZ-LORENTE, I.M., ITURRIAGA, T., LARROSA, M., GARCÍA-MERINO, J.A., SÁNCHEZ-BARROSO, L., JIMÉNEZ, A., FERNÁNDEZ-ELÍAS, V.E., PÉREZ, M., SANTIAGO, C., YVERT, T.

UNIVERSIDAD EUROPEA

INTRODUCTION: Mitochondrion is the cellular organelle that produces energy for the organism generating adenosine triphosphate (ATP) using O2 and nutrients. Physical capacity levels are thus directly related with mitochondrial activity (1). Mitochondrial DNA (mtDNA) copy number is proportional to the mtDNA volume in a cell, and can be used as a marker of mitochondrial function (2). Several polymorphisms in the genes of the cellular mitochondrial regulation pathway are already known to be related with the elite athlete status and physical capacity (3,4). Nevertheless, to date, there is few information about the functional relationship between these polymorphisms and the physiological mechanisms leading to an improvement of the physical capacity. The aim of this study was to evaluate the possible functional relationship between mitochondrial pathway genes and the mitochondrial activity in men with high cardiorespiratory fitness level.
METHODS: We measured the leukocyte mtDNA copy number in 38 healthy men aged between 18-45 with a VO2max above 55 ml.kg-1.min-1 using a Mitochondrial to Nuclear DNA Ratio kit. The analysed singles nucleotide polymorphisms (SNPs) of the biogenesis pathway were: Peroxisome proliferator-activated receptor-gamma coactivator-1-alpha (PPARGC1A) G482S (rs8192678); Nuclear Respiratory Factor 1 (NRF1) A>G (rs6949152) and Nuclear Respiratory Factor 2 (NRF2) A>C (rs12594956); Mitochondrial Transcription Factor-A (TFAM) S12T (rs1937); Peroxisome Proliferator-Activated Receptor-delta (PPARD) A>G (rs2267668)). For statistical analyses, we used the SPSS for Windows software version 25.0 (SPSS Inc., Chicago, IL, USA).
RESULTS: None of the analyses presented significant association between the different genotypes of the selected polymorphisms and the mtDNA copy numbers (all P>0,071).
CONCLUSION: Our results in this pilot study presented important inter-individual variability for mtDNA copy number, even in the groups of subjects presenting the same genotypes in each SNP. This could explain the lack of signification for the studied associations. Furthermore, our results did not show the significant relationship generally found by other authors between the genotypes of the polymorphisms of the biogenesis pathway genes and markers of physical capacity like VO2max (all P>0,062). In the future, we plan to increase the number of subjects, in order to try to reduce the variability of our results.

THE IMPACT OF ACUTE AEROBIC EXERCISE ON MICRORNAS ASSOCIATED WITH CARDIOVASCULAR HEALTH: A PILOT STUDY

PETERS, R., WOOD, N., BALCHIN, C., PRICE, O.J., CAMPBELL, M.D., JOHNSON, D.L., STAVROPOULOS-KALINOGLOU, A.

CARNEGIE SCHOOL OF SPORTS, LEEDS BECKETT UNIVERSITY; SCHOOL OF FOOD SCIENCE AND NUTRITION, UNIVERSITY OF LEEDS

INTRODUCTION: MicroRNAs (miRNAs) are non-coding RNAs that have an important role in regulating gene expression. Although circulating miRNAs are considered good markers of response to acute aerobic exercise (1) change in expression according to workload has yet to be investigated. The aim of this study was therefore to determine the impact of maximal vs. sub-maximal intensity aerobic exercise on plasma concentrations of circulating miRNAs associated with inflammation, vascular adaptation and cardio-protection (miRNA 146a, miRNA 222, miRNA 21) (2).
METHODS: Following local research ethics approval and written informed consent, ten healthy recreationally active males (Age=24±3 years; BMI=25.5±2.8kg/m2) were enrolled into the study. Participants attended the laboratory on two occasions separated by a period of 3-7 days. During visit 1, maximal aerobic capacity (VO2peak) was assessed via a cardio-pulmonary exercise test (CPET) on a cycle ergometer. During visit 2, participants completed a sub-maximal cycling protocol at a workload equivalent to 70% VO2peak (isocaloric to CPET). Venous blood samples were obtained pre- and immediately post- exercise. Acute changes in miRNA expression were investigat-

ed using Qiagen real-time quantitative polymerase chain reaction (RT-qPCR) kits and protocols. Log2fold expression for each miRNA was calculated from the RT-PCR data.
RESULTS: VO2peak (47.8±7.0 ml/kg/min) did not correlate with miRNA expression and no difference was observed between visits (P>0.05) (miRNA 146a P=0.160; miRNA 222 P=0.268; miRNA 21 P=0.118). Both exercise protocols resulted in only a minor change in miRNA expression. Specifically, following the CPET, miRNA 146a decreased (-0.706±1.86), whereas an increase was observed following submaximal cycling (0.150±0.162). On the contrary, miRNA-222 and 21 increased following the CPET (0.110±1.05 and 0.077±1.59, respectively) and decreased following sub-maximal cycling (-0.106±0.247 and -0.033±0.521).
CONCLUSION: Our findings indicate that the intensity and type of aerobic exercise used in this study have a minimal impact on expression of the selected miRNAs. Small sample size and/or timing of blood sampling may have affected our results. Further research is required to determine how exercise-induced miRNA expression and associated target protein interaction relate to cardiovascular function and adaptation.

INFLUENCE OF APOE POLYMORPHISM AND PHYSICAL ACTIVITY ON THE WELL-BEING OF HUMAN ERYTHROCYTES

DANIELE, S., PICCARDUCCI, R., PIETROBONO, D., TRINCAVELLI, M.L., FUSI, J., FRANZONI, F., MARTINI, C.

VAT N. IT00286820501 UNIVERSITY OF PISA

INTRODUCTION: Apolipoprotein E (ApoE) is a lipid-transport protein, whose allele epsilon 4 is the strongest genetic risk factor for Alzheimer's Disease (AD) (1). Concurrently, the main environmental factor which leads to AD is the oxidative stress (OS) that triggers damaging of DNA and lipids, and contributes to the alteration of cellular membranes (2).
Epidemiological studies have demonstrated that regular exercise is an important preventive and therapeutic tool in AD, because it upregulates the enzymatic antioxidant system and modulates of oxidative damage, increases neurogenesis and capillarization and enhances proteolytic degradation of toxic oligomers (3).
Thus, to evaluate the influence of ApoE epsilon 4 polymorphism together with level of physical activity on the well-being of Red Blood Cells (RBCs), a cohort of healthy human subjects was enrolled to measure antioxidant capability, and the RBC membrane's composition/oxidative status.
METHODS: Subjects, sex-matched, has been classified on the base of ApoE epsilon 4 polymorphism by the technique of restriction fragment length polymorphism (RFLP). Consequently, the volunteers have been divided in epsilon 4 carriers and non-carriers. In each group, sedentary and athletes were distinguished on the base of endurance exercise (Borg Rating of Perceived Exertion scale). RBCs were collected from each subject for the analysis of the levels of Aβ, phosphatidylethanolamine (PE), phosphatidylcholine (PC) and membrane fluidity, instead plasma was used to evaluate the levels of antioxidant capability (AOC) and lipid peroxidation.
RESULTS: The results showed that both ApoE non-epsilon 4 polymorphism and the level of physical activity increased AOC, membrane fluidity, the level of PC in RBCs; the same reduced the amount of amyloid beta protein. Moreover, physical activity decreased the levels of PE but not lipid peroxidation.
CONCLUSION: Overall, our data confirm RBCs as a good model to monitor biochemical alterations due to OS. Moreover, we demonstrated that a regular and moderate physical activity can reduce the risk to develop AD or at least to slow the onset of symptoms, even in the ApoE epsilon 4 carrier subjects.

RESISTANCE TRAINING AS POTENTIAL THERAPEUTIC INTERVENTION IN TYPE 2 DIABETES MELLITUS: A META-ANALYSIS OF RANDOMIZED CONTROL TRIALS

ACOSTA-MANZANO, P., RODRIGUEZ-AYLLON, M., ACOSTA, F.M.

DEPARTMENT OF PHYSICAL EDUCATION AND SPORTS, FACULTY OF SPORTS SCIENCE. UNIVERSITY OF GRANADA, SPAIN; SPORT AND HEALTH RESEARCH CENTRE, UNIVERSITY OF GRANADA, SPAIN.

INTRODUCTION: Type 2 diabetes mellitus (T2DM) represents one indirect cause of death worldwide1. Considering the disorders related to T2DM, and the foretold increase of its prevalence1, this global threaten and socioeconomic burden needs to be addressed through the implementation of effective-tailored strategies. In this regard, resistance training (RT) has been highlighted as a first-line intervention for the management of T2DM. Therefore, the main aims were to assess the effects of RT on glycaemic control, physical fitness, body composition, lipid profile, blood pressure, C-reactive protein, and quality of life in patients with T2DM; and to update the information regarding the factors that could explain between-study heterogeneity on health outcomes.
METHODS: An electronic database search was performed on PubMed and Web of Science from January 1998 to November 2017. Randomized control trials (RCTs) analysing the effects of RT (≥4 weeks, without co-interventions) on clinical outcomes of interest in adults with T2DM, were included. In the fixed/random effect models, RT was compared vs. control/aerobic training (AT) group (within-group changes from RT minus the comparison group).
RESULTS: Forty RCTs were meta-analysed. The raw mean difference in the within-group change in glycated haemoglobin (HbA1c) was -0.42% (p=0.001) between the RT and control group, and 0.07% (p=0.505) between the RT and AT group. RT improved significantly insulin levels and sensitivity, cardiorespiratory fitness, muscle strength, weight, body mass index, waist circumference, fat and lean body mass, triglycerides, high density lipoprotein-cholesterol (HDL-C), systolic blood pressure (SBP), and C-reactive protein compared to the control group (all p<0.02). Compared to the AT group, RT showed similar effects on these outcomes; excepting muscle strength (RT was more effective), and cardiorespiratory fitness and body mass index (AT improved them more). The meta-regressions suggested that some methodological aspects, and characteristics of the RT programs and patients, might influence the change in magnitude of specific outcomes: statistical analyses (total cholesterol), general methodological quality of studies (HbA1c; diastolic blood pressure), attrition and reporting bias (HbA1c), random sequence (SBP), age of the participants (HDL-C; SBP), HbA1c baseline levels (muscle strength; SBP), duration of the interventions (HbA1c; fasting glucose), and weekly volume (SBP).
CONCLUSION: RT is a life-enhancing therapeutic intervention with beneficial effects on glycaemic control, physical fitness, body composition, lipid profile, blood pressure, and C-reactive protein in adults with T2DM. Specific characteristics of the RT and patients should be considered to promote more tailored RT programs in this population.

CARDIORESPIRATORY TOLERANCE TO MAXIMUM EXERCISE IN INDIVIDUALS WITH INTELLECTUAL DISABILITY WITH AND WITHOUT DOWN SYNDROME INVOLVED IN COMPETITIVE ADAPTED FOOTBALL

BARRIOS, C., LIZONDO, V., ESCRIVÁ, D., PÉREZ-ENCINAS, C., MARISCAL, G., CAPLLIURE-LLOPIS, J., VERA, P.

VALENCIA CATHOLIC UNIVERSITY

INTRODUCTION: Previous studies described very low levels of cardiorespiratory fitness in people with intellectual disability (ID). This finding is questionable when evaluating young adults with ID (20-30 years), since some authors stated that the level of cardiorespiratory fitness in these young individuals with ID is comparable to that reported in healthy sedentary people. This study evaluates the cardiorespiratory tolerance to maximum exercise in people with ID, with and without Down syndrome (DS), involved in a national league of adapted football.
METHODS: A total of 70 male young adults with ID (22 with DS and 48 with ID of varied etiology) performed a maximal exercise test with metabolic gas analysis. The average age was 25.6+/- 8.7 years. A ramp protocol in cycloergometer was used with increments of 10 Watt / min until exhaustion. All the cardiorespiratory parameters were compared with those obtained in a group of 17 men who occasionally practiced sports as leisure, but never in a regular and competitive way. There were no differences in the mean age of the control group with respect to individuals with ID.
RESULTS: Heart rate (HR) at anaerobic threshold and HR-max were lower in subjects with ID than in controls ($p < 0.01$). Within the ID group, participants with DS showed lower HR-max than those registered in individuals with non-Down ID ($p < 0.01$). The maximum oxygen uptake per kg of weight (VO2max/kg) was also lower in the individuals with ID in relation to the controls (47.0+/-15.0 versus 30.8+/-10.8; $p<0.01$)). In addition, participants with DS reflected lower values than those of non-Down ID, both in the aerobic and anaerobic thresholds and in maximal exercise (23.4+/-6.8 versus 34.3+/-10.6, $p < 0.01$). These figures represent 39.3% and 16.7% below that expected VO2max for non-athletic healthy subjects. Ventilation per minute in both thresholds and maximal exercise were lower in DS participants than in non-Down ID (VEmax: 50.1+/-21.3 versus 83.12+/-5.9 l/min, $p < 0.001$). The control subjects exhibited a higher maximal ventilatory capacity (114.4+/-26.6, $p < 0.01$). The peak respiratory exchange rate (RER) was higher in subjects without DS (1.07+/-0.07 versus 1.00+/-0.09, $p < 0.01$). An analysis of peak maximal ventilation, heart rate and VO2 of subjects with a peak RER above 1.1 revealed the same results.
CONCLUSION: These data show that people with intellectual disability have low levels of cardiovascular tolerance to exercise. Individuals with DS have even lower levels of oxygen up-take, maximum ventilation and respiratory efficiency than their peers with ID without DS.

SHOULD BALANCE AND JUMP PERFORMANCE ASSESSMENT OF CHRONIC LATERAL ANKLE SPRAINS BE PERFORMED UNDER FATIGUE?

KARKATSELOU, A., GKRILIAS, P., TSEPIS, E.

SCHOOL OF HEALTH & WELFARE, TECHNOLOGICAL EDUCATIONAL INSTITUTE OF WESTERN GREECE

INTRODUCTION: Muscle fatigue, has been shown to affect the necessary for postural control proprioceptive system (1). The aim of this study was to examine the effect of functionally induced fatigue on balance and vertical jump performance in individuals with a history of unilateral ligament injury to the ankle joint.
METHODS: Twenty-three participants volunteered for the study. The experimental group (EG n=12) comprising from injured participants, was tested against healthy controls (CG n=11). All subjects completed questionnaires detailing the history of ligament injuries, the functional instability of ankle ligament and foot dominance. The injured limb from the EG and the dominant limb from the CG were tested. Balance was assessed via a single leg balance test with open eyes on a force platform for 20 sec. The Center-of-Pressure (COP) excursion on the anteroposterior (Y-axis) and the mediolateral (X-axis) were recorded. Additionally, maximal single-leg vertical jump height (VJH) was assessed on a specific platform. Ankle fatigue was induced through performing the modified Square-hop test until exhaustion. Statistical analysis comprised of 2(Group) x2(Time) ANOVA.
RESULTS: Analysis revealed statistically significant interaction for Time X Group for the COP on the X-axis ($F=4.329$, $p=0.050$) and in the VJH ($F=5.374$, $p=0.031$), while the COP on the Y-axis didn't yield significant differences ($F=0.543$, $p=0.470$). Post-hoc analysis showed that COP-X increased significantly in EG ($p=0.005$) post fatigue, while no change was noticed in CG. Also, EG showed higher COP-X post fatigue values, compared to the CG ($p=0.015$), while there were no statistically significant pre-fatigue differences. Post-hoc analysis for VJH showed that both groups (EG & CG) had a significant decrease in VJH after the fatigue protocol in addition to the baseline values (EG: $p=0.001$, CG: $p=0.000$). For the same parameter (VJH), both in the pre-and post-fatigue stages the EG performed worse than the CG ($p=0.000$ & $p=0.003$ respectively).
CONCLUSION: Fatigue induced after repeated multidirectional jumps performed on a standardized manner, caused significant balance and VJH impairments in patients with a history of lateral ankle sprain. The more dynamic activity (VJH) was mostly affected, while the less dynamic balance performance, was affected only on the mediolateral axis. Additionally, the VJH exposed significant baseline difference between groups, while balance deteriorated only post-fatigue. While functionally assessing patients after ankle-ligament injury, performance under fatigue appears to reveal otherwise possibly concealed deficits, potentially influencing susceptibility for re-injury.

QUADRICEPS MUSCLE SIZE AND KNEE FUNCTION IN LONG TERM AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

HARPUT, G., DEMIRCI, S., SOYLU, A.R., BAYRAKCI-TUNAY, V.

HACETTEPE UNIVERSITY

INTRODUCTION: Persistent quadriceps weakness and atrophy following anterior cruciate ligament reconstruction (ACLR) has been shown to be related with decreased functional performance and poor self-reported knee function (1-3). However, it is not clear if quadriceps muscle size and function remain altered in long term after ACLR. The aim of this study was to determine if individuals with a history of ACLR had quadriceps muscle atrophy, asymmetry in knee function and lower self-reported knee scores at least 5 years after ACLR

METHODS: Eleven individuals who had undergone ACLR (age = 23.7 ± 3.4 years, time since ACLR = 61.2 ± 0.3 months) and 11 healthy individuals (age=23.5 ±2.4 years) were included in this study. Individuals with ACLR were matched to controls by age and lower-limb dominance. Real-time ultrasound (US) was used to measure vastus medialis obliquus (VMO) vastus medialis (VM), rectus femoris (RF) and vastus lateralis (VL) thickness. Limb symmetry index (LSI) was calculated to evaluate isokinetic quadriceps strength and single leg hop (SLH) performance. Self-reported knee function scores including "International Knee Documentation Committee" (IKDC) score and "Knee Injury and Osteoarthritis Outcome Score" (KOOS) subscores were also evaluated. Student t test was performed for statistical analysis
RESULTS: VMO and VL thicknesses were smaller in reconstructed limb compared to healthy limb of the ACLR group (p=0.04, p=0.001, respectively). When compared to healthy controls, quadriceps thickness was not found different (p>0.05). LSI outcomes for concentric quadriceps strength (mean±SD, ACLR: 98%±14.7, Healthy: 100.2%±8.8) and SLH (mean±SD, ACLR: 101%±7, Healthy: 101.5%±3.66) were not different between groups (p>0.05). The IKDC score and KOOS subscores were lower in ACLR group compared to control group (p=0.008, p<0.05).
CONCLUSION: Although individuals with ACLR had lower self-reported knee function score, they demonstrated symmetrical quadriceps strength and hop performance. Thus, smaller VMO and VL thickness in the reconstructed limb may not be related to physical scores but it may have an effect on self-reported knee function.

THE EFFICACY OF CONTRALATERAL MUSCLE REHABILITATION EXERCISE ON QUADRICEPS PERFORMANCE FOLLOWING ANTERIOR CRUCIATE LIGAMENT (ACL) RECONSTRUCTION

MINSHULL, C., GALLACHER, P., ROBERTS, S., BARNETT, A., BAILEY, A.
RJAH ORTHOPAEDIC HOSPITAL

INTRODUCTION: ACL reconstructive surgery results in significant decreases in muscle performance and an asymmetry of quadriceps peak force (QPF) that may persist for several years (Goleker et al. 2014). The cross-education (CE) phenomenon describes the strength gain in the opposite (contralateral), untrained limb following unilateral contralateral resistance training. Despite its potential utility in rehabilitating unilateral injuries, only recently has it been investigated orthopaedic populations, yielding equivocal results. The aim of this study was to investigate the effects of CE on QPF and rate of force development (RFD) following ACL reconstruction surgery.
METHODS: 44 patients (n = 18 female; age: 31.8 +/- 9.7yrs) electing to undergo unilateral ACL reconstruction surgery were randomly allocated to one of two groups: CE (n = 22 contralateral limb strength training), or a CONTROL (CON n = 22, time-matched bilateral upper limb flexibility programme). Both groups followed the same standardised ACL rehabilitation plus 8 weeks of CE or CON that commenced 2-weeks post surgery. CE comprised of 3 sets 3-5 repetitions maximum of knee extension, knee flexion and leg press resistance exercises, 3 times per week. CON comprised of 5 static upper limb stretches (3 x 20 sec, 3 times per week). Isometric QPF and RFD were assessed prior to and 10-weeks following surgery, at a functional joint angle of 30 degrees knee flexion.
RESULTS: ACL reconstructive surgery resulted in a significant reduction in QPF of the injured limb from pre- to 10-weeks post-surgery, but that was significantly attenuated in the CE (16.6%) vs. the CON group (32%) (p<0.05). RFD (0-150ms) declined by approximately 28% in both groups, however, early phase RFD (0-50ms) was significantly preserved in the CE (4% decrease) vs. the CON group (46.2%) (p<0.05).
CONCLUSION: These data show that a period of post-operative strength training in the non-operative limb attenuated the acute decline in quadriceps neuromuscular performance in the operative limb at 10-weeks post-surgery and adds to the evidence that CE should be incorporated into early phase ACL rehabilitation (Harput et al. 2018). Data at 24-weeks post-surgery will reveal if these differences remained and whether or not CE conferred an accelerated recovery.

EXTERNAL TRAINING-LOAD PRIOR TO MUSCLE, TENDON AND LIGAMENT INJURIES IN A LARGE COHORT OF PROFESSIONAL SOCCER PLAYERS.

ENRIGHT, K., MALONE, J.J.
LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Studies investigating the relationship between training-load and non-contact injury have typically used a range of methods to calculate the acute:chronic ratio (1, 2) and combined all non-contact injury 'types' together. Considering that muscle, tendon and ligament, have unique mechanical intensity thresholds that initiate distinct temporal responses, (3) it is possible that each injury could have a specific loading 'signature' prior to each injury. The aim of the present study was to assess if cumulative 1-, 2-, 3-, 4- weekly loads, coupled (C), uncoupled (UC) or exponentially weight moving average (EWMA) acute:chronic ratios (ACR) could differentiate between different types of non-contact injuries in a large cohort of professional soccer players.
METHODS: Twenty-eight days of retrospective training data prior to 264 non-contact injuries (n=124 used in the final analysis) were retrospectively collected for 192 professional football players. Injury type (muscle, tendon, ligament) were categorized by medical staff. Training data were recorded using global positioning system (GPS) devices (Optimeye S5, Catapult Sports, Melbourne, Australia). Cumulative 1-, 2-, 3-, 4- weekly loads, C, UC and EWMA 1:3 and 1:4 ACRs were calculated for total distance (TD), high intensity distance (HI; >5.5 m/s-1) and sprint distance (SPD; >7.0 m/s-1) and compared using a one-way ANOVA.
RESULTS: There were no differences in cumulative 1-, 2-, 3-, 4- weekly loads between muscle, ligament and tendon injuries (P>0.05). There were no differences in any ACR for TD, HI or SPD ACRs between muscle, ligament and tendon injuries; (P>0.05) (1:4 ACR [C] TD; 1.09±0.37, 1.09±0.41, 1.05±0.36); (1:4 ACR [C] HI; 1.04±0.50, 1.12±0.34, 1.10±0.48); (1:4 ACR [C] SD; 1.14±0.77, 1.24±0.76, 1.06±0.65); (1:3 ACR [C] TD; 1.08±0.32, 1.12±0.31, 1.03±0.31); (1:3 ACR [C] HI; 1.04±0.47, 1.13±0.27, 1.09±0.44), (1:3 ACR [C] SD; 1.15±0.71, 1.24±0.69, 1.02±0.59); (1:4 ACR [UC] TD; 0.58±0.66, 0.58±0.54, 0.52±0.30); (1:4 ACR [UC] HI; 0.87±1.35, 0.58±0.35, 0.59±0.48); (1:4 ACR [UC] SD; 1.56±1.5, 0.90±1.14, 0.62±0.53); (1:3 ACR [UC] TD; 0.97±0.71,1.05±0.89, 0.98±0.81); (1:3 ACR [UC] HI; 1.34±1.41, 1.07±0.62, 1.34±2.17), (1:3 ACR [UC] SD; 2.97±1.86, 3.19±3.47, 1.56±1.37).
CONCLUSION: An increasing number of practitioners and researchers have adopted the ACR approach to quantify training in recent years. The present study suggests that the ability of cumulative, coupled, uncoupled and EWMA external load (TD, HI & SPR) ACRs to differentiate between injury type is poor. There is a need for larger studies to explore a range of internal/external training load metrics

and other training information; (e.g., resistance training, sequence of training, recovery time between sessions, athlete 'wellness', and sleep data) whilst controlling for other modifiable/non-modifiable injury risk factors.

SCAPULAR 3D KINEMATICS DURING FUNCTIONAL SPIRAL-DIAGONAL ARM MOVEMENT. CLINICAL IMPLICATIONS ON SHOULDER REHABILITATION OF THE OVERHEAD ATHLETE

PASCOAL, A.1, MORAIS, N.2, CRUZ, J.2, VILAS-BOAS, J.3

[1] UNIVERSITY OF LISBON, PORTUGAL; [2] POLYTECHNIC INSTITUTE OF LEIRIA, PORTUGAL; [4] UNIVERSITY OF PORTO, PORTUGAL

INTRODUCTION: In the late-stage of the athlete's shoulder rehabilitation, therapeutic exercise should simulate the dominant upper limb motion pattern (1). Two categories of movements are often used with and without load: arm elevation and a spiral-diagonal movement associated with proprioceptive neuromuscular facilitation (PNF). Scapular contribution during arm elevation is well known. However, information is scarce about scapular motion during PNF pattern and the use of elastic progressive resistance. Thus, this study describes the scapular 3D kinematics during a spiral-diagonal arm movement with and without load (elastic resistance). The upper limb diagonal motion include diagonal-to-flexion (D2F) and diagonal-to-extension (D2E). The D2F involve a combination of arm flexion, abduction, and external rotation, while D2E combine extension, adduction, and internal rotation.
METHODS: Shoulder kinematics of male volleyball players were recorded using an electromagnetic tracking system (Polhemus Fastrak), following a standardized protocol (2). In a sitting position, athletes performed, with their dominant arm and a self-paced rhythm, 5 repetitions of D2F unloaded, D2F loaded (self-select elastic resistance; TheraBand tube) and D2E unloaded phase (arm elevation; eccentric phase; favor to the elastic resistance). Shoulder kinematics were analyse in consecutive increments of 15 degrees, between 15 to 90 degrees of humerothoracic (HT) elevation. Repetitions were averaged for analysis. Two-way repeated measures ANOVA with interaction was conducted to assess the effects of HT elevation intervals, and (un)loaded conditions on humeral elevation plane and axial rotation, and scapular upward/downward rotation, internal/external rotation and anterior/posterior tilting. Alpha was set to 0.05.
RESULTS: Preliminary results are yielded from 10 elite volleyball players (mean[SD] age=23.0[4.4]yrs, height=1.9[0.1]m, body mass=84.8[8.9]kg, BMI=23.7[2.4] kg/m2). Only the phase of arm elevation (PNF D2F) was analysed. Overall, from 15 to 90 degrees of HT elevation, arm moved from sagittal-flexion to frontal-abduction plane (mean[SE]; degrees; 56.8[7.1]) and rotated externally (17.9[4.8]). Scapula moved to upward rotation (20.3[1.6]), external rotation (16.6[3.0]), and posterior tilting (6.8[1.7]). Main effects of interval were found for all dependent variables ($P<0.004$). Differences between both loaded conditions ($P<0.006$) were found for arm elevation plane and arm axial rotation and scapular upward. Interaction effects ($P=0.001$) were observed in humeral axial rotation, at 15 and 30 degrees of HT elevation and between loaded conditions.
CONCLUSION: In PNF D2F pattern, a combination of arm flexion, abduction, and external rotation, the scapula move to upward rotation, external rotation and posterior tilting. The direction of elastic resistance significantly alter shoulder kinematics, which should be considered in the future.

IS-PM11 Reasons and remedies for the age-related decline in skeletal muscle adaptability

PHYSIOLOGICAL CONTRIBUTORS TO BLUNTED HYPERTROPHIC RESPONSES TO RESISTANCE EXERCISE TRAINING

PHILLIPS, B.E.

UNIVERSITY OF NOTTINGHAM

The mechanisms driving skeletal muscle atrophy and dysfunction with ageing have been the subject of intense study, with a number of suggested factors, including physical inactivity and more intrinsic factors of ageing, such as epigenetic changes, oxidative stress, inflammation, DNA damage, and mitochondrial dysfunction. However, one known major driver of age-related muscle atrophy is so-called "anabolic resistance"; the phenomena whereby the main signals (namely amino acids (AA) and resistance exercise training (RET)) that maintain muscle protein metabolic homeostasis and therefore muscle mass, irrespective of age, become dysregulated.
Despite this dysregulation, RET arguably remains the most potent non-pharmacological anabolic stimulus for skeletal muscle and has been shown to enhance muscle mass and function in healthy younger, aged, and cachectic populations. Nonetheless, when looking at comparative gains in muscle mass following an allied program of supervised RET, hypertrophic responses are typically blunted in older (vs. younger) individuals, likely attributable to long-term reductions in muscle protein synthetic responses to both nutrition and exercise.
Based on studies utilising assorted tracer methodologies and novel imaging techniques, this talk will explore: i) the concept of anabolic resistance to both nutrition and resistance exercise in older adults; including the temporal assessment of 'chronic' age-related anabolic resistance to RET; ii) the point in the life-course at which the diminution in the capacity for muscle hypertrophy (and other positive physiological adaptations) in response to RET manifests, and iii) the role of muscle microvascular blood flow in muscle protein synthetic responses. The impact of certain age-associated conditions on muscle adaptive capacity will also be discussed.
Given the ageing demographic across Europe, and the known link between low muscle mass and poor health outcomes, this work has relevance for future research to further explore the mechanistic basis of age-associated muscle loss and for the development of appropriate exercise regimes specifically for older adults, thus being relevant to academics, clinicians and allied health professionals.

UNDERSTANDING INJURIES LINKED TO RUNNING IN DIFFERENT POPULATIONS

DIXON, S.

UNIVERSITY OF EXETER

INTRODUCTION: Running is fundamental to many sporting activities, with both training and competition frequently involving large volumes of running activity. Running is also a key component of military training. Aspects of individual running style, such as impact loading and lower limb movement, have been associated with injury risk (1). These intrinsic risk factors are likely to be both injury- and population-specific. The aim of this work has been to identify biomechanical risk factors for lower limb overuse injury in populations undergoing repetitive activities that involve running.
METHODS: Studies have involved the collection of biomechanical measures for two different populations where running is a key element of training – military recruits and a rugby union squad. Biomechanical assessment has been performed at the start of a training/playing period to provide baseline, uninjured data for both populations (1065 military recruits and 86 rugby players). Biomechanical measures have included synchronised lower limb kinematics and force plate data, allowing estimation of lower limb joint moments. Barefoot pressure data have also been collected. Injury status has then been tracked during training with a specific focus on lower limb stress fractures for the military population and on Achilles tendinopathy for rugby players. Logistic regression models have been used to identify significant predictors of injury risk.
RESULTS: For military recruits, biomechanical measures associated with tibial stress fracture have included high magnitude of heel loading and restricted internal tibial rotation. Second metatarsal stress fractures have been associated with low dynamic arch index (high arch) and low foot abduction, and third metatarsal stress fractures with delayed forefoot loading. For rugby players, low propulsive force and low ankle plantar-flexor moment have been identified as risk factors for Achilles tendinopathy.
CONCLUSION: Prospective studies involving the collection of biomechanical data at the start of a training period can be used to identify risk factors for injury. These results are being used to inform the development of interventions aiming to reduce the likelihood of injury.

PRIMING ELDERLY SKELETAL MUSCLE FOR HEAVY RESISTANCE TRAINING

MACKEY, A., KARLSEN, A.

UNIVERSITY OF COPENHAGEN AND BISPEBJERG HOSPITAL

The content of this last talk will be focused on potential ways in which the skeletal muscle of elderly individuals can be preconditioned, or primed, prior to commencing a heavy resistance training program in order to improve the gains in muscle mass and strength. Examples from our group will include mechanical stimuli to induce regeneration as well as pharmacological interventions. We have shown that the process of myogenesis after necrosis leads to renewal of the satellite cell pool and a complete rebuilding of the satellite cell niche (Mackey & Kjaer, 2017). It is possible that this forced activation of satellite cells, and other cells influencing their activity (Mackey et al., 2017), could accelerate tissue adaptation to heavy loading. In addition, the potential of the blood pressure lowering medication losartan to enhance hypertrophy with training will be considered (Heisterberg et al., 2018a; Heisterberg et al., 2018b). The relevance of this approach is the poorer ability of elderly muscle to mount a hypertrophy response, as outlined by the first speaker, Bethan Phillips, and the

need to address this in order to ameliorate the development of sarcopenia and improve the quality of life of ageing individuals, in particular during the last 12-15 years of life where disability presents itself. The target audience is exercise physiologists, as well as those working with this population in a clinical context.

OP-PM42 Nutrition: Other supplements

THE EFFECT OF CAFFEINE SUPPLEMENTATION ON SUBSEQUENT SLEEP QUALITY IN SUB-ELITE RUGBY LEAGUE PLAYERS

DASCOMBE, B.J.1, GARDINER, N.2, THORNTON, H.R.3, DUNCAN, M.J.1
(1) UNIVERSITY OF NEWCASTLE, (2) QUEENSLAND UNIVERSITY OF TECHNOLOGY, (3) GOLD COAST SUNS FOOTBALL CLUB

INTRODUCTION: The use of caffeine supplementation may disturb sleep in athletes, which may negatively impact on recovery processes following training and/or competition. However, the majority of data has focused on the use of caffeine around competition performance despite athletes commonly using such stimulants to improve their training response. The present study aimed to determine whether low- or high-dose caffeine supplementation prior to training affected subsequent sleep quality in well-trained rugby league athletes.
METHODS: Eleven male athletes (18.8±0.8 yr; 183±8 cm; 93.2±12.1 kg) were supplemented with anhydrous caffeine [low-dose: 3mg·kg-1 (CAF3); high-dose: 6mg·kg-1 (CAF6)] or placebo (PLA) 60 minutes prior to afternoon training in a randomised cross-over design. Internal and external training responses were monitored via GPS, HR and s-RPE. Sleep quality was evaluated using wrist actigraphy and the Leeds Sleep Evaluation Questionnaire. Sleep and wellness measures were recorded for baseline (BL), the night of intervention (INT) and the night following intervention (INT+1). Factorial Analysis of Variance Analysis was used to determine the effect of caffeine dose on measures of sleep quality. Cohens Effect Size analysis were also employed to determine practical changes within and between conditions.
RESULTS: No significant effects of caffeine dosage were observed for athlete wellness or internal and external training responses ($P > 0.05$). Following supplementation (INT), CAF6 resulted in a decreased sleep efficiency compared to CAF3 (d = -1.55, 90% CI [-1.52, -0.06]) as well as better awakening from sleep than PLA (d = 0.98, 90% CI [0.18, 1.65]). CAF3 resulted in a significantly shorter time in bed than either the PLA (d = -0.81, 90% CI [-1.68, -0.20]) or CAF6 (d = 0.76, 90% CI [0.06, 1.52]) conditions at INT+1, despite no differences in total sleep duration ($P>0.05$). Significant ($P < 0.05$) decreases were observed in sleep efficiency in all conditions at INT compared to baseline.
CONCLUSION: This data demonstrates that a high-dose caffeine supplementation protocol reduced self-reported quality of sleep in sub-elite rugby league players. This suggests that the higher dose of caffeine might not be fully metabolised prior to the athletes going to bed. Low-dose supplementation did not significantly affect any measures of sleep quality. As such, athletes should consider whether a higher dose of caffeine provides further performance benefits that outweighs the negative impact on measures of sleep quality. Sleep efficiency was reduced in all conditions at INT, supporting previous research that has reported negative effects of high-intensity exercise on sleep quality, regardless of stimulant use. The results suggest that a low-caffeine dosage of 3mg·kg-1 may be employed as an ergogenic aid without negatively impacting on sleep-facilitated recovery.

SODIUM CITRATE INGESTION PROTOCOL IMPACTS INDUCED ALKALOSIS, GASTROINTESTINAL SYMPTOMS AND PALATABILITY.

URWIN, C.S., SNOW, R.J., ORELLANA, L., CONDO, D., WADLEY, G.D., CARR, A.J.
DEAKIN UNIVERSITY, VICTORIA, AUSTRALIA

INTRODUCTION: Sodium citrate ingestion induces alkalosis (1), although performance outcomes have been equivocal to date (2), potentially due to variation in ingestion protocols used across previous studies. Identifying an ingestion protocol which induces alkalosis, minimises gastrointestinal (GI) symptoms, and has high palatability may increase the likelihood of benefit to athletes' performance. The primary aim of this study was to compare a) physiological responses (peak [HCO3-]), b) GI symptoms (rating) and c) palatability of sodium citrate (rating) when ingested using two different protocols.
METHODS: Using a repeated-measures, cross-over design, 24 healthy and active male (n = 13) and female (n = 11) participants completed two testing sessions, with sodium citrate ingested using two different protocols (500 mg.kg-1 body mass ingested via capsules or solution). Capillary blood sampling was used to determine [HCO3-] every 30-min for 240-min post-ingestion. A validated questionnaire quantified GI symptoms at 30-min intervals (3). Palatability was assessed immediately after ingestion using a validated scale (4). Linear mixed models were fitted to compare the two conditions.
RESULTS: Following sodium citrate capsule ingestion, peak [HCO3-] (mean ± SD) was 30.6 ± 2.1 mmol.L-1; significantly higher ($p = 0.0003$) than after solution ingestion (28.9 ± 2.4 mmol.L-1). Peak [HCO3-] occurred 205.0 ± 35.0 min after capsule ingestion, which was significantly later ($p = 0.0029$) than after solution (162.5 ± 46.7 min). GI symptoms rating did not differ between ingestion modes across the overall session ($p = 0.6439$) or any individual time point (all $p > 0.05$). GI symptoms were minor (rating of 5.8 and 5.2 out of a possible 360 for capsules and solution), and symptoms returned to baseline levels 150-min post-ingestion. There was a higher palatability in the capsule treatment compared with solution ($p < 0.0001$).
CONCLUSION: When comparing two sodium citrate ingestion protocols, there was greater induced alkalosis following capsule ingestion compared with a dose-matched solution. Sodium citrate ingestion via capsules may facilitate improved passage from the stomach to the intestine due to slowed capsule digestion times (5) compared with solution, allowing a greater proportion of ingested sodium and citrate ions to enter the circulation and increase blood alkalosis (5, 6). While GI symptoms were observed in both conditions, these were minor and returned to baseline levels before peak alkalosis occurred. Further, capsules were more palatable than solution. Therefore, we

recommend that athletes ingest 500 mg.kg-1 sodium citrate in capsules at least 3 hours pre-exercise, in order to reach peak alkalotic state, while avoiding GI discomfort at the commencement of exercise.

THE USE OF DIETARY SUPPLEMENTS AMONG ELITE FEMALE SOCCER PLAYERS: A SURVEY OF CURRENT PRACTICES

ABREU, R., TEIXEIRA, V.H., RAGO, V., SOUSA, M., FIGUEIREDO, P., BRITO, J.
FPF- PORTUGUESE FOOTBALL FEDERATION

INTRODUCTION: Women's soccer fixtures have grown exponentially over the last years [1]. Consequently, both athletes and teams search for tools and strategies to maximize performance and accelerate recovery. In this context, dietary supplements (DS) are commonly adopted to enhance health condition, performance and recovery. Dietary supplements should only be used after a food-first approach and guaranteeing evidence-based good practices, considering proved physiological effects for each nutrient, respective dosage and usage conditions. Besides, the use of DS in sports also raises questions regarding safety, namely avoiding over-ingestion of nutrients and inadvertent doping [2]. However, the current nutritional practices adopted by elite female soccer players are unknown. This study aimed to investigate the use of DS in elite female soccer players.
METHODS: The survey was conducted during an official international tournament (Algarve Cup 2018). Overall, 112 female elite adult soccer players from 6 National teams accepted to participate in the study. The players fulfilled a questionnaire regarding the DS they were using during the last 12 months. Generally, the questionnaire focused on how players were using supplements, endorsement for use and own motivations. Data regarding training and match/training frequencies were also collected to understand patterns of DS use. The use of DS was quantified using frequency analysis.
RESULTS: The majority (79%) of the inquired players reported ingesting at least one type of DS. Among players using supplements, 79% revealed to take more than one substance, with players reported using up to 21 different DS over the last year. Moreover, all players (100%) aged >29 years reported using DS. The most frequent supplements among the inquired female soccer players were vitamin D (51%), omega 3 (48%) and protein (45%), which included whey protein and casein. The major reasons mentioned for nutritional supplementation were to "keep healthy" (64%), "accelerate recovery" (58%), and "reduce fatigue" (53%). Among motives for not using DS, "risk of positive doping test" was the major reason (36%). Medical doctors (46%) and nutritionists (44%) were referred as the main endorsers for using DS.
CONCLUSION: The current self-reported survey showed that nearly 4 out of 5 elite female soccer players report using DS. As health-related professionals were reported as the main endorsers, and considering concerns about effectivity, cost and safety, it should be questioned whether balanced diets and a food-first approach are being properly promoted/adopted, in order to prevent widespread, unnecessary use of DS.

BEET ON ALPS: EFFECTS OF DIETARY NITRATE SUPPLEMENTATION ON SKELETAL MUSCLE FRACTIONAL O2 EXTRACTION DURING SUBMAXIMAL EXERCISE IN HYPOBARIC HYPOXIA

RASICA, L., MARZORATI, M., BIANCHI, G.A.D., GELMINI, F., BERETTA, G., PORCELLI, S.
INSTITUTE OF BIOIMAGING AND MOLECULAR PHYSIOLOGY

INTRODUCTION: Dietary NO3- supplementation potentiates NO3- -NO2- -NO pathway and, particularly in low O2 environments, may lead to an increased skeletal muscle blood flow, an improved vascular conductance and a reduced O2 consumption during exercise. Skeletal muscle deoxygenation ([deoxy(Hb+Mb)]) measured by near-infrared spectroscopy (NIRS) is considered to provide an index of fractional O2 extraction and hence to reflect the dynamic balance between muscle O2 delivery and O2 consumption within myocytes and microvessels.
This study aimed to investigate the effects of dietary NO3- supplementation on muscle fractional O2 extraction measured by NIRS during submaximal exercise in hypobaric hypoxia. Data collected during exercise performed with lower or upper limbs were compared in order to discriminate potential effects of NO3- supplementation on muscles with different structural and functional characteristics.
METHODS: Fourteen subjects (28±6 yrs) participated in a double-blind randomized crossover study carried out at Casati Hut (3269m a.s.l). Following 5 days of acclimatization, an incremental exercise test was carried out in order to assess V'O2peak and gas exchange threshold (GET) by cycle- and arm-ergometers. Then, each subject was supplemented for 3 days either with beetroot juice (2x70mL/day, 8.4mmol NO3-/day [BR]) or placebo [PLA]. At the end of each supplementation period, subjects exercised at two different intensities: an 8 min moderate-intensity (80% of GET) constant work rate (MOD) and a severe-intensity (50% of the difference between V'O2peak and GET) constant work rate exercise up to exhaustion (SEVERE). Resting plasma [NO3-] and [NO2-] were measured by chemiluminescence before and after both supplementation periods. V'O2, V'CO2 and V'E were measured breath-by-breath. NIRS probe was placed on vastus lateralis and triceps muscles during cycling and arm cranking, respectively.
RESULTS: After BR, [NO3-] and [NO2-] were significantly higher compared to PLA (314.7±148.3 vs 27.0±17.3 μM, $p<0.001$ and 966.5±386.4 vs 678.4±343.9 nM, $p<0.01$). In MOD, BR (vs PLA) significantly decreased oxygen cost of exercise (about 4%) and increased Δ[deoxy(Hb+Mb)] in both cycling (43±8 vs 29±6%) and arm cranking (36±5 vs 30±9%). In SEVERE, BR did not affect V'O2 and Δ[deoxy(Hb+Mb)] at the end of both cycling and arm-cranking exercises, but time to exhaustion significantly improved (+9% for cycling and +23% for arm-cranking). V'O2 slow component amplitude was significantly lower in BR (about 20%) vs PLA (about 25%). After 6 min of exercise, Δ[deoxy(Hb+Mb)] was higher in BR vs PLA for both cycling (63±6 vs. 53±7%) and arm-cranking (70±6 vs. 56±8%).
CONCLUSION: This study shows that in hypobaric hypoxia dietary nitrate supplementation positively affects skeletal muscle fractional O2 extraction measured by NIRS during submaximal exercise. These changes were associated with a reduced oxygen cost during moderate-intensity exercise and an improved exercise tolerance during severe-intensity exercise.

CATECHIN-RICH GREEN TEA INTAKE REDUCES EXERCISE-INDUCED BLOOD PRESSURE ELEVATION AND ENHANCES EXECUTIVE FUNCTION

TSUKAMOTO, H.1,2,3, HATTORI, T.1, HASHIMOTO, T.1

1 RITSUMEIKAN UNIVERSITY, 2 UNIVERSITY OF SOUTH WALES, 3 JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE

INTRODUCTION: Our recent study demonstrated that improvement of executive function (EF) after exercise could be enhanced by high cocoa flavanol consumption [1]. Whereas catechin is also classified as a "flavanol" [2], the impact of a combination of catechin-rich green tea (CGT) and aerobic exercise on cognitive function remains unknown. Meanwhile, blood pressure is increased during exercise and it relates the risk of cardiovascular event [3]. It has been established that a habit of CGT intake as antioxidant supplementation reduces blood pressure, perhaps due to increasing systemic nitric oxide via decreased oxidative stress [4]. Thus, we hypothesized that a CGT would not only enhance exercise-induced EF improvement but would also attenuate blood pressure elevation during exercise. To address these hypotheses, we aimed to examine cognitive function and blood pressure in response to aerobic exercise following intake of CGT.
METHODS: Eleven young healthy male volunteers (22 ± 2 yrs) were randomized to receive a CGT (catechin 600 mg) and a placebo green tea beverage (both 750 ml, ITO EN, Japan) 1 h before exercise in a single blind counterbalanced manner. The participants performed cycle ergometer exercise at 60 % VO2 peak for 30 min. Blood pressure was measured at each time point (Pre-intake, Pre-exercise, End of exercise, Post exercise 1 h) by using mercury manometer. Cognitive function was assessed by using Face-name matching (short memory) and Color-word Stroop tasks (EF) after blood pressure measurement.
RESULTS: Exercise-induced mean arterial pressure elevation was attenuated by CGT consumption ($P < 0.01$, CGT vs. placebo). EF 1 h after exercise in CGT intake trial was better than placebo beverage intake trial ($P < 0.05$), but not in terms of short memory.
CONCLUSION: These results demonstrated that CGT intake 1 h before exercise can not only enhance exercise-induced EF improvement but also reduce blood pressure elevation. These findings may support that catechin works to improve cognitive performance during sports, to maintain brain-related health, and to prevent cardiovascular event.

EFFECTS OF SALVIA MILTIORRHIZA EXTRACT SUPPLEMENTATION ON CARDIAC BIOMARKERS AFTER HIGH INTENSITY INTERVAL EXERCISE.

FANG, C.C.1,2, LIN, S.C.2, CHIU, B.K.2, CHEN, Y.A.2, CHAN, K.H.2

1: NATIONAL TAIPEI UNIVERSITY OF BUSINESS, 2: NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Studies indicated high intensity interval exercise (HIIE) elevated of serum cardiac troponin (cTnI), pro-brain natriuretic peptide (NT-porBNP) and ischemia-modified albumin (IMA), which were accepted biomarkers for the identification of cardiac damage (Li et al., 2016). As herbal supplementation, the Chinese medicine of Danshen (Salvia miltiorrhiza) was adopted for treating cardiovascular disease and potentially provided myocardial protection (Wu et al., 2008). Therefore, the aim of this study was to examine the effects of Salvia miltiorrhiza extract (SME) supplementation on cardiac biomarkers after acute HIIE. We hypothesized that SME supplementation would reduce the releasing of cardiac biomarkers after HIIE.
METHODS: Twenty-four female basketball players (aged 18-23 years) were recruited into the study. Subjects were divided into SME or placebo (PLA) groups according to their maximal oxygen uptake (VO2max), and then consumed 3 g of SME (equal to 12 g raw herbal of Salvia miltiorrhiza) or lactose per day for eight weeks.
Subjects performed the HIIE tests with sixteen 2-min running bouts at the velocity of 90% VO2max separated by 2-min rest periods before (Pre) supplementation, at the 4th-week (Mid), and 8th-week (Post) after the supplementation. Blood samples were drawn before, immediately after and at 4-hour after HIIE to assay the concentrations of cTnI, NT-porBNP and IMA. The cutoff values of cTnI and NT-proBNP for acute myocardial injury are over 40 pg/mL and 125 pg/mL, respectively.
RESULTS: The result showed that some athletes revealed positive response of cTnI and NT-proBNP at 4-hour after HIIE. In PLA group, 33.3%, 25% and 33.3% athletes presented positive cTnI at Pre, Mid, and Post of the supplementation. Moreover, 16.7% athletes exposed positive NT-proBNP at the three supplementation time periods. However, only 33.3% and 16.7% athletes presented positive cTnI and NT-proBNP before the supplementation in SEM group. No athlete displayed positive response of cTnI and NT-proBNP after SEM supplementation. There were no significant differences in IMA between SME and PLA groups or among the supplementation time periods.
CONCLUSION: In support of hypothesis, this study indicated that 4 weeks and 8 weeks of SEM supplementation ameliorate the releasing of cTnI and NT-proBNP after HIIE. Therefore, Salvia miltiorrhiza extract supplementation for more than 4 weeks could exert protective effects on the myocardial dysfunction induced by acute HIIE.

THE EXPERIMENTAL STUDIES ON THE LATEST REFORMS FOR TABLE TENNIS

XIAO, D.

CHINA INSTITUTE OF SPORT SCIENCE

Three experimental studies on the latest reforms for table tennis were carried out by the kinematic test method, questionnaire survey method, tribological test. The first study was the experimental research on the observe effect of the two color table tennis. The second was the experimental study on the influence of the implementation of the plastic table tennis on table tennis velocity, and rotational speed. The third was the study on the change of friction coefficient of the ball and rubber after the implementation of the plastic table tennis. The results showed that (1) The colored ball could improve the ornamental value of the table tennis game; white and orange with black stripes of the ball was the ideal choice. (2) As to the speed and rotational speed of the ball, there was no difference at the moment

after attacking, but decreased significantly after reaching the opponent' table between the celluloid and plastic ball. (3) The friction coefficient of ball and rubber was decreased , the ball rotation was reduced by 3.25% by the use of plastic table tennis.(4) The roughness on the surface of the plastic ball was lower than celluloid.(5) The uniformity on the surface of plastic ball was lower than celluloid ball. The purpose of this study was to provide theoretical basis for table tennis project further reform, at the same time provide the basis for national table tennis team to adapt to the plastic table tennis.

THE EFFECT OF EXERCISE, DIETARY RESTRICTION AND HYPOXIA ON BLOOD LIPID IN OBESE PEOPLE

ZHANG, L.

CHINA INSTITUTE OF SPORT SCIENCE

High blood lipid is a severe risk factor for human health and usually combined with obesity. Dietary Restriction, exercise as well as hypoxia have showed influence on lipid metabolism according to many published papers. From 2006, we have done several experiments on effects of these intervention measures on lipid metabolism in obese rats and obese people. In obese rat experiments we saw both hypoxia and endurance exercise showed good effect by decreasing TG, TC and increasing HDL-C without dietary restriction. However, this effect didn't appear in old male subjects after 1 month of low intensity endurance training or hypoxic endurance training, but significant FFA rising can be seen. While in old people underwent 12 weeks of HIIT training, significant decrease was seen in TG. In other two experiments that combined dietary restriction with aerobic or resistance strength exercise, both TG and TC decreased significantly. In conclusion, exercise, no matter high or low intensity, is easy to influence human blood triglycerides but hard to influence human blood cholesterol. Cholesterol can be changed only when dietary restriction was combined with exercise. It seems that hypoxia exposure can improve the effect of exercise.

THE EFFECT OF EXERCISE AND HYPOXIA ON INSULIN SENSITIVITY

DELA, F.

UNIVERSITY OF COPENHAGEN

Insulin and muscle contraction stimulate glucose transport into muscle cells by separate signalling pathways, and hypoxia has in rat muscle been shown to operate via the contraction-signalling pathway1. A positive effect of hypoxia in stimulating glucose transport has also been demonstrated in insulin resistant human muscle2. This has given the grounds for studying the effect of hypoxia alone or in combination with insulin in patients with insulin resistance, because if exercise is not an option, it has been hypothesized that hypoxia may replace or add to exercise in order to improve insulin sensitivity.
Most studies in humans have been performed in healthy, insulin sensitive individuals, which makes it difficult to extrapolate any effect to insulin resistant patients, e.g. patients with type 2 diabetes. In addition, studies have also been performed at altitude whereby other confounding factors (lower barometric pressure, sympatho-adrenal responses to altitude, acute mountain sickness) makes it difficult to conclude on the isolated effect of hypoxia. But, with altitude hypoxia a transient decrease in whole-body insulin sensitivity occurs which only lasts about one week3. Hepatic insulin sensitivity does not seem to be affected with this exposure3. Studies in patients with type 2 diabetes/insulin resistance4;5 or healthy individuals5 indicates that hypoxia alone in fact decreases insulin sensitivity. Studies combining hypoxia with exercise training have shown opposite results in indices of insulin resistance6;7, and inactivity with or without simultaneous hypoxia results in similar decreases in these indices8.

CHARACTERISING CEREBRAL HAEMODYNAMIC OSCILLATIONS DURING RUNNING

IMI, G., SKINNER, B.D., LUCAS, R.A.I., LUCAS, S.J.E.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: The running gait induces a 'beat phenomenon', identified as a summation of two pressure waves that result in periodic pulse pressure oscillations. The origin of the pressure waves arise from the mechanical impact of the heel strike during running gait, shocking blood vessels and generating a wave that combines with arterial pressure waves from the cardiac cycle. This study aimed to a) examine the effect of changing heel strike force and pattern on cerebral blood flow response profiles during running, and b) compare the response profiles between running and cycling modalities.

METHODS: Ten participants (6 females; age: 27±7 y; VO2peak: 44±6 mL/min/kg) completed three submaximal exercise sessions using a randomised crossover design. Heel strike force was manipulated by the participant performing 10-min bouts of flat (1% gradient; 65% VO2peak), uphill and downhill running on a treadmill (initial gradients of 6% and -6% respectively, with belt speed and gradient adjusted to match 65% VO2peak). Secondly, participants completed 5-min bouts of flat, toe- and heel-weighted running (1% gradient) to manipulate heel strike force, followed by matching cadence to two audio-cue rhythms while performing their normal running style. Finally, participants completed 30 min continuous cycling at 65% VO2peak. Continuous measures of middle cerebral artery velocity (MCAv) were recorded. Oscillation amplitude was determined from the pulsatility index (PI; sMCAv -dMCAv), oscillation frequency was counted across 30 s at 65% VO2peak for gradient running and cycling, and the final 30 s of each running style. The duration of the oscillation cycle (i.e. wavelength) was averaged from the last 3 oscillations of these 30-s periods.
RESULTS: MCAv oscillations were present during each running bout with a variety of oscillatory patterns between participants, gradients, heel strike force and cadence. MCAv oscillation wavelength duration (~7s; p=.61) and frequency (~8; p=.21) were similar between running gradients. Manipulation of running heel strike force elicited similar MCAv oscillation duration (~7s; p=.56) and frequency (~7; p=.76) between flat, toe- and heel-weighted conditions. Alteration of step cadence produced similar MCAv oscillation duration (~6s; p=.39) and frequency (~6; p=.26) across the range of step frequencies tested. No MCAv oscillations were observed during cycling, and PI was significantly lower in cycling when compared to all running gradients (p<.01).
CONCLUSION: Running produces MCAv oscillatory patterns that are absent in cycling. Despite the non-significant differences reported here, observations of the individual MCAv traces show changes in the oscillatory pattern when running style or cadence is altered, especially initially. Such differences in blood flow profile between exercise modalities and oscillatory patterns within running bouts may have implications for mechanical vascular shear forces linked to functional vasculature changes.

VAGAL-RELATED HEART RATE VARIABILITY, BUT NOT ITS CO-EFFICIENT OF VARIATION, INDICATES IMPAIRED EXERCISE PERFORMANCE DURING FUNCTIONAL OVERREACHING

BELLENGER, C.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: Vagal-related heart rate (HR) variability indicates positive (i.e. training leading to improved performance) and negative (i.e. overreaching leading to attenuated performance) training adaptation. Recently, the co-efficient of variation in vagal-related HR variability has also been investigated as a measure of day-to-day fluctuation in parasympathetic modulation, though not in the context of overreaching. This study determined whether the co-efficient of variation in vagal-related HR variability could indicate a state of functional overreaching in endurance athletes.
METHODS: This is a retrospective analysis of 3 separate studies where 3 groups of recreational endurance athletes (2 groups of runners; RUN1 [n=15] and RUN2 [n=11], and 1 group of cyclists; CYC [n=12], for a total n=38) completed daily morning-waking HR assessments during 7 days of light training (LT), 14 days of heavy training (HT) and 10 days of taper (T). Root mean square of successive RR wave differences (RMSSD; analysed as a rolling 7-day average) and the 7-day co-efficient of variation in RMSSD (RMSSD CV) were calculated. Training load was quantified by Training Impulse (TRIMP) and endurance performance was assessed via a 5 km treadmill time-trial in runners and a 5 min time-trial in cyclists (peak HR was also assessed during performance testing). Endurance performance at HT and T were analysed relative to performance at LT to account for the different performance tests.
RESULTS: Data are presented for total n=38 unless specified. TRIMP at HT was greater than at LT (effect size ± 95% CI, 2.82±0.46; p<0.001) and T (3.29±0.54; p<0.001). Performance at HT was lower than at LT (-1.54±0.64; p<0.001) and T (-1.81±0.53; p<0.001). Performance at T was greater than at LT (2.33±0.64; p<0.001). Peak HR at HT was lower than at LT (-0.96±0.16; p<0.001) and T (-0.91±0.17; p<0.001). RMSSD at HT was greater than at LT (0.75±0.28; p<0.001) and T (0.31±0.21; p=0.006). RMSSD at T remained greater than at LT (0.35±0.30; p=0.04). RMSSD CV did not change during the intervention (ES≤0.23±0.36; p≥0.25). In comparison to LT, RMSSD at HT increased in all groups (ES≥0.56±0.47; p≤0.04), but remained increased at T in RUN1 only (0.51±0.30; p=0.05). Similarly, peak HR decreased in all groups at HT compared to LT (ES≤-0.79±0.27; p<0.001), but remained decreased at T in RUN1 only (-0.28±0.24; p=0.02).
CONCLUSION: Increased RMSSD following HT indicates parasympathetic hyperactivity in the fatigued state, potentially contributing to the concurrent decrease in peak HR and impaired performance. Despite changes in RMSSD, RMSSD CV as a measure of day-to-day fluctuation in parasympathetic modulation was unchanged following HT, and thus is not a sensitive measure of training status in the context of functional overreaching. Elevated RMSSD at T (compared to LT) in RUN1, along with the remaining suppression of peak HR at this timepoint, may indicate that this group had not fully recovered following T.

CARDIORESPIRATORY RESPONSE OF PARAMEDICS TO WORKLOAD IN DAY AND NIGHT SHIFTS

FENGER, A.1, WOLLESEN, B.1, STOLL, R.2

1: UNIVERSITY OF HAMBURG; 2: ROSTOCK UNIVERSITY MEDICAL CENTER

INTRODUCTION: Research has indicated that people working in professions such as rescue services are exposed to stress when acting in emergency situations (Karlsson, 2011). Physiological parameters such as heart rate (HR) can be seen as clinical indicators of stress exposure. However, little is known about paramedics' objective workload response, whether the physiological reactivity differs between day and night shifts, and whether there is a need for individual load control. This paper explores the effect of shifts on HR and breathing rate (BR) reactivity by implementing a mobile health system in the natural work environment of paramedics.
METHODS: 24 healthy German paramedics (3 women, 21 men; 34,4 ± 8,9 yrs) participated in this study including a within-subjects design with repeated measures for trial (day or night). Physiological parameters were recorded continuously using a real-time monitoring system based on a sensor electronic module (Hidalgo Ltd., Cambridge) and a touchscreen-based smartphone. Data were analyzed taking into account an entire 12-hour day and night shift and assigned to different work conditions conforming to the activity information given by participants on the smartphones. A two-way ANOVA with repeated measures was performed with SPSS (IBM SPSS 25.0, Armonk, NY).
RESULTS: Comparisons of workload responses revealed that overall HR differed significantly between day and night shifts (82,8 ± 12,0 vs. 71,6 ± 9,2 bpm; $F(1,22) = 891,6$, $p < .001$, $\eta p^2 = .98$) whereas mean HR when being on call (78,7 ± 10,5 vs. 78,1 ± 9,4 bpm; $F(1,23) = 0,16$, $p = .69$) and mean HR during emergencies (90,7 ± 13,2 vs. 87,4 ± 10,9 bpm; $F(1,17) = 1,29$, $p = .27$) did not. BR showed significant differences in overall BR (19,9 ± 2,4 vs. 17,3 ± 2,2 breaths per minute; $F(1,22) = 43,2$, $p < .001$, $\eta p^2 = .66$) and BR during emergencies (22,5 ± 2,5 vs. 21,7 ± 2,1 breaths per minute; $F(1,16) = 5,27$, $p < .05$, $\eta p^2 = .25$), but no differences were found for BR behavior when being on call ($F(1,22) = 3,93$, $p = .06$). Within day shifts more emergency cases occurred (62 vs. 31 call-outs). However, subjective ratings of difficulty of emergencies, assessed subsequent to emergency operations, did not differ between shift types ($\chi^2(3) = 1,55$, $p = .67$).

CONCLUSION: The organization of shift work can influence the amount of circadian disruption which can be responsible for health problems and disease (Nicoletti, 2015). Our results revealed that physiological reactivity differs between day and night shifts. Differences in cardiovascular reactivity may be attributed particularly to the circadian rhythm with a prevalence of sympathetic tone during the day and an increase in parasympathetic tone during the night. We conclude that an individual load control is not necessary if shift systems are implemented that reduce circadian disruption.

ACUTE EFFECTS OF HIGH INTENSITY INTERVAL TRAINING (HIIT) VS. MODERATE INTENSITY CONTINUOUS TRAINING (MICT) ON ARTERIAL STIFFNESS AND WAVE REFLECTION IN YOUNG OBESE WOMEN

LOPES, W.A., HORTMANN, K., LOCATELI, J.C., SIMÕES, C.F., OLIVEIRA, G.H., MENDES, V.H.S., OKAWA, R.T.P.

STATE UNIVERSITY OF MARINGA

INTRODUCTION: Although aerobic exercise seems to exert beneficial effects on arterial stiffness, the responses of HIIT versus CMIT are still sparse and controversial (1). Thus, we investigated the acute effects of HIIT versus MICT on arterial stiffness parameters in young obese women.
METHODS: Fifteen obese women (25.2±4.8 years) underwent high-intensity interval training (HIIT) (85-95% of HRmax), moderate intensity continuous training (MICT)(65-75% of FCmax) and control condition (CON) (rest at sitting position). Carotid-femoral pulse wave velocity (cfPWV) and augmentation index (AIx) were measured at baseline and 1 min, 30 min and 60 min after both conditions. AIx and cfPWV were measured by SphygmoCor Xcel system (AtCor medical, Sydney, Australia). ANOVA for repeated measures was used to analyze of the data.
RESULTS: There was a significant reduction in AIx after HIIT (1, 30 and 60 min from baseline, $p<0.01$) and MICT (60 min from baseline, $p<0,05$). HIIT induced a greater reduction in AIx compared to MICT (Δ=-16% and -6%, $p<0.001$) in 30 and 60 min after the session. CfPWV remained unchanged ($p>0,05$) after exercise in both conditions in young obese women.
CONCLUSION: There is rising evidence that HIIT is an alternative exercise modality capable of providing the same or greater health benefits than moderate-intensity continuous training (MICT) (1). However, the superiority of HIIT in acutely reducing AS is less clear. Hanssen et al. (2) found that HIIT promoted a greater reduction on AIx after the session in comparison with MICT. On the other hand, Siasos et al. (3) did not observe any reduction in carotid-femoral PWV after HIIT or MICT session. Both studies were conducted in men who were apparently healthy. Our study indicates that the HIIT is superior to MICT in reducing wave reflection in young obese women.

CARDIOVASCULAR PHYSIOLOGY FOLLOWING REPEATED MAXIMAL EXERCISE IN MYALGIC ENCEPHALOMYELITIS

HODGES, L.

MASSEY UNIVERSITY

INTRODUCTION: Unlike other chronic conditions, fatigue becomes exacerbated with physical activity in those with ME. Peak oxygen consumption a measure of cardiorespiratory fitness has been identified as a potential method for objectively assessing the clinical status of ME/CFS. However, findings in comparison to healthy controls have been inconsistent. As VO2 is a byproduct of cardiac output and arteriovenous difference, cardiovascular indices may provide better objective measures for this group.
Aims: The purpose of the study was to examine the effects of 24 hour repeated exercise on measures of cardiovascular physiology on individuals with Myalgic Encephalomyelitis compared with healthy controls.
METHODS: We recruited 7 individuals with ME/CFS and 6 Healthy controls. Individuals with ME/CFS were included if they met the diagnostic criteria of, the Fukuda case definition (Fukuda et al., 1994), the Canadian Consensus Criteria (2003) and the International Consensus Criteria (2011). Peak oxygen consumption (VO2peak) was assessed using an incremental cycle ergometer exercise test. Following a 40-minute recovery period, peak cardiac output (QT) was measures during a constant load test that elicited VO2 peak (• 5%) using the Defares CO2 rebreathing technique. Peak cardiac power output (CPOpeak) was calculated as described by (Cooke et al., 1998). Exercise testing was repeated 24 hours later and all variables were remeasured
RESULTS: Despite fitness being poor amongst both the healthy control and ME group, there was a moderate to large difference in cardiac output (0.5), stroke volume (0.7), cardiac power output (0.7) and cardiac index (0.9). This was further enhanced 24 hours later following repeated exercise testing and was despite a small difference in between groups in VO2peak (0.4).
CONCLUSION: Myalgic Encephalomyelitis have significantly impaired cardiovascular response to exercise. Peak oxygen consumption demonstrates a small change in fitness levels between those with ME compared with those who are healthy controls. However cardiac indices show a greater difference between the two groups. Therefore it would be better to measure and report cardiac indices in individuals with ME. These values may be able to objectively assess the clinical status within this group.

EFFECTS OF ISOMETRIC RESISTANCE TRAINING AND DETRAINING ON AMBULATORY BLOOD PRESSURE AND MORNING BLOOD PRESSURE SURGE IN YOUNG NORMOTENSIVES

BAROSS, A.W.1, MCGOWAN, C.L.2,3, JAY, G.1, STOODLEY, L.1, SWAINE, I.L.4

1: SPORT AND EXERCISE SCIENCE, UNIVERSITY OF NORTHAMPTON , 2: DIVISION OF CARDIOVASCULAR MEDICINE, THE UNIVERSITY OF MICHIGAN, ANN ARBOR, MICHIGAN, , 3: DEPARTMENT OF KINESIOLOGY, UNIVERSITY

INTRODUCTION: Hypertension is a modifiable risk factor for cardiovascular disease (CVD) and is a leading cause of morbidity and premature mortality globally. Diurnal blood pressure (BP) variability, particularly the morning blood pressure surge (MBPS) is associated with increased end-organ damage and increased risk of stroke, and is a destabilising factor for atherosclerotic plaque. Isometric resistance training (IRT) has been shown to reduce ambulatory BP following 4-12 weeks of training and there is preliminary data to suggest that it can reduce the MBPS. However, there is no data available regarding how long, after cessation of IRT, the effects on ambulatory BP and the MBPS are maintained during detraining. Therefore, the purpose of this study was to determine the effects of IRT on ambulatory BP and the MBPS in young normotensives following (i) 8 weeks of IRT and (ii) 8 weeks of detraining.

METHODS: Twenty-five normotensive individuals (16 men, age=23±6 years; 9 women, age=22±4 years) were randomly assigned to a training-detraining (TRA-DT, n=13) or control (CON, n=12) group. Ambulatory BP and MBPS were measured prior to, and after 8 weeks of bilateral leg IRT using an isokinetic dynamometer (4 x 2-minute contractions at 20% MVC with 2-minute rest periods, 3 days/week). These measurements were then repeated, following an 8-week detraining period. A two-way repeated measures MANOVA was used to assess the within and between groups changes in ambulatory BP and MBPS. MBPS was calculated as: mean systolic BP 2 hours after waking, minus the lowest sleeping 1-hour mean systolic BP.
RESULTS: There were significant reductions in 24-h ambulatory systolic BP following IRT (pre-to-post training, -8±4 mmHg, p=0.00) and these reductions were maintained after detraining (pre-to-post detraining, -6±5 mmHg, p=0.008). There were significant reductions in daytime BP (pre-to-post training, -5±4 mmHg, p=0.001) which were maintained after detraining (pre-to-post detraining, -4±5 mmHg, p=0.022), but there was no change in night-time systolic BP (pre-to-post training, -2±4 mmHg, p=0.25) and this was also the case after detraining (pre-to-post detraining, 1±6 mmHg, p=1.0). Additionally, there were significant reductions in the MBPS (pre-to-post training, -6±9 mmHg, p=0.000) which were maintained after detraining (pre-to-post detraining, -5±9 mmHg, p=0.02).
CONCLUSION: These results confirm that IRT causes significant reductions in ambulatory BP. Furthermore, there are significant reductions in the MBPS, which could offer the potential for clinically meaningful CVD and stroke risk reduction. Importantly, ambulatory systolic BP and the MBPS changes remained significantly lower than baseline for 8-weeks after cessation of training, suggesting that the effects of IRT on these measures are prolonged.

OP-BN27 Neuromuscular fatigue II

CENTRAL FATIGUE KINETICS IN KNEE EXTENSOR MUSCLES DURING A SUSTAINED LOW-INTENSITY CONTRACTION TO TASK FAILURE.

SOURON, R.1, VOIRIN, A.C.1, KENNOUCHE, D.1, ESPEIT, L.1, MILLET, G.Y.1, RUPP, T.2, LAPOLE, T.1

1UNIV LYON, UJM SAINT-ETIENNE, LABORATOIRE INTERUNIVERSITAIRE DE BIOLOGIE DE LA MOTRICITÉ, EA 7424, F-42023, SAINT-ETIENNE, FRANCE

INTRODUCTION: Fatigue may be defined as a progressive decline in maximal-force generating capacities and can occur although the target force can still be maintained (Zijdewind et al. 1998). Fatigue may arise in daily life activities when postural muscles are often involved over long periods of low-intensity contractions. To date, most studies have examined fatigue etiology during maximal or high intensity exercise. The main purpose of this study was to provide a comprehensive description of central fatigue appearance in locomotor muscles (i.e. knee extensors) during a submaximal contraction performed to task-failure (TF) by using a newly described method for assessing voluntary activation with transcranial magnetic stimulation (Mira et al. 2017).
METHODS: Eleven recreationally active healthy men (age: 24 ± 5 yr) volunteered for this study. The experimental sessions consisted in a sustained isometric contraction at 10% maximal voluntary contraction (MVC) force until TF. Neuromuscular evaluations (NME) were performed before (PRE), every 3 min during the sustained contraction, and immediately at TF. Each NME consisted in a series of one maximal (MVC) and two submaximal voluntary contractions at 75 and 50% MVC with no resting period in between and with superimposed transcranial magnetic stimulation to each of the 3 contractions to assess voluntary activation (VATMS), motor evoked potentials (MEPs) and silent periods (SPs). After interpolation, data were expressed in percentage (every 10% until TF) of the total time to exhaustion (TTE).
RESULTS: When compared to PRE, MVC was significantly decreased as early as 10%TTE ($p < 0.05$), with a plateau observed in the decline from 60%TTE (i.e. no differences observed when compared to TF). A gradual decrease in VATMS was reported but was found to be statistically significant only from 40%TTE ($p < 0.05$), with a plateau also observed in the decline from 50%TTE. A lengthening in SPs duration and a decrease in MEPs area, during submaximal but not maximal contractions, was observed at 10%TTE ($p < 0.05$) yet with no further changes thereafter.
CONCLUSION: Decreased corticospinal excitability and increased inhibition (i.e. changes in MEPs and SPs), likely explained by the repetitive activity within the motor pathway, plateaued from 10%TTE. Whether those changes could be at least responsible for initial decrease VATMS remains to be established but cannot explain the further decrease in VATMS up to 50%TTE. Why a plateau occurred in VATMS as well as in MVC decline before the end of the exercise is not clear but represents an original result when a sustained (rather than self-paced) very low intensity exercise model is used.

THE EFFECT OF FATIGUE ON THROWING PERFORMANCE AND NEUROMUSCULAR ACTIVATION IN ELITE FEMALE ATHLETES IN AQUATIC SPORTS

KING, S., CARON, M., CÔTÉ, J.

MCGILL UNIVERSITY

INTRODUCTION: Previous literature has suggested that expertise influences motor variability in order to maintain performance (1). However, few studies have investigated motor variability and muscle activity during ballistic movements. In this study we investigated changes in myoelectrical activity in 9 shoulder muscles during a throwing task before and after a fatiguing protocol.
METHODS: Thirty-Seven female participants (11 expert water polo players [WP], 12 expert swimmers [SW], 14 controls [CT]) performed 5 maximal throws of a standard female water polo ball before and after a fatiguing protocol. The protocol was performed using a Con-TREX isokinetic dynamometer (Con-TREX MJ; SW) in prone, with the shoulder abducted 90°, at 50% of their maximal torque. Peak throwing speed was collected during the throws, and electromyography (EMG) was collected throughout the entire protocol. A GEE statistical model was used to compare pre- and post- fatigue measures of median power frequency (MdPF), EMG Root-Mean Square (RMS), and calculated coefficients of variation (COV) for the 9 muscles within each group. All statistical analyses were performed at a Sequential Bonferroni Correction (SBC) of .05.
RESULTS: SW and WP showed a significant decrease in throwing speed after fatigue, whereas CT showed none. SW displayed lower RMS in the fatigue (FT) condition in the middle trapezius (MT), latissimus dorsi (LAT), supraspinatus (SS), infraspinatus (IS), and subscapularis

(SUB). CT showed lower RMS in the LAT and IS at FT. All three groups displayed no changes in MdPF from the NF to FT. Results for changes in COV showed SW had an increased variability for anterior deltoid (AD), and a decrease in SUB. CT demonstrated an increased variability for upper trapezius and IS, and a decrease for pectoralis major and AD. WP showed no significant changes in RMS, MdPF or COV.
CONCLUSION: The CT showing no decrease in throw speed is explained by their lack of expertise and inability to achieve a true maximum before fatigue. Therefore, fatigue of the muscles did not impede them from throwing the same speed, in comparison to the expert athletes. SW's and CT's decreases in RMS post fatiguing task are interpreted as a decreased recruitment of high amplitude type II muscle fibers due to fatigue. Concurrently, the lack of change in MdPF for all three groups is interpreted as an increased recruitment of type I fibers to compensate for fatigue of the type II fibers. Past research suggests that increases in COV is a search for strategies to use non-fatigued fibers. The decrease in variability for SW and CNTL in the stabilizing muscles could be explained by a strategy to produce a maximal throwing speed in combination with fatigue. In comparison, the ball-throwing expertise of WP allowed them to replicate the exact neuromuscular activation even under fatigue. This further reinforces the notion of task-specificity in fatigue adaptation strategies (2).

FATIGUE AND METABOLIC RESPONSES TO AGILITY-LIKE SPEEDCOURT SPRINT PROTOCOLS AND THEIR RELATIONSHIPS TO MARKERS OF ATHLETIC PERFORMANCE IN ELITE SOCCER PLAYERS

RAEDER, C., PRAETORIUS, A., SCHOEPP, C.

BG KLINIKUM DUISBURG

INTRODUCTION: The SpeedCourt (SC) is a tool for assessing agility-like sprint performance due to change-of-direction (COD) movements in response to a visual stimulus. However, the accumulated fatigue and metabolic responses to repeated bouts of SC sprints are not well investigated. Moreover, it is not yet clear how SC performance is related to other variables of athletic performance. Therefore, first aim of the study was to analyze the fatigue and lactate responses to SC sprint protocols. Second aim was to examine the relationships between SC performance and markers of jump and sprint ability.
METHODS: Using a cross-sectional design, 26 male elite soccer players (mean±SD; age: 25.4±3.9 yrs) of the 2nd German division volunteered for a complex test battery, including measures of jump, sprint and agility-like SC sprint performance. Jump tests consisted of CMJs, multiple rebound jumps and bilateral hops. Linear sprint tests included the measurement of 5m and 10m times followed by 180°-COD sprint tests, using a modified 505 test. Then, the players performed 12 consecutive SC sprint protocols with a work-to-rest ratio (W:R) of approximately 1:2 (≈12-15s:30s) consisting of 10 multidirectional CODs over a distance of 30m in random fashion. Trial 1-3 (SC-3) served as specific familiarization at 80-90% of maximal effort. The remaining nine SC protocols were performed all-out. Split times were determined for trial 4-6 (SC-6), trial 6-9 (SC-9) and trial 10-12 (SC-12). Total time (SC-TT) was also calculated. The percentage decrement score (PDS=100 x (total sprint time/ideal sprint time)-100) was used to measure accumulated fatigue. Blood lactate (LAC) was determined pre and post SC-3 as well as post SC-6, SC-9 and SC-12. For all measures, the mean was taken for analysis. All tests were preceded by a standardized dynamic warm-up.
RESULTS: After SC-3 (14.4±1.1s) there was a gradual decrease in agility-like SC sprint performance with significant differences (paired t-tests; $p<.001$, $d>.85$) between SC-12 (14.1±1.1s) and SC-9 (13.3±0.9s) as well as SC-12 and SC-6 (13.1±0.9s). Accumulated fatigue in PDS reached 19.6±7.6%. LAC concentrations changed significantly ($p<.01$; $d>.65$) between all time points from 1.44±0.75mmol/L pre SC-3 to 4.63±1.58mmol/L post SC-3, 7.56±2.20mmol/L post SC-6, 8.80±2.87mmol/L post SC-9 and 9.53±2.63mmol/L post SC-12. The Pearson correlation showed trivial to small relationships (r ranging from -0.14 to 0.30; $p>.05$) between SC-TT and the markers of jump and sprint ability.
CONCLUSION: The present SC protocol design using a soccer specific W:R elicited accumulated fatigue of about 20% indicated by a gradual drop in SC performance. This could be linked to insufficient recovery time between successive sprint bouts causing a high metabolic load. Jump, sprint and 180°-COD capabilities seem not to be related to the given SC performance possibly making it an additional valuable measure for functional performance. The provided reference data may be further helpful in Return-to-Play scenarios.

NEUROMUSCULAR FATIGUE IN SPRINT AND OLYMPIC TRIATHLON

LAVARDA, M.1.2, RASICA, L., LA TORRE, A., PORCELLI, S.

1: INSTITUTE OF MOLECULAR BIOIMAGING AND PHYSIOLOGY; 2: INSTITUTE OF CLINICAL EXERCISE AND HEALTH SCIENCE

INTRODUCTION: Triathlon is a multi-disciplinary sport including swimming, cycling, and running. In the literature, several data regarding cardiovascular response to exercise suggest athletes normally exercise at an average heart rate of about 90% of the maximum heart rate. As for muscle fatigue, data are scarces and suggest no reduction in the lower limbs muscle force production at the end of the race, although sprint performance is impaired. However, previous muscle force data were assessed by indirect methods (squat jump and counter-movement jump tests) only at the end of the race and possible confounding factors occurring during the competition were not taken into account. The aim of this study was to evaluate neuromuscular fatigue occurring during and immediately after triathlon competitions of different duration in order to define the mechanistic bases of the force impairment.
METHODS: Eleven male triathletes (age: 40±8years, VO2peak: 55.9±4.2 ml/kg/min), were enrolled in the study. Each subject participated at two triathlon races: sprint (SPRINT) and olympic (OLYMPIC) distance. Neuromuscular evaluation tests were performed: i) few hours before (PRE) the start of the race; ii) during the transition phases after swimming (T1) and cycling (T2); iii) immediately after the end of the running phase (POST). At each point, subjects performed isometric maximum voluntary contractions (MVC) of the quadriceps muscle. Single (Tw), doublet low-frequency (Db10) and doublet high-frequency (Db100) stimuli were delivered to femoral nerve in order to investigate the mechanistic bases of the neuromuscular impairment. Surface electromyography sensors were placed in correspondence of the vastus medialis, vastus lateralis, and rectus femoris. Voluntary activation (VA) was investigated by Interpolated Twitch Technique. Rate of perceived exertion (RPE) was monitored by Borg scale and a chest band monitored heart rate (HR). Data regarding speed and pace were obtained by a GPS system positioned on the athletes' wrist.
RESULTS: Athletes completed SPRINT and OLYMPIC in 80±7min and 161±16min, respectively. Average HR was 160±3 during SPRINT and 157±5 during OLYMPIC, corresponding to 91% and 88% of HRpeak respectively. Final RPE was 18±2 in both races. In PRE, maximal isometric force (MVF) was 606±186N and 568±166N for SPRINT and OLYMPIC, respectively. MVF progressive decreased in both SPRINT and OLYMPIC, resulting 25±9% and 38±14% lower in POST (vs PRE), respectively. In POST, a decrease in VA (12±6% and 18±4%), Db100 (12±4% and 10±6%) and Db10/Db100 (19±5% and 22±8%) was observed in both SPRINT and OLYMPIC.

CONCLUSION: The present results suggest that lower limbs muscle force impairment in triathlon races is due to both central and peripheral neuromuscular fatigue without any difference between short and long distances. The development of peripheral fatigue seems to be more related to excitation-contraction coupling failure.

EFFECTS OF SHORT-TERM KNEE IMMOBILISATION ON NEUROMUSCULAR FUNCTION

CAMPBELL, M.1, ELY, I.1, FULFORD, J.1, MILEVA, K.2, TAYLOR, B.3, BOWTELL, J.1

1: UNIVERSITY OF EXETER, 2: LONDON SOUTH BANK UNIVERSITY, 3: UNIVERSITY OF LEEDS.

INTRODUCTION: Declines in muscle strength occur concomitantly with muscular atrophy in response to periods of limb immobilisation. However, the reductions in muscle size do not explain fully the loss in function (1). Literature suggest that changes in neuromuscular function are similarly important with regards to functional loss and therefore require further investigation. Our recent systematic review highlighted that the rate of loss of muscle strength and neuromuscular function (NMF) are greatest in the early phase of immobilisation and yet very few studies have investigated the effects of short-term immobilisation (<7 days) (1). We therefore investigated the effect of 48 h knee immobilisation on knee extensor strength, size and NMF.
METHODS: Nine healthy participants (5F, 4M; 174 ± 11 cm, 77.4 ± 14.0 kg) underwent 48 h of single-leg knee brace immobilisation at ~40° of knee flexion randomised to either the dominant (n = 4) or non-dominant (n = 5) leg. Muscle strength, structural magnetic-resonance imaging scans (MRI) and neuromuscular assessment of the knee extensors were conducted pre and post immobilisation. Neuromuscular assessment was conducted using femoral nerve electrical stimulation (PNS) and transcranial magnetic stimulation (TMS) to elicit measures of excitability (M-wave amplitude and area, motor evoked potential [MEP] amplitude and area), contractility (contraction time, half relaxation time, relaxation rate) and descending neural drive (voluntary activation [VA] via PNS and TMS) across both the immobilised (IMB) and control (CON) limbs. Data are presented as mean ± SD and were analysed by 2-way repeated measures ANOVA.
RESULTS: There were no statistically significant pre to post effects on knee extensor strength (IMB: 374 ± 144 to 357 ± 156, CON: 369 ± 159 to 356 ± 149 N; $p > 0.05$), whole limb cross sectional area (IMB: 12971 ± 2865 to 12942 ± 3022; CON: 11807 ± 5096 to 11883 ± 5112 mm2; $p > 0.05$), VA ($p > 0.05$) or contractility measures ($p > 0.05$). However, despite no change in resting m.vastus lateralis M-wave amplitude and area ($p > 0.05$), MEP amplitude and area both significantly declined following immobilisation (interaction effect: $p < 0.05$). In addition, a significant positive correlation was observed between % change in strength and PNS VA in the immobilised leg ($r = 0.830$, $p < 0.01$).
CONCLUSION: Following 48 h of knee immobilisation there was significant reduction in corticospinal excitability despite no significant changes in strength or muscle size. The absence of any loss of muscle strength may be due to compensatory increases in descending neural drive as evidenced by association between strength and VA.

OP-MI15 Strength and power II

INTERACTION BETWEEN UPPER BODY KINEMATICS AND POWER PRODUCTION DURING BALLISTIC MEDICINE BALL THROWS

SAYERS, M.

UNIVERSITY OF THE SUNSHINE COAST

INTRODUCTION: While outcome variables such as jump/throw height or peak force (Fpeak) and power (Ppeak) are used frequently to assess power in ballistic activities, researchers in this domain acknowledge that measures such as these occur as a function of the complex integration of multiple neuromuscular and mechanical systems (1,2). This project examined this concept by exploring the complex interrelationships between upper body kinematics and power production during a series of medicine ball push-press (MBP-P) throws.
METHODS: Following a standard warm-up, 25 regular weight trainers (body mass = 86 ±10 kg) performed a series of ballistic vertical MBP-P throws at loads representing 5% and 10% of their assessed 5RM bench press. Throws were performed lying supine on a force platform (1 kHz) with upper body kinematics assessed using standard infra-red motion capture techniques (500 Hz). Gross outcome measures of performance and power production such as peak vertical ball velocity (Velpeak), peak force (Fpeak) and power (Ppeak) were recorded during the propulsive phase of the movement. The influence of medicine ball load on the various kinematic and power related variables were determined via a series of paired t-tests. The relative magnitude of differences between medicine ball loads were quantified using standard Effect Size (ES) analyses. Coefficient of variation (CV%) data for each of the text variables were used as an indication of inter-trial consistency.
RESULTS: analyses. Coefficient of variation (CV%) data for each of the text variables were used as an indication of inter-trial consistency.
RESULTS: Comparative analyses indicated that despite significant reductions in Velpeak from the 5% to 10% loads ($P<0.001$, ES=1.76), Fpeak remained largely unchanged ($P=0.167$, ES=0.17). Similarly, peak elbow extension velocity was the only upper body kinematic variable that either differed significantly or achieved greater than a moderate difference between the two medicine ball loads ($P<0.001$, ES=1.14). Analysis of inter-trial variability showed that the gross measures of performance such as Velpeak, Fpeak and Ppeak were relatively stable (CV% 3-13%), while most upper limb segmental kinematics varied considerably between trials (CV% up to 70%). Analyses of time-series data indicate the peak wrist flexion velocities occur after the peak elbow extension and shoulder horizontal flexion velocities, with the latter working largely synchronously.
CONCLUSION: The stability of the gross outcome measures in the presence of considerable variance in movement kinematics is representative of neurobiological degeneracy, a term used in ecological dynamics research to describe how the same outcome can be achieved using a variety of movement strategies. Practitioners and sport scientists need to be aware of the nature of these complex relationships when testing and training athletes who perform light load, high velocity upper body movements.

ASSESSMENT OF FORCE-VELOCITY PROFILE IN ELITE FEMALE HANDBALL PLAYERS

PETRIDIS, L., PÁLINKÁS, G., SZABÓ, T.

UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Force-velocity (F-v) profile has been found to have a significant contribution in ballistic push-off movements (Samozino, 2014). By correcting individual imbalance between actual and optimal F-v profiles for a given maximal power (Pmax) jumping performance theoretically can be maximized. The purpose of this study was to assess the F-v profile of elite female handball players during vertical jump using two methods to calculate average velocity during pushoff.
METHODS: 27 female handball players members of the Hungarian national team participated in the study (age: 24.4±3.7 years, body height (BH): 175.1±5.1 cm), body weight (BW): 69.4±7.3 kg). Participants performed unloaded and loaded (25%, 50%, 75%, and 100% of BW) countermovement jumps (CMJ) on a force platform (HUR labs). Based on previously reported methods (Samozino, 2012) actual and optimal F-v profiles and F-v imbalance were calculated. Average force ($\bar{F}$) during pushoff was extracted from force platform data. Average velocity ($\bar{v}$) was calculated with two methods: based on jump height or based on measured average power and average force from force platform data.
RESULTS: Mean±SD values for jump height and for the theoretical maximal force (Fo) were 0.32±0.03 m and 29.6±4.4 N/kg respectively. 26 players presented F-v imbalance with deficit in force and only one player with a deficit in velocity. Theoretical maximal velocity (v0) and F-v imbalance (F-vimb) differed between the two calculation methods, when calculating $\bar{v}$ from the force platform force and power data we had significantly higher v0 values and therefore significantly higher F-vimb (3.2±0.8 vs. 5.3±1.5 m/s and 28.2±14.9% vs. 57.5±18.2% respectively). Accordingly, the theoretical maximal jump height also differed (0.36±0.06 vs. 0.53±0.1 m).
CONCLUSION: Establishment of an athlete's F-v profile can be really useful for more individualized and specific training of muscle mechanical properties. Female handball players demonstrated notable deficit in force, which highlights the need for strength training, mainly when they have to work with larger loads. However, the magnitude of F-vimb differs according to the method used to calculate average velocity. Lower values of v0 obtained when calculating average velocity from jump height may refer to a lesser force application efficiency resulting in lower jump height, but this still has to be examined. On the other hand, theoretical maximal jump height obtained when calculating average velocity from the force and power data seem unrealistically high.

TUNING MUSCLE COORDINATION PATTERNS WITH LEARNING THE POWER CLEAN

BENIO, K.1,2, SHINSAWA, Y.3, KOUZAKI, M.2,3

1 WASEDA UNIVERSITY; 2 KYOTO UNIVERSITY; 3; KYOTO UNIVERSITY

INTRODUCTION: The power clean is popular free weight exercise for athletes who need to exert explosive power. However, the power clean training has difficulty of learning. The objective evaluation for proficiency of power clean will facilitate learning. In particular, evaluating muscle coordination might be useful, because the power clean is never achieved without coordinating whole body muscles. Recently, the muscle synergy analysis is utilized to quantify muscle coordination patterns. We can quantify synchronous activation patterns in several muscles by the muscle synergy analysis [1,2]. The muscle synergies contribute to reveal how whole body muscle coordination changes through learning the power clean. Then, our purpose was identifying modification of whole body muscle coordination with learning the power clean by using the muscle synergy analysis.
METHODS: We performed an experiment for measuring kinematic data during the power clean, and also performed training experiment. In these experiments, six men who have continued the power clean training over one year and four men who have not experienced the power clean training were participated. In the skilled group, subjects were only participated in the experiment for measuring kinematic data during power clean. In novice group, subjects were participated in measurement at first. Next, they practiced the power clean during one month (twice a week, total was 7 times). At last, novices were participated in the measurement again. In the measurement, we recorded surface electromyograms from 18 muscles in lower limb, upper arm, shoulder and trunk. The muscle synergies were extracted from time series of muscle activities by using non-negative matrix factorization [1,2].
RESULTS: Average number of muscle synergies in the skilled group (Skilled), pre-training of novice group (pre-Novice), and post-training of novice group (post-Novice) were 6.7±0.94, 4.8±1.5 and 6.3±1.5 respectively. The number of synergies in the Novice increased through the power clean training. This indicates that number of muscle coordination patterns in the Novice increased as much as the Skilled. In addition, we observed changes of muscle synergy activities. An extracted muscle synergy (Synergy4) was constructed from ankle dorsiflexor and knee extensor muscles, and this muscle synergy activated from the scoop and second pull phase within the power clean. Synergy4 might contribute to the double knee bend which causes unweighting. In the pre-Novice, activation of Synergy4 was small from the scoop and second pull phase. However, activation increased in the post-Novice. This tuning of muscle synergy activation might be related to improvement of the double knee bend by learning.
CONCLUSION: We concluded that patterns of muscle synergies during the power clean increased after learning, and tuning of muscle synergy activities was related to improvement of the power clean.

ASSOCIATION BETWEEN COUNTERMOVEMENT JUMP-DERIVED MARKERS OF NEUROMUSCULAR STATUS AND STRENGTH GAIN WITH CONCURRENT TRAINING

FYFE, J.J., PATTISON, K.J., DRINKWATER, E.J., STEPTO, N.K., BISHOP, D.J.

DEAKIN UNIVERSITY

INTRODUCTION: Concurrent training can impair strength development versus resistance training alone (2); however, the underlying mechanisms are unclear. One hypothesis suggests that residual neuromuscular fatigue from endurance training compromises resistance training performance, leading to impaired strength gain over time (3). We sought to determine the role of altered neuromuscular status in the interference to maximal strength gain with concurrent training via implementation of countermovement jump (CMJ) testing (1).

METHODS: Twenty-three recreationally-active males (mean ± SD: age, 29.6 ± 5.5 y; height, 182.4 ± 5.9 cm; body mass, 84.9 ± 11.4 kg) performed eight weeks of resistance training alone (RT group, n = 8) or combined with either high-intensity interval training cycling (HIIT+RT group, n = 8) or moderate-intensity continuous cycling (MICT+RT group, n = 7). Maximal (1-RM) strength and CMJ performance were assessed before (PRE) and 72 h after (POST) the training intervention.
RESULTS: The improvement in both relative peak force and flight time to contraction (F:C) time was impaired for both HIIT-RT (ES: -0.72, ±0.61 and -0.53, ±0.39, respectively) and MICT+RT (ES: -1.25, ±0.63 and -0.60, ±0.55, respectively) versus RT alone. Changes in both relative peak force and F:C time were also positively associated with relative 1-RM strength gain (r2 = 0.26, P = 0.026 and r2 = 0.19, P = 0.056, respectively) after the training period.
CONCLUSION: Selected CMJ-derived markers of neuromuscular status were impaired with concurrent training versus resistance training alone, potentially reflecting accumulated neuromuscular fatigue. Changes in these markers were also associated with maximal strength gain, suggesting a potential contribution of impaired neuromuscular status to the interference effect with concurrent training.

REST REDISTRIBUTION ATTENUATES VELOCITY AND POWER LOSS IN BACK SQUATS PERFORMED BY WOMEN

MERRIGAN, J.J.1, TUFANO, J.J.2, FIELDS, J.B.1, OLIVER, J.M.3, WHITE, J.B.1, JONES, M.T.1

1: GEORGE MASON UNIVERSITY, 2: CHARLES UNIVERSITY, 3: UNITED STATES MILITARY ACADEMY

INTRODUCTION: Kinetics and kinematics of resistive exercise are important stimuli for training induced adaptations. Redistributing rest (rest redistribution, RR) via inclusion of intra-set rest (cluster sets) help maintain velocity and power production during sets of back squat exercise (BS) in resistance trained (RT) men. However, such effects are unknown in RT women. Therefore, the aim was to examine the effect of RR on BS kinetics and kinematics in RT women.
METHODS: Twelve RT women (mean ± SD; 23.7 ± 4.1 yr; 5.0 ± 2.2 yr training) participated in a repeated measures crossover design. Body composition and one-repetition maximum (1RM) BS were determined in Session 1. In Session 2 (+72 hr post Session 1) and Session 3 (+96 hr post Session 2), participants were randomly assigned to traditional sets (TS, 4 sets x 10 repetitions (reps) with 120 s rest) and RR (4 sets x 2 clusters x 5 reps) with 30 s between clusters and 90 s between sets) at 70% 1RM. Total rest (360 s) was the same between TS and RR conditions. Kinematic and kinetic measurements were sampled at 1600 Hz via force plate and four linear position transducers using custom-built Lab View software. The greatest value of rep 1-3 (peak rep) was used to calculate percent loss [rep10 – peak rep) / peak rep) x 100] and maintenance [100 – ((set mean – peak rep)/peak rep)) x 100] of velocity and power for each set. A 2 (CONDITION) x 4 (SET) x 10 (REP) repeated measures analysis of variance (RMANOVA) was used for analysis ($p<0.05$). To compare percent loss and maintenance of velocity and power across each set, a 2 (CONDITION) x 4 (SET) RMANOVA was used.
RESULTS: Mean and peak force did not differ between TS and RR. A CONDITION*REP interaction effect was observed for peak power ($p=0.049$), but not peak velocity ($p=0.110$). Peak power was greater in the later RR reps: rep 7 [CI95%: 50.62, 253.33 Nm/s; ES, 1.27], rep 8 [CI95%: 29.25, 226.65 Nm/s; ES, 1.10], and rep 9 [CI95%: 27.49, 200.33 Nm/s; ES, 1.12]. Mean velocity loss and mean power loss were -3.72% [CI95%: -0.22, -7.22%; $p=0.039$] and -4.70% [CI95%: -1.53, -7.87%; $p=0.008$] lower in RR. Main condition effects on maintenance calculations occurred for mean and peak velocity ($p=0.004$), mean power ($p=0.002$), and peak power ($p=0.006$). Mean velocity across set 3 ($p=0.036$; ES=1.90) and set 4 ($p=0.015$; ES=2.30), as well as mean power across set 4 ($p= 0.006$; ES=2.65) were better maintained in RR.
CONCLUSION: Greater power output is driven by greater velocity during later reps of the back squat with RR in RT men. When performed by RT women in the present study, RR resulted in the maintenance of velocity and power. These data indicate that RR maintain velocity and power in RT women, but may differ in the pattern across repetitions.

EFFECT OF DIFFERENT TYPES OF LOADS ON THE FORCE-VELOCITY RELATIONSHIP OBTAINED DURING THE BENCH PRESS THROW EXERCISE

NEDELJKOVIC, A.1, COSIC, M.1, KNEZEVIC, O.M.2, DJURIC, S.3, ZIVKOVIC, M.Z.1, GARCIA-RAMOS, A.4

1: UNIVERSITY OF BELGRADE - FACULTY OF SPORT AND PHYSICAL EDUCATION, 2: UNIVERSITY OF BELGRADE - INSTITUTE FOR MEDICAL RESEARCH, 3: UNIVERSITY OF LJUBLJANA - INSTITUTE OF KINESIOLOGY, 4: UNIVERSITY OF

INTRODUCTION: The relationship between the velocity (V) of muscle contraction and the force (F) that it can produce is one of the main muscular properties (1). Therefore, it is not surprising that the F-V relationship has been frequently used to assess muscular function (2). The most standard type of load that has been used to assess muscular function has two main components: weight (mass × gravity) and inertia (mass × acceleration). However, it can be modified to provide almost exclusively gravitational (W) or inertial (I) type of loads. Therefore, the aims of this study were: (I) to evaluate the degree of linearity of the force-velocity (F-V) relationship across different types of loads (W, I and W+I), (II) to compare the magnitude of the F-V relationship parameters (maximum values of force [F0], velocity [V0] and power [Pmax]) between the different types of loads (W, I and W+I), and (III) to explore the concurrent validity of F0 with traditional measures of maximal strength.
METHODS: The F-V relationships of 15 physically active men (age: 20.9±2.0 years, bench press 1-repetition maximum [1RM] relative to body mass: 1.20±0.10 kg·kg-1) were determined during the bench press throw (BPT) exercise (the load magnitudes: 40, 50, 60, 70 and 80 kg) using predominantly gravitational (W), inertial (I) and combined (W+I) loads. The type of load was manipulated by combining the extended rubber bands with the weight plates added to the barbell. The bench press maximal isometric force (Fiso) and the 1RM were also assessed. All tests (BPT, Fiso and 1RM) were performed on a custom-made Smith machine.
RESULTS: The individual F-V relationships were highly linear regardless of the type of load considered (median r [range] = 0.98 [0.94, 1.00]). The W+I load provided the largest value of F0 (972±45 N; 6.0% and 14.6% higher than W and I, respectively), the I load the largest value of V0 (2.99±0.34 m·s-1; 40.4% and 20.1% higher than W and W+I, respectively), and the W load the lowest value of Pmax (501±46 W; -22.7% and -17.1% lower than I and W+I, respectively). The F0 obtained from the W load presented the highest association with Fiso and 1RM values ($r > 0.90$).
CONCLUSION: The F-V relationship was highly linear regardless of the type of load considered. The comparison of the F-V relationship parameters revealed that the W+I load provided the largest F0, the I load the largest V0, and both W+I and I loads provided comparable values of Pmax. Therefore, practitioners should consider using W+I and I loads over W loads for the development of Pmax, being prefer-

able to apply a W+I load to stimulate F0 development and an I load to develop V0 capacity. The F0 obtained from the F-V relationship modelled with a W load should be recommended to assess maximal strength capacity since it provided the highest correlation with Fiso and the 1RM.

KNEE JOINT MOMENTS IN ELITE HIGH JUMPERS

GOLDMANN, J.P.1,2, BRAUNSTEIN, B.1,2, HEINRICH, K.1, SANNO, M.1,2, STAEUDLE, B.1,4, RITZDORF, W.3, BRUEGGEMANN, G.P.1, ALBRACHT, K.1,4

GERMAN SPORT UNIVERSITY COLOGNE, UNIVERSITY OF APPLIED SCIENCE AACHEN***

INTRODUCTION: The knee joint is the largest joint in the human body with numerous studies reporting loading during activities of daily living or moderate sporting activities. The effects of malalignment on knee joint loading in osteoarthritis as well as anterior cruciate ligament loading during high-risk movements are perceived as important biomechanical questions (e.g. review Maly 2008). However, the magnitudes of knee joint moments during extreme single leg jumping movements are not documented. The purpose of this study was to estimate knee joint loads as they occur during the take-off contact in elite high jumpers.
METHODS: Motions of seven elite high jumpers (personal best 2.24 ± 0.06 m) during take-off were filmed with 19 Infrared-Highspeed-Cameras (300 Hz, Vicon, Oxford, UK) and ground reaction forces were captured with a force plate (1200 Hz, Kistler, Winterthur, Switzerland). Inverse dynamics were calculated with a customized full-body model (Alaska Dynamicus, Institute of Mechatronics, Chemnitz, Germany). Statistics: Wilcoxon signed-rank test ($\alpha = 0.05$).
RESULTS: The athletes raised their centre of mass to a height of 2.13 ± 0.05 m with run-up velocities of 6.87 ± 0.43 m/s and ground contact times of 187 ± 33 ms. Maximal ground reaction forces in the vertical direction attained 3800 to 6000 N (5 to 8 times BW) and in the horizontal direction 2000 to 3000 N (3 to 4 times BW). Peak external knee joint moments ranged as follows: flexion 416 to 542 Nm (481 ± 45 Nm), extension 143 to 586 Nm (395 ± 155 Nm), adduction 146 to 822 Nm (331 ± 247 Nm), and abduction 121 to 345 Nm (222 ± 83 Nm). Mean external knee joint moments: flexion 231 ± 51 Nm, adduction 51 ± 40 Nm.
CONCLUSION: Compared to running, sprinting, cutting and landing, two to ten times higher peak external knee joint moments were observed in elite high jumpers (Stefanyshyn et al. 2006, Pollard et al. 2010, Dupré et al. 2019). Based on coaches' reports, we estimated 1000 jumps (70% of the jumps with maximum effort) across the bar per athlete per year. In regard to the loads estimated in this study it appears surprising that acute as well as overuse injuries of the knee's passive tissue caused by the take-off loading in elite high jumpers are rare or less reported (Kettunen et al. 2001). Tissue quality might play a more important role for injury prevention rather than the mechanical stress itself. If the tissue is well prepared for extreme loading, it might tolerate high internal stress. The knees of elite high jumpers may have structurally adapted to be particularly well-suited for sustaining the loads experienced during this task. It should be mentioned that the presented values underestimate internal joint loading due to disregarding muscle forces in the used model. For further analysis, muscle forces have to be considered.

STRETCH-SHORTENING CYCLE IN ROWING

HELD, S., SIEBERT, T., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Addressing temporal and electromyographic (EMG) characteristics of stretch-shortening cycles (SSC) are crucial for the conceptualization of discipline-specific testing and training. In addition, each SSC (e.g. jumping), is characterized by utilising optimal movement-parameters (e.g. muscle shortening velocity) for maximum power-output (jump height) (Komi, 2003). Thus, the present studies aimed at elucidating whether the SSC in rowing can be attributed to slow or fast SSC. Furthermore, it should be checked if relevant SSC movement-parameters in rowing, such as stroke-rate and gearing, have to be maximised to obtain maximum power-output or if an optimum relation between power-output and movement-parameters emerges.
METHODS: Surface EMG activity of vastus medialis and gastrocnemius was captured using bipolar electrodes during rowing (single scull) and subsequently compared to EMG-activity in slow (countermovement jump, CMJ) and fast (drop jump, DJ) SSC. The elapsed time between EMG-onset and start of eccentric phase was monitored, with periods up to 120 ms assigned to the reflex-induced phase (RIA). Ten male rowers of the national squad (n = 10, 22.8 ± 3.1 years, 190 ± 6 cm, 82.1 ± 9.8 kg) were included in this EMG-study (cross-sectional study with repeated testing design). In addition, rowing-power (Prow) were measured in dependence of varying stroke-rates (20-45 spm), gearings (inboard-changes 0.87-0.90 m) and drag-factors (100-180 Ws3/m3). These sprint-series were performed on (single scull, n = 69, 20 ± 2 years, 186 ± 7 cm, 84 ± 9 kg) and off the water (rowing-ergometer, n = 30, 19 ± 3 years, 185 ± 11 cm, 77 ± 19 kg).
RESULTS: Notable EMG-activity was observed during DJ before the start of eccentric phase ($p < 0.001$) as well as during the RIA-phase ($p < 0.001$). By contrast, CMJ ($p < 0.05$) and race-specific rowing ($p < 0.05$) showed an EMG-onset during the eccentric phase. Prow increases with stroke-rate for the ergometer-test ($r = 0.97$, $p < 0.001$) and the boat-measurements ($r = 0.98$, $p < 0.001$) by 2.7%/stroke and 4.4%/stroke, respectively. Drag-factor (ergometer: $r = 0.83$, $p < 0.001$) and gearing (boat: $r = 0.60$, $p < 0.001$) yielded moderate to high correlations to Prow.
CONCLUSION: As a consequence, the SSC in rowing is most-likely attributable to a slow SSC, which is characterized by a lack of pre-activation and reflex-activity. These EMG-related findings implicate that any forms of muscle action in the fast SSC domain does not reflect discipline specific muscle actions and could hamper rowing performance enhancement. Furthermore, no optimum stroke-rate, gearing

and drag-factor exist for maximum power-output during sprint rowing, but maximum power-output for maximum stroke-rate, gearing, and drag-factor occurred.

THE EFFECTS OF CLUSTER-SET AND TRADITIONAL-SET PAP PROTOCOLS ON VERTICAL JUMP PERFORMANCE

DELLO IACONO, A., BEATO, M., HALPERIN, I.

UNIVERSITY OF THE WEST OF SCOTLAND, UNIVERSITY OF SUFFOLK, TEL AVIV UNIVERSITY, SYLVAN ADAMS SPORT INSTITUTE.

INTRODUCTION: The present study aimed to compare the acute effects of two post activation potentiation (PAP) protocols using traditional or cluster-set configurations on countermovement jump (CMJ) performance.
METHODS: Twenty-six male basketball players were evaluated on three occasions separated by 72 hours. On the first session, athletes performed barbell squat jumps with progressively heavier loads to determine their individual optimum power loads. On the second and third sessions, athletes completed two PAP protocols in a randomized, counterbalanced order: 3 sets of 6 repetitions of squat jumps using optimum power loads performed with either a traditional (no inter-repetition rest) or a cluster-set (20 s rest every 2 repetitions) configurations. After a comprehensive warm-up, CMJ height was measured using a force platform before, 30 s, 4 min, and 8 min after completing the PAP protocols.
RESULTS: While at post-30 s athletes jumped lower compared to baseline in both conditions, jump height was 0.71 cm lower following the traditional compared to the cluster-set condition (95% CI: 0.37, 1.05 cm). While athletes jumped higher compared to baseline at post-4 and post-8 min in both conditioning, jump height was higher following the cluster-set compared to the traditional condition in post-4 min by 1.33 cm (95% CI: 1.02, 1.65 cm) and in post-8 min by 1.64 cm (95% CI: 1.41, 1.88 cm).
CONCLUSION: Both traditional and cluster-set configurations induced a PAP response in vertical jump performance using optimum power loaded squat jumps, but the cluster-set configuration led to superior performance likely due to the reduced accumulation of muscular fatigue. Strength and conditioning professionals and their athletes might consider the inclusion of PAP protocols simular to those investigated in this study during the specific warm-up to acutely improve athletic performance during the onset (≤ 8 min) of training or competition.

TRICEPS SURAE MUSCLE-TENDON UNIT PROPERTIES IN PREADOLESCENT CHILDREN: EFFECTS OF ATHLETIC TRAINING

PENTIDIS, N.1, MERSMANN, F.1, BOHM, S.1, GIANNAKOU, E.2, AGGELOUSIS, N.2, ARAMPATZIS, A.1

1> HUMBOLDT-UNIVERSITÄT ZU BERLIN; 2> DEMOCRITUS UNIVERSITY OF THRACE, GREECE

INTRODUCTION: Systematic athletic training in adolescence can cause imbalances of muscle strength and tendon stiffness, which results in a higher mechanical demand for the tendon (1). In this study, we investigated Achilles tendon stiffness, plantar flexor muscle strength and jumping performance in preadolescent athletes and non-athletes to identify the effects of systematic athletic training.
METHODS: Twenty-one preadolescent artistic gymnastic athletes and a group of eleven similar-aged untrained participants performed maximum isometric contractions on a dynamometer for the assessment of plantar flexor muscle strength and Achilles tendon stiffness. Vertical ground reaction forces during squat (SJ) and countermovement jumps (CMJ) were measured to assess jumping height and mechanical power. We documented the training of the athletes in order to quantify their training intensity and volume. The pubertal status of each child was determined using the Tanner scale.
RESULTS: The athletes completed a training program of 20 hours/week with almost 5h of specific muscle strength and jumping training. Athletes generated significantly greater plantar flexion moments (normalized to body mass) compared to controls (A: 1.75 ± 0.32, C: 1.31 ± 0.33 Nm/kg; p=0.001), but the absolute plantar flexion moments between groups did not show any significant differences (p=0.07). We found a significantly greater jump height in athletes in both jumps (A: 21.2 ± 3.6, C: 14.9 ± 2.3 cm; p<0.001 in SJ and A: 23.4 ± 4.1, C: 16.4 ± 4.1 cm; p<0.001 in CMJ) and a higher mean mechanical power during the propulsion phase (A: 16.1 ± 2.0, C: 13.0 ± 3.2 W/kg; p=0.002 for SJ, and A: 22.2 ± 2.9, C: 18.5 ± 3.2 W/kg; p=0.006 for CMJ). Achilles tendon stiffness did not show any statistically significant differences between the two groups (A: 116.3 ± 32.5, C: 106.4 ± 32.7 N/mm; p=0.506). During the maximum isometric contractions athletes were more likely to reach strain magnitudes close to or higher than 8.5% strain compared to controls (frequency of A: 24% and C: 9%).
CONCLUSION: The present study demonstrated that athletic training during preadolescence is associated with increased plantar flexor strength normalized to body mass and jumping performance. Achilles tendon stiffness did not differ between athletes and non-athletes, likely due to the similar levels of absolute muscle strength. However, in some individual athletes, an increased level of tendon strain during maximum isometric contractions indicates imbalances between muscle strength and tendon stiffness, resulting in a high mechanical demand for the tendon. The potential contribution of the mechanical demand to the increasing risk of tendon overuse call for the implementation of specific exercises in preadolescent athletes that support a balanced adaptation within the muscle-tendon unit.

ARE THERE DIFFERENCES IN JUMP HEIGHT AND MUSCLE ACTIVATION PATTERN ACROSS SAND AND RIGID SURFACE SPECIFIC ATHLETES?

BRODATZKI, Y.1, WIRTZ, S.1, SZWAJCA, S.1, BÜSCH, D.2, ZENTGRAF, K.3, EILS, E.1

1: INSTITUTE OF SPORT AND EXERCISE SCIENCES, UNIVERSITY OF MÜNSTER, 2: INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF OLDENBURG, 3: INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF FRANKFURT

INTRODUCTION: Player transferability between certain surfaces are essential for maximal performance during specific season times in sports, such as volleyball and handball. It has been previously reported that in male and female volleyball players, there are differences in muscle activation during drop jumps on varying surfaces. Whereby, athletes activate their lower limb muscles earlier on rigid than unstable surfaces (1). Thus, we aim to investigate the differences in jump height and lower limb activation between sand and firm ground athletes across both sand and rigid surfaces.
METHODS: 19 beach handball (19±3y; 184±12cm; 78±12kg) and 23 handball players (22±5y; 182±11cm; 81±15kg), participated in this study. Players were instructed to perform three drop jumps on sand (DJS) and on rigid (DJR) surface. Drop height was set at 40cm. Sand pit (125cm x 125cm x 40cm) for DJS was placed on four force plates. DJR were performed on a separate force plate. Kinematic data was recorded via motion-capture system (Qualisys AB, Goteborg, Sweden) at 300Hz, force plates (Kistler, Winterthur, Switzerland) at 1500Hz and sEMG (Noraxon, Scottsdale, USA) for gastrocnemius medialis (GM) and tibialis anterior (TA) at 1500Hz. Jump height, ground contact

time and sEMG data for GM and TA were calculated via MATLAB (MathWorks, Natick, USA). Data was analysed using a 2x2 MANOVA (play type [beach-/handball players] x surface [sand/rigid]) (SPSS v.25, IBM, Armonk, USA), α was set at p≤0.05.
RESULTS: Using Pillai's trace, there was a significant effect for play type, F(6, 160)=8.592, p<.001, peta²=.179. However, separate univariate ANOVAs on the outcome variables revealed non-significant interaction effect between surface and play type F(6, 160)=.168, p=.683, peta²=.002 nor an effect of surface F(3, 80)=1.572, p=.214, peta²=.019. Whereas, there was a significant difference between play type and pre-activation F(3, 80)=15.951, p<.001, peta²=.166 and no significant difference between play type and jump height F(3, 80)=.815, p=.369, peta²=.010.
CONCLUSION: The findings suggest that both sand and firm ground athletes jump performance was greater on firm ground, which is in line with previous findings (2). Interestingly, sand specific athletes jumped higher on sand surface along with a lower pre-activation of the GM and TA in contrast, firm ground athletes activated their GM and TA earlier and performed reduced jump heights. Therefore, training intervention or athlete preparation is important when transferring between the indoor and outdoor season for those athletes who compete across surfaces.

JUMP PERFORMANCE MEASUREMENTS ON RIGID AND SAND SURFACES IN A STANDARDIZED LABORATORY SETTING – USING MARKER-BASED INFORMATION TO DETECT GROUND CONTACT TIMES

EILS, E.1, WIRTZ, S.1, BRODATZKI, Y.1, BÜSCH, D.2, ZENTGRAF, K.3, SZWAJCA, S.1
1: INSTITUTE OF SPORT AND EXERCISE SCIENCES, MÜNSTER UNIVERSITY, 2: INSTITUTE OF SPORT SCIENCES, OLDENBURG UNIVERSITY, 3: INSTITUTE FOR SPORTS SCIENCES, FRANKFURT UNIVERSITY

INTRODUCTION: Jump performance is an important factor in sand sports like beach handball. Measuring vertical jump height and ground contact times on sand surfaces is challenging because of the properties of the sand surface and the limited access to high-end measuring systems on outdoor sand pitches, e.g. force platforms. Therefore, the aim of the present study was to evaluate jumping performance on sand and rigid surfaces in a controlled laboratory situation by using marker-based information to detect ground contact times (gct) to enable full jump performance analysis on outdoor sand situations.
METHODS: 41 high-skilled team handball players (age: M=21, SD=4, height: M=183, SD=12, weight: M=79, SD=14, 21m/20f) performed Counter Movement Jumps (CMJ) and Drop Jumps (DJ) on a rigid and sand surface in a controlled laboratory situation. Jumping height and ground-contact-times were evaluated using marker- (Qualisys) and forced-based (Kister) systems. Jump performance on sand surfaces was measured using a sand-box that was placed on 4 force plates. 3 trials for each jump and surface condition were performed. Ground contact times in DJ were evaluated using the vertical ground reaction force (vGRF) and the vertical component of 3d-markers attached to the lower back and the foot. A repeated-measures ANOVA was calculated to detect differences in jump and ground contact performance (α-level=5%). ICC estimates and their 95% confident intervals were calculated based on absolute-agreement and 2-way mixed-effects model to detect correlation between gtc.
RESULTS: Results showed a significant influence of the factors jump (DJ, CMJ) and surface (rigid, sand) on vertical jump performance (F(1,39)=75.6, p<.001, ηp2=.66 and F(1,39)=15.5, p<.001, ηp2=.28). Athletes jumped higher with CMJ compared to DJ and on rigid compared to sand surfaces. No significant interaction jump x surface was found. A significant effect was also found for different detection methods of gct (F(2,80)=13.2, p<.001, ηp2=.25). Post-hoc analysis revealed that gct did not differ for vGRF and foot marker but for back marker compared to vGRF and foot marker. High correlations indicating excellent reliability were found for vGRF and foot as well as vGRF and back marker. Bland-Altman diagrams revealed that gct methods are in close agreement.
CONCLUSION: Jumping performance results are consistent with results from the literature but show a more distinct picture due to consistent laboratory conditions, especially for sand surface. Results of different gct detection methods show that using 3d-markers is most suitable to reliably detect gct without using force plates thus enabling full jump performance analysis on outdoor sand situations.

Oral presentations

OP-BN29 Motor learning and motor control: Children

THE ASSOCIATION BETWEEN SELF-PERCEIVED AND ACTUAL MOTOR COMPETENCE IN DRYLAND VS AQUATIC ENVIRONMENTS.

PRATT, N.
COVENTRY UNIVERSITY

INTRODUCTION: Perception of competence is an important factor in a child's personal development in the motor domain and influences fundamental movement skill (FMS) proficiency as well as physical activity levels (1).The most important time frame for the development of perception motor skill competence is from early to middle childhood due to adaptations in cognitive development, perception of performance during this time frame relates more to their actual performance (2). This study investigated the association between perception in performance and actual performance in both dryland and aquatic environments.
METHODS: British primary school children (n=96 males, n=105 females) with an average age 7.8 ± 0.63 years completed measures of self-perceived motor competence using the Pictorial Scale for Perceived Movement Competence in Young Children (PMSC) and the Aquatic Perceived Competence Pictorial Scale (APCPS). Teacher perception were recorded for both dryland and aquatic movements. Actual motor competence was assessed with the Test of Gross Motor Development–Second Edition (TGMD-2) incorporating 8 fundamental movement skills (3 locomotor and 5 object control). Aquatic motor competence was assessed by the Aquatic Movement Protocol (AMP) (3 Strokes and 8 aquatic skills). Tertile analysis were used to categorise the children into high, medium and low in perceived competence in both dryland and aquatic environments. Univariate ANCOVAs controlling for age with Bonferroni adjustments were used to examine the associations between actual and self-perceived data sets. Analysis across both process and product measures were analysed using 2 (gender) and 3 (high, medium and low perception of dryland and aquatic motor competence). Bivariate Correlations were implemented to carry out cross analysis between TGMD-2 and AMP measures.

RESULTS: Individuals with higher TGMD-2 scores were categorised within the high perceptions of performance and have significantly higher perceptions of performance compared to those with lower TGMD-2 scores (P=0.01). Children within the high aquatic perceived motor competence group have significantly higher scores on AMP compared to those categorised in the low perceived aquatic motor competence group (P=0.02). Individuals with greater aquatic motor competence had significantly higher teacher perception of performance scores (P=0.01) compared to those who had low aquatic motor competency.
CONCLUSION: Children with poorer actual performances in both AMP and TGMD-2 are found to have a lower perception of competence (4), similar results were found for aquatic actual motor competence with those showing poorer aquatic motor competence had lower self-perceptions. Teacher perceptions of performance in both dryland and aquatic environments were higher for those with greater aquatic and general motor competency scores. Indicating teacher's perceptions of motor competence to be a valid measure of actual ability.

A COMPARISION OF MOTOR PERFORMANCE BETWEEN GERMAN AND CHINESE 7- TO 8-YEAR-OLD CHILDREN

YIN, X.F.1, HOHMANN, A.2, ZHANG, B.1, YANG, S.T.1, YANG, T.1

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: According to Ortega (Ortega, et al. 2011), motor performance has been shown to be an important predictor of health across the lifespan. Studies show that the development of motor performance depends on movement experiences as well as growth and maturation processes and must be assessed in the context of age and gender (Ahnert, et al. 2009). In addition, country-based educational and cultural backgrounds have also been considered to be a major factor in influencing the development of motor abilities(Bardid, et al. 2015). Given the importance of motor performance in the motor field, the main aim of this study was to detect the existing performance differences within the broad spectrum of 7- to 8-year old age range in both boys and girls between German and Chinese primary schools children.
METHODS: Firstly, In order to establish the standardized norm of childrens motor performance in Shanghai of China, a total of 5723 children (Nmale=3115; age M = 92.62 mon, SD = 4.03) who completed the German Motor Test 6-18 (GMT 6-18; Boes & Schlenker, 2016) plus a ball throw, were included.
Secondly, Participants were 189 German children (Nmale=99; age M = 92.92 mon, SD = 5.57) from Fulda and 325 Chinese children (Nmale=179; age M = 92.20 mon, SD = 3.65) from Shanghai who completed revised GMT 6-18. The raw scores of nine test items were converted into norm values, respectively, based on two nation's norm. In line with the original manual of the GMT 6-18, the transformation methods were used for the conversion of the nine items norm values into four aspects of children's motor performance, namely strength, endurance, time-based coordination, and control-based coordination.
One-way ANOVA was executed to determine whether there were a significant interaction and/ or significant differences among four gender groups(Chinese boys group, Chinese girls group, German boys group and German girls group) in regard to four aspects of motor performance.
RESULTS: In terms of motor performance, the test result showed that there was a significant interaction effect among four gender groups in regard to norm scores of endurance ($F= 9.99$, $p=0.00$), strength ($F= 5.26$, $p<0.05$), time-based coordination ($F= 17.05$, $p=0.00$), except control-based coordination ($F= 0.85$, $p> 0.05$). Post hoc Analysis indicated that overall German children scored significantly better than the Chinese children on three of the four aspects of motor performance: endurance, strength, and time-based coordination.
CONCLUSION: This study provides valuable information on the cross-cultural comparison of motor performance levels in children using the revised GMT6-18. Overall, children from Germany demonstrated a higher level of motor performance. The results demonstrate growth environment and cultural background can affect the development of motor performance significantly(Bardid, et al. 2015). Thus, future research is needed to investigate the role of PE and organized sports on cross-cultural differences in motor performance.

MOTOR COMPETENCE IN SCHOOL CHILDREN IS CORRELATED WITH LEISURE TIME BUT NOT PE-CLASS ACTIVITY LEVELS

KRIJGER-HOMBERGEN, M., SCHIPHOF-GODART, L., HOEBOER, J., DE VRIES, S.I.

THE HAGUE UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: In The Netherlands most children benefit from 90 minutes of Physical Education (PE) per week. PE aims at developing children's motor competence (MC) by teaching a broad range of fundamental movement skills (FMS). MC is a determinant of children's physical activity (PA) level and consequent health outcomes[4]. The aim of this study was to examine the relative importance of PA during PE and leisure time PA in influencing MC.
METHODS: PA of 61 children (36 girls (m=9,25 +/- 1,56 years) and 25 boys (9,16 +/- 1,63 years) from a primary school in The Hague, The Netherlands was measured during 5 days (3 weekdays and the weekend) using data acquired from Actigraph (wGT3X-BT) accelerometers [5]. MC was measured by means of the Athletic Skills Track (AST), and all classes were given by a qualified PE-teacher[2]. Time spent in sedentary, light (LPA), moderate (MPA) and vigorous PA (respectively (LPA, MPA and VPA) was calculated in total, during PE, and during leisure time [1]. Due to small sample size, MC-levels were clustered into three categories using age-expected norm values (below average, average and above average), based on an existing five-category-scale[3].
RESULTS: MC was positively associated with leisure time MVPA (MVPA-LT) ($\rho = 0{,}338$) and negatively with sedentary activity ($\rho = -0{,}255$). No significant correlation between MVPA-PE and MC was observed.
CONCLUSION: Against our expectations, PA level during PE-class was not associated with MC in this sample, but MVPA-LT was. High activity levels during PE alone might not be key to develop MC. It might be discussed whether PE-lessons should focus instead on the development of a broad range of FMS and enjoyable PA rather than on MVPA, especially in children of below average MC-levels. It would be interesting to further explore the relation between MC and after-school MVPA, whether in organised sport setting or 'free play' in future studies.

NEW INSIGHT ON MOTOR BEHAVIOUR UNDERLYING FITNESS AND GRAPHO-MOTOR, FINE, AND GROSS COORDINATIVE SKILLS IN SCHOOL CHILDREN

BONDI, D.1, ROBAZZA, C.2, PIETRANGELO, T.1

UNIVERSITY OF CHIETI - PESCARA

INTRODUCTION: The neuromotor framework of grapho-motor skills has been widely studied. It has also been argued than fine and gross motor coordination may not share common bases. However, the spectrum of coordinative skills is a fundamental topic in the studies on motor development, with emerging attention on the use of modern technological devices. Using a multi-domain paradigm to approach motor behavior in the developmental stage, we aimed to evaluate the relationships among grapho-motor performance, coordination, and fitness in First Level School children.
METHODS: A first study involved 41 participants from the 2nd grade (24 girls and 17 boys) and 32 participants from the 4th grade (16 girls and 16 boys). Assessment included sport participation data, anthropometric measures, the Korperkoordinations Test fur Kinder (KTK), tracing performance using a tablet test (1), and the Handgrip Strength (HS) test.
A second study involved 132 participants from the 1st grade (60 girls and 72 boys) and 107 participants from the 2nd grade (52 girls and 55 boys). Additional measures entailed side dominance, the 4×10m shuttle run test, two tests of fine motor coordination (Thumb: a common intransitive test; Floppy: an original transitive test with increasing difficulty during the process), the velocity constraint in the tracing performance test, and Perceived Movement Skill Competence (PMSC) test.
RESULTS: In the first study, the Hopping sub-test of the KTK was the main node linking functionally gross-coordination and grapho-motor performance. Fine coordinative performances were shown to be strongly related to age and gender, and HS was found to be highly related to age. In the second study, older children performed significantly better on the shuttle run, Floppy, and Thumb tests. Factor analysis of tracing performance data revealed different structures by gender. In a network analysis, three domains were identified: anthropometric data with the shuttle run test, tablet performance variables, grapho-motor and fine coordination test. Side dominance didn't influence the results.
CONCLUSION: Grapho-motor skills and fine coordinative skills were shown to be strongly related, task-dependent and test-dependent. Moreover, the relationship among different motor domains was found to follow developmental trajectories differentiated by gender. Motor strategy planning may be a common basis in the execution of fine and gross-motor coordinative tasks, and it deserves further investigation. Motor control represents a crucial perspective for the evaluation of motor behaviour during early school age.

THE INFLUENCE OF SEX ON LEARNING A DYNAMIC BALANCE TASK IN PRIMARY SCHOOL-AGED CHILDREN

SCHEDLER, S.1, BRUECKNER, D.1, KISS, R.2, MUEHLBAUER, T.1

1: UNIVERSITY OF DUISBURG-ESSEN, 2: BIELEFELD UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: In youth, balance performance is affected by sex with girls outperforming boys (1). Therefore, sex might also influence the learning of a new balance task in youth. However, the influence of sex on exercise-induced adaptations in postural control in youth remains questionable. Thus, the present study aimed to identify possible sex differences in children during learning a new dynamic balance task.
METHODS: Thirty-two healthy children (50% girls, mean age: 8.5 ± 0.5 years) from two primary schools participated on that study. After anthropometrics were measured, participants were instructed to balance on a stability platform (i.e., stabilometer) in order to keep it as horizontal as possible, while gazing at a fixed target. After practicing this new complex balance task on two consecutive days (7 trials per day) and receiving knowledge of results (KR) after each trial, retention (no KR) and transfer tests (additional motor task) took place on day three to assess learning progress. To quantify performance, root-mean-square error (RMSE) of the stability platform was calculated for each trial and used for further analysis.
RESULTS: Girls and boys did not differ in age, height, mass, and leg length. RMSE values significantly decreased in both girls and boys over the two days of practice, indicated by significant main effects of day ($p < 0.01$, $d = 3.81$) and trial ($p < 0.01$, $d = 3.08$) for both sexes. Although, the main effect of sex showed a tendency towards significance ($p = 0.058$, $d = 0.72$), no ´sex´ × ´day´ × ´trial´ interaction was observed ($p > 0.05$, $d = 0.45$). On day three, girls obtained significantly smaller RMSE values than boys during retention ($p < 0.01$, $d = 1.01$) and transfer tests ($p < 0.05$, $d = 0.91$).
CONCLUSION: During practicing trials, girls and boys improved performance similarly. However, girls showed significantly better performances during retention and transfer tests on day three, indicating better learning compared to boys. These findings might be explained by earlier maturation of central nervous structures involved in postural control in girls (2). However, higher agitation in boys and potential sex-specific differences in focus of attention in youth could additionally serve as explanatory factors that should be analyzed in future research. Our findings may indicate that practitioners (e.g., teachers) should pay attention to sex-specific differences when designing balance training programs and/or evaluating the learning progress of balance tasks in youth.

OP-PM58 Endurance: Winter sports

TRAINING CHARACTERISTICS OF HIGHLY-TRAINED CROSS-COUNTRY SKIERS THROUGHOUT THE TRANSITION FROM JUNIOR TO SENIOR LEVEL

KARLSSON, Ø., LAAKSONEN, M., MCGAWLEY, K.

MID SWEDEN UNIVERSITY

INTRODUCTION: Reaching an international level in any endurance sport requires a large volume of systematic training performed over time. While the annual training characteristics of senior, elite-level cross-country (XC) skiers are well documented (1), limited data exist regarding the long-term training of developing XC skiers. The current study aimed to describe the training undertaken by a group of highly-trained XC skiers throughout their transition from junior- to senior-level athletes.
METHODS: In this retrospective cohort study, self-reported training data were obtained from 32 highly-trained female (n = 13) and male (n = 19) XC skiers for the season they turned 16 years old (y) until the season they turned 23 y. At the time of inclusion, 26 skiers (11 females and 15 males) had represented at least one of the Swedish national teams (senior, development or junior), and eight of these skiers (6 females and 2 males) had won at least one individual U23 or Junior World Championship medal. The remaining six skiers were part of a specialist ski university in Sweden, where selection is based on the potential to perform at a world-class level. Training data were organized by training form (endurance, strength, and speed), mode (e.g. on-snow skiing, roller skiing, running, and cycling), and intensity (using a 4-zone model), which were then divided into five annual training phases (transition, general preparation [GP], specific preparation [SP], competition [CP], regeneration).
RESULTS: Data from 155 seasons, including 59 026 individual training sessions and 94 964 h of training, were analysed. From age 16 to 22 y the total volume of endurance training increased from 472 ± 70 to 721 ± 86 h/yr ($p < 0.001$). Low-intensity training (LIT, below the first lactate threshold, <85% HRmax) and high-intensity training (HIT, above the first lactate threshold, >85% HRmax) increased from 414 ± 61 to 656 ± 72 h/yr ($p < 0.001$) and 58 ± 33 to 65 ± 16 h/yr ($p = 0.018$), respectively. The training-volume distribution developed progressively from a more even distribution across training phases at age 16 y (GP: 10.6 ± 1.8 h/wk; SP: 10.4 ± 1.5 h/wk; CP: 8.6 ± 1.5 h/wk) to a more traditional periodised model at age 22 y (GP: 17.5 ± 1.7 h/wk; SP: 12.7 ± 1.9 h/wk; CP: 11.1 ± 2.1 h/wk), whereby a higher proportion of the total training volume was performed in GP, and a lower proportion in SP and CP, as athletes developed.
CONCLUSION: In conclusion, this group of highly-trained XC skiers progressively increased their endurance training volume from age 16 to 22 y, to a level that is required of elite XC skiers. This increase in training volume was primarily due to an increase in LIT in the general preparation phase. In addition, training-volume distribution became more periodised as athletes developed from junior to senior level.

THE IMPORTANCE OF PACING BEHAVIOR FOR CURRENT AND FUTURE PERFORMANCE IN JUNIOR ELITE SPEED SKATING.

STOTER, I.K.1, HETTINGA, F.J.2, WIERSMA, R.1, VISSCHER, C.1, ELFERINK-GEMSER, M.T.1

1> UNIVERSITY MEDICAL CENTER GRONINGEN, UNIVERSITY OF GRONINGEN 2> NORTHUMBRIA UNIVERSITY

INTRODUCTION: Distribution of energy over a race, so called pacing, is important for performance in time-trial sports. Pacing behavior changes during adulthood and later elites appear to pace differently compared to their less performing peers (1). Nevertheless, the importance of pacing behavior at different stages of adolescence remains unknown. Therefore, the explanatory value of pacing behavior in three age categories for current and future performance in junior elite speed skating is investigated.
METHODS: 1500 m season best time, corresponding pacing behavior and 1500m season best time of 2 and 4 years later were obtained for 47 male elite junior speed skaters. This was done repeatedly with the same 47 skaters in three competitive seasons, namely 2010-2011, 2012-2013 and 2014-2015. By then, the speed skaters were respectively in the age categories 13-14 yrs, 15-16 yrs and 17-18 yrs. Linear regression analyses were executed for each age category separately to explain current and future season best times by pacing behavior. Season best times were converted to a percentage of the prevailing world record. Input variable pacing behavior was operationalized by the percentage of end time needed to cover each of the four race segments (i.e., 0-300 m, 300-700 m, 700-1100 m and 1100-1500 m).
RESULTS: At age 13-14 yrs, pacing behavior explained 56.1% of current season best times and 10.7% of season best times 2 years later. Relative slower 0-300 m and relative faster 300-700 m were associated with better current season best times. Better future season best times were associated with relative slower 0-300 m. At age 15-16 yrs, pacing behavior explained 23.9% of current season best times and 29.2% and 15.9% of future season best times, respectively 2 and 4 years later. Relative slower 0-300 m and relative faster 300-700 m were associated with better current season best times. Better future season best times over 2 years were associated with relative slower 0-300 m, 300-700 m and 1100-1500 m, whereas better future season best times over 4 years were associated with relative faster 300-700 m. At age 17-18 yrs, pacing behavior explained 44.4% of current season best times, but did not explain future season best times. Relative slower 0-300 m and relative faster 300-700 m were associated with better current season best times.
CONCLUSION: Pacing behavior was of explanatory value for current performance in all three age categories. However, there appears to be a temporary decline in the explanatory value at age 15-16 yrs, suggesting that other performance determining factors become more dominant than pacing for current performance at that age category. It is not likely that pacing behavior at age 15-16 yrs is less important as it was associated with future performance. Therefore, proper pacing behavior appears to be of importance for all junior age categories in speed skating.

DEVELOPMENT OF 1500-M PACING BEHAVIOUR IN ELITE YOUTH SHORT-TRACK SPEED SKATERS: A LONGITUDINAL STUDY.

MENTING, S.G.P., KONINGS, M.J., HUIJGEN, B.H.G., ELFERINK-GEMSER, M.T., HETTINGA, F.J.
THE UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: The goal-directed distribution of velocity (i.e. pacing behaviour) over an exercise task has proven to be a decisive factor in athletic competition. In the development of pacing behaviour as a self-regulatory learning skill, adolescence is theorised to be an important phase (1, 2). Particularly in developing athletes, a solid understanding of pacing regulation is a key component in performance optimisation and safeguarding athlete wellbeing (1). Short-track speed skating features head-to-head races in a highly interactive environment in which skaters must balance an optimal velocity distribution with tactical decisions on drafting, overtaking and collision avoidance (2). The aim of the current research was to, for the first time, longitudinally study the development of pacing behaviour of elite youth athletes in short-track speed skating.
METHODS: Lap times were analysed of elite short-track speed skaters in the age range 16 to 19 years (n=473, 1184 observations), performing in one or more 1500-m races (13.5 laps) during Junior World Championships between 2010 and 2018. Race type was classified as fast or slow when the winner of a particular race was faster or slower than the average completion time of all race winners. Races were divided into four sections (laps 1-3, laps 4-7, laps 8-11 and laps 12-14). Multilevel prediction models in which the seasons (level-1) are nested within the skaters (level-2) were used to analyse the effect of race type, sex and age on relative section time (RST; i.e. the percentage of total race time spent in a specific section of the race). Analyses were carried out in MLwiN ($p<.05$).
RESULTS: The RST of laps 1-3 and laps 4-7 increased with age, whereas the RST of laps 8-11 and laps 12-14 decreased with age. The RST of laps 1-3 was higher in males compared to females. There was no difference in RST between sexes in laps 4-7. The RST of laps 8-11 and laps 12-14 were lower in males compared to females. The RST of laps 1-3 and laps 4-7 were lower in fast races, compared to slow races, and vice versa for laps 8-11 and laps 12-14.
CONCLUSION: The pacing behaviour of youth short-track skaters develops throughout adolescence and skaters adopt a relatively slower start and faster finish, as previously theorised (2). Young male skaters exhibit a more conservative pacing behaviour compared to females. Additionally, fast races are more evenly paced compared to slow races, with slow races having a predominantly slow first half and fast finish. Coaches should take under consideration that the pacing behaviour of elite youth skaters develops during adolescences and differs between sexes. Furthermore, coaches are advised to prepare skaters for the differences in velocity distribution between race types.

RIFLE CARRIAGE DECREASES SPEED AT LACTATE THRESHOLD, ANAEROBIC ENERGY CONTRIBUTION AND PERFORMANCE IN BIATHLON SKIING.

JONSSON KÅRSTRÖM, M., MCGAWLEY, K., LAAKSONEN, M.S.
SWEDISH WINTER SPORTS RESEARCH CENTRE, MID SWEDEN UNIVERSITY

INTRODUCTION: Biathlon is an endurance sport combining rifle shooting and intermittent cross-country skiing while carrying a rifle (minimum weight 3.5 kg). Previous studies have shown that the skiing component explains 60% of overall biathlon performance (1) and that rifle carriage affects different physiological responses such as blood lactate, oxygen uptake (VO2) and heart rate during skiing (2, 3). However, the effects of rifle carriage on skiing performance and variables such as maximal VO2 (VO2max), lactate threshold, efficiency of movement and anaerobic energy contribution have not yet been investigated.
METHODS: Seventeen biathletes (9 females, 8 males; age 23.0 (3.3) years, VO2max 59.8 (7.3) mL/kg/min), competing at a national and/or international level, and completing approximately three biathlon training sessions/week with the rifle on the back, performed a submaximal incremental test and a 900–1000-m maximal time-trial (TT) using treadmill roller-skiing (gear 3 skating technique) on two occasions separated by at least 48 hours. One condition involved carrying the rifle on the back (WR) and the other no rifle (NR), with the order randomized. The VO2 and skiing speed at 4 mmol/L of blood lactate (VO2@4mmol and speed@4mmol, respectively), gross efficiency (GE), metabolic aerobic (MRae) and anaerobic (MRan) rates, and VO2max were determined.
RESULTS: Submaximal VO2 at all levels and GE (16.7 (0.9) vs 16.5 (1.1) %, $p<0.05$) were higher for WR compared to NR, while speed@4mmol (11.3 (1.5) vs 11.7 (1.5) km/h, $p<0.05$) and MRan (27.3 (6.7) vs 30.5 (7.6) kJ/min, $p<0.01$) was lower. There were no differences in VO2@4mmol or MRae between the two conditions. The mean speed during the TT was higher for NR compared to WR (16.5 (1.5) vs 15.5 (1.4) km/h, $p<0.001$), but there was no difference in VO2max. Mean speed during the TT was correlated to speed@4mmol (WR: $r=0.810$, $p<0.001$; NR: $r=0.659$, $p<0.01$), GE (WR: $r=0.691$; NR $r=0.529$, both $p<0.05$) and VO2max (WR: $r=0.514$; NR: $r=0.526$, both $p<0.05$). Speed@4mmol together with MRan explained more than 80% of performance in the TT (WR 83.7%, NR 81.5%). There was no difference between male and female biathletes in response to rifle carriage, although the relative mass of the rifle was higher for the females (5.6 (0.4) vs 5.0 (0.4) % of body mass, $p<0.01$).
CONCLUSION: According to this study, the most important variables for skiing speed in biathlon seem to be the speed at lactate threshold combined with the metabolic anaerobic rate, both of which were lower for skiing with the rifle compared to without. In addition, GE was related to biathlon performance and was also affected by rifle carriage. Thus, to improve skiing performance in biathlon, improving speed at the lactate threshold, anaerobic energy delivery and GE while carrying the rifle are recommended.

A COMPARISON BETWEEN DIFFERENT ESTIMATES OF ANAEROBIC ENERGY PRODUCTION DURING SUPRAMAXIMAL ROLLER-SKIING EMPLOYING THE DOUBLE POLING AND DIAGONAL STRIDE SUB-TECHNIQUES

ANDERSSON, E.P., LÖGDAL, N.

SWEDISH WINTER SPORTS RESEARCH CENTRE

INTRODUCTION: The maximal accumulated oxygen (O2) deficit (MOAD) method is frequently used to estimate anaerobic energy production during supramaximal exercise (Medbø et al., 1988). The method is based on a linear relationship between submaximal oxygen uptake (VO2) and speed, from which a VO2 demand at supramaximal speeds is estimated by extrapolation. For classic cross-country roller-skiing, a linear relationship between submaximal VO2 and speed has been observed for the diagonal stride (DS) sub-technique. However, the relationship between submaximal VO2 and speed appears to be non-linear for the double poling (DP) sub-technique (Andersson et al., 2017). Hence, this study aimed to compare two different procedures for estimating the O2 deficit during treadmill roller-skiing using the DP and DS sub-techniques.
METHODS: Sixteen male cross-country skiers (age, 26 ± 5 yr; body mass, 77 ± 7 kg; height, 182 ± 6 cm) performed two continuous submaximal protocols, each consisting of eight 4-min stages, along with two supramaximal all out 4-min time trials (TT), one using each sub-technique (DP [1.5° incline] and DS [6.5° incline]) on separate occasions in a randomized order. Speed and VO2 were measured continuously during the TT. The linear relationship between treadmill speed and VO2 during the final minute of each submaximal stage was used for the MAOD method, and an alternative procedure, based on an exponential relationship between submaximal speed and VO2 (MAODexp) was used. The two regression equations were used to estimate the VO2 demands and O2 deficits during the TT for both DP and DS.
RESULTS: The mean speeds during the TT were 25.9 ± 1.2 and 13.6 ± 0.5 km/h, in DP and DS respectively, with average VO2 values of 58 ± 4 and 62 ± 4 mL/kg/min ($P < 0.001$) and peak VO2 values of 66 ± 4 and 69 ± 4 mL/kg/min ($P < 0.01$). The post-TT blood lactate concentrations were 11.7 ± 2.1 and 12.6 ± 2.6 mmol/L in DP and DS, respectively. For DP, the estimated VO2 demand was 14 ± 7% higher for the MAODexp (71 ± 8 mL/kg/min) than the MAOD (62 ± 4 mL/kg/min) procedure ($P < 0.001$). The corresponding O2 deficits were 49 ± 23 and 15 ± 13 mL/kg for MAODexp and MAOD, respectively ($P < 0.001$), resulting in a mean difference of 35 ± 20 mL/kg. For DS, the estimated VO2 demand was 77 ± 11 mL/kg/min for the MAODexp and 76 ± 4 mL/kg/min for the MAOD procedure with corresponding O2 deficits for MAODexp and MAOD of 59 ± 36 and 58 ± 9 mL/kg, respectively, resulting in a mean difference of 1 ± 31 mL/kg. Corresponding typical errors for the two O2 deficit estimates in DP and DS were 14 and 22 mL/kg.
CONCLUSION: The main finding of the current study was the high disagreement between the MAODexp and MAOD procedures in DP. Although the same comparison in DS yielded similar average estimates of anaerobic capacity, the overall agreement was low as indicated by the high typical errors.

EXTERNAL COMPRESSION TROUSERS SLIGHTLY IMPROVE SYSTEMIC HAEMODYNAMICS DURING CYCLING IN ENDURANCE-TRAINED AND UNTRAINED MALES.

COTTER, J.D.1, LIND-HOLST, M.2, POTT, F.C.2, BOUSHEL, R.2,3, AUGUSTESEN, H.2, HELGE, J.W.2

1: UNIVERSITY OF OTAGO, 2: UNIVERSITY OF COPENHAGEN, 3: UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: Compression garments are often assumed to compress veins and improve venous return to the right atrium, but such an effect has not – to our knowledge - been shown for normal exercise, and may depend on aerobic fitness because of fitness-related differences in cardiovascular function. We anticipated that any compression-mediated improvements in cardiovascular function might be more evident in untrained people during exercise but not following exercise.
METHODS: We tested this hypothesis by directly measuring central haemodynamic effects of compression trousers during upright exercise in untrained and endurance-trained participants (maximal oxygen uptake: 42 ± 5 and 69 ± 7 vs. mL O2/min/kg; n=9 for both), using a randomised crossover order within one session.
RESULTS: Wearing compression trousers led to small increases in mean central venous pressure (95%CI: by 0 – 2 mm Hg) and mean arterial pressure (0 – 4.5 mm Hg) during exercise and recovery, but these effects were not measurably altered by fitness. A small increase in cardiac output (indocyanine green) was attributable to an inotropic effect without any observable attenuation in heart rate during exercise or recovery. Indices of aerobic and anaerobic metabolism were largely unclear but likely to be small anyway.
CONCLUSION: External compression by way of regular compression trousers can alter central haemodynamics during and following moderate intensity endurance exercise, irrespective of one's cardiovascular capacity, but not by enough to measurably attenuate the heart rate.

OP-PM71 Injury prevention III

INVESTIGATION OF CUMULATIVE SPORT RELATED CONCUSSIONS ON COGNITIVE PERFORMANCE AND HEMODYNAMIC RESPONSE

COENEN, J., HENCKERT, S., HELMICH, I.

GERMAN SPORT UNIVERSITY

INTRODUCTION: Sport related concussion is a complex sport related injury. Athletes who experience an increasing number of concussions are at a greater risk of cumulative impairments (1). The aim of the present project is to gain a greater understanding of a cognitive impairment post injury and identify possible underlying metabolic alterations. Using the athletes' performance on Stroop task to score selective attention and Near-Infrared Spectroscopy (fNIRS) to detect metabolic alterations the present project fosters the following hypotheses: for cognitive performance, we hypothesize that there will be a positive correlation between number of concussions and variance in performance, as measured by Stroop task time. Additionally, we hypothesize that there will be a correlation between number of concussions and hemodynamic response.

METHODS: Fifty-two athletes actively engaging in sports were selected for this project (age: M = 22.42 years, SD = 8.46; sex: 43 males, 9 females; sports: 13 American football, 16 rugby, 16 hockey & 7 other). As part of the inclusion criteria, all athletes had experienced at least one concussion (M = 1.81, SD 3.36). Performance scores were gathered electronically through Stroop task. During the Stroop task hemodynamic changes were additionally collected from the frontal cortices using fNIRS.
RESULTS: There exists a positive correlation between variance of Stroop task time and number of concussions (rs(48)= 427, p= 0.002). Additionally, a positive correlation between deoxy hemodynamic changes and number of concussions (rs(45)=.294, p= 0.047).
CONCLUSION: The current project presents a significant relationship between number of concussions with cognitive performance and hemodynamic response. It seems that the amount of concussions received disturbs the athletes' selective attention during Stroop task. As sports demand a high level of attention, when this is impaired it could present a vulnerable environment for further injury. Therefore, it is necessary to gain a greater understanding of the risks pertaining to sport related concussions. Through this knowledge the injury could be managed more objectively and limit cumulative impacts by preventing return-to-play too soon.

GOALKEEPER INJURIES IN AN ELITE FOOTBALL CLUB: A DIFFERENT PATTERN COMPARED TO FIELD PLAYERS

LARRUSKAIN, J.1,2, LOPEZ, J.M.1,2, BIKANDI, E.1, SANTISTEBAN, J.M.1,2, MARTIN-GARETXANA, I.1,2, GIL, S.M.2, LEKUE, J.A.1,2
1: ATHLETIC CLUB, 2: UNIVERSITY OF THE BASQUE COUNTRY

INTRODUCTION: The distinct activity profile of football goalkeepers compared to field players suggests the need for tailored preventive strategies in order to avoid the negative performance, economic and health consequences of injuries. As the literature is scarce in this regard,[1,2] the aim of this study was to describe the epidemiology of goalkeeper injuries in an elite football club and to compare it to that of field players.
METHODS: Injuries and individual exposure time in Athletic Club's male goalkeepers (n=158 player-seasons) and field players (n=1354 player-seasons) were prospectively recorded by the medical staff over seven seasons (2011-2018) following the FIFA consensus. Players were divided in ≤under(U)16 (U12, U14 and U16) and ≥U19 (U19, Reserves and First team) groups. Injury burden was calculated as the number of absence days due to injury/1000 hours of exposure. Injury burden ratios were compared using z-tests, and the percentage of match availability using Student's t-test.
RESULTS: Compared to field players, the percentage of match availability was higher in ≥U19 goalkeepers (mean±SD, Goalkeepers vs. Field players: 88.9±17.1 vs. 84.0±20.3%, p=0.03), but lower in ≤U16 goalkeepers (84.9.4±18.5 vs. 89.5±13.6%, p=0.05). The burden of training injuries was similar in the ≥U19 group (92 vs. 89 days lost/1000 h, p=0.12), but 1.6 times higher in ≤U16 goalkeepers (143 vs. 90/1000 h, p<0.01). The burden of match injuries was 2 times lower in ≥U19 goalkeepers (309 vs. 615/1000 h, p<0.01), but 1.3 times higher in ≤U16 goalkeepers (899 vs. 667/1000 h, p<0.01). In both ≥U19 and ≤U16 groups, the burden of upper limb, quadriceps, spondylolysis, and growth-related injuries was higher in goalkeepers; in contrast, the burden of hamstring, knee joint/ligament and ankle joint/ligament injuries was higher in field players. The predominant sources of absence were upper limb injuries (28% of all absence days), knee joint/ligament injuries (16%), and quadriceps strains (11%) in ≥U19 goalkeepers, and growth-related injuries (40%), upper limb injuries (14%) and spondylolysis (10%) in ≤U16 goalkeepers. No goalkeeper sustained an ACL rupture.
CONCLUSION: The different injury profile observed in goalkeepers calls for tailored prevention strategies based on their specific activity profile. Interventions aimed at improving their physical conditioning, the monitoring of appropriate load metrics and the management of psychosocial stress seem necessary. The high injury burden in the younger goalkeepers is concerning, and consideration of their growth and maturation characteristics and avoidance of early specialization are important.

ASYMMETRY OF THE INTERNAL OBLIQUE IN ADOLESCENT TENNIS PLAYERS WITH FEMOROACETABULAR IMPINGEMENT: A VOLUMETRIC MRI STUDY

KUX, J.1, BALIUS, R.2, ALOMAR, X.3, RUIZ-COTORRO, A.4, SANCHIS-MOYSI, J.5
1.GESUNDHEITSCAMPUS GÖTTINGEN, GERMANY. 2 CONSELL CATALÂ DE LESPORT. GENERALITAT OF CATALONIA, BARCELONA, SPAIN. 3 CLÍNICA CREU BLANCA, BARCELONA, SPAIN. 4 REAL FEDERACIÓN ESPAÑOLA DE TENIS

INTRODUCTION: The prevalence of femoroacetabular impingement (FAI) is increasing in young tennis players (1). It has been hypothesized that bilateral imbalances in the lumbo-pelvic musculature may play a role (2). Healthy young tennis players display bilateral asymmetries in the abdominal muscles (3). The main aim was to determine differences in the degree of asymmetry of rectus abdominis (RA), external oblique (EO), internal oblique (IO) and transversus abdominis (TA) muscles, in tennis players (TP) with FAI and healthy tennis players.
METHODS: Thirty male TP participated in the study (15.4±2.2 years, playing frequency 5-6 sessions/week, at least 2 years), 15 had FAI (6 unilateral dominant leg, 6 unilateral non-dominant, 2 bilateral) and 15 were healthy, asymptomatic TP (CG). All TP used the two-handed backhand stroke. The volume of RA, EO, IO and TA was determined independently by MRI in the dominant (arm holding the racket) and non-dominant side. Slice thickness was 2 mm without inter-slice interval. MRI images were manually segmented. Side-to-side differences were assessed using Student's paired t-tests and differences between groups using ANCOVA with Bonferroni-Holm post hoc test. Statistical significance was set at P<0.05.
RESULTS: In the FAI group, the volume of RA, EO and IO was greater in the non-dominant than in the dominant side (16.2±11.4, 18.1±19.9 and 7.5±12.3%, respectively, all P<0.05), whereas the TA displayed similar volumes in both sides (asymmetry 2.1±15.7%, p=0.65). In the CG, the volume of RA and EO was greater in the non-dominant than in the dominant side (16.2±11.4 and 19.9±13.3%, respectively, both P<0.05), whilst the volume of IO and TA was similar in both sides (asymmetry 0.9±13.6, p= 0.58 and 1.2±19.2%, p=0.60, respectively).
CONCLUSION: This study shows, for the first time, that FAI is associated with an asymmetric development of the internal oblique in young tennis players, whereas in healthy tennis players the internal oblique is symmetric side-to-side.

THE ASSOCIATIONS OF RS1107946 POLYMORPHISM IN THE COL1A1 WITH FATIGUE-FRACTURE AND MUSCLE INJURY IN JAPANESE ATHLETES

MIYAMOTO-MIKAMI, E.1, KUMAGAI, H.1, KIKUCHI, N.2, KAMIYA, N.3, KOHMURA, Y.1, SUZUKI, K.1, NAITO, H.1, MIYAMOTO, N.1, FUKU, N.1

1. JUNTENDO UNIVERSITY, 2. NIPPON SPORT SCIENCE UNIVERSITY, 3. TENRI UNIVERSITY

INTRODUCTION: Properties of tissues, such as bone mineral density and skeletal muscle stiffness, are associated with risk for sports-related injuries (1,2). One of the candidate polymorphisms affecting bone mineral density is the rs1107946 A/C polymorphism located in the promoter region of the collagen type I alpha 1 chain gene (COL1A1) (3). Type I collagen is an abundant protein in bone and is also a major component of intramuscular connective tissues. We hypothesized therefore that the rs1107946 polymorphism is associated with risk of both fatigue fracture and muscle injury in athletes, and tested this hypothesis.
METHODS: In study 1, the history of sports-related injury was assessed by questionnaire in 1680 Japanese athletes (males: n = 1145, females: n = 535). In study 2, the training exposure hours and injury occurrences in a year were investigated in 391 Japanese athletes (males: n = 287, females: n = 104). In both studies, we focused on fatigue fractures and non-contact muscle injuries diagnosed by a doctor, and the rs1107946 A/C polymorphism in the COL1A1 was analyzed using TaqMan SNP Genotyping Assay in all subjects.
RESULTS: In study 1, female subjects with the history of fatigue fracture showed a higher frequency of C allele carriers than those without the history after adjustment for main sport and competitive level (CC+AC vs. AA: Odds Ratio [OR] = 2.44, 95% confidence interval [CI] = 1.17-5.77, adjusted for main sport, playing years, and competitive level). The association was prominent in female subjects with irregular menstruation (n = 133, OR = 5.11, 95% CI = 1.29-34.50, adjusted for main sport, playing years, and competitive level). Female subjects with the history of muscle injury showed a lower frequency of C allele carriers than those without the history (CC+AC vs. AA: OR = 0.46, 95% CI = 0.24-0.91, adjusted for main sport, playing years, and competitive level). In study 2, C allele carriers showed a low incidence of muscle injury compared with AA genotype carriers (Hazard Ratio = 0.35, 95% CI = 0.13-1.04, P = 0.0453, adjusted for main sport and competitive level) with borderline significance in all subjects.
CONCLUSION: Our results suggest that C allele of the COL1A1 rs1107946 polymorphism has the opposite effects (i.e., susceptible and protective) against fatigue fracture and muscle injury in Japanese athletes.

PRE-SEASON HIP/GROIN STRENGTH AND HAGOS SCORES ARE ASSOCIATED WITH PROSPECTIVE INJURY IN PROFESSIONAL FOOTBALL PLAYERS

BOURNE, M., WILLIAMS, M., JACKSON, J., WILLIAMS, K., TIMMINS, R., PIZZARI, T.

GRIFFITH UNIVERSITY

INTRODUCTION: Hip and groin injuries are a significant cause of time lost from training and competition in elite football (soccer) and an improved understanding of predisposing risk factors is needed to inform the design of effective injury prevention practices. The purpose of this study was to explore the association between hip/groin injury in professional football players and pre-season assessment of 1) hip adductor and abductor strength using a novel field-test; and 2) the Copenhagen Hip and Groin Outcome Score (HAGOS).
METHODS: In total, n=204 elite male football players from ten professional clubs were recruited. During the pre-season, players underwent assessments of hip adductor and abductor strength and completed a physical copy of the HAGOS. In-season hip/groin injuries were assessed and reported by team medical staff. Data reduction was conducted using principal component analysis. The subsequent factor component for HAGOS, and three factor components for strength and imbalance measures, were entered with age into a multivariate logistic regression model to determine their association with prospectively occurring hip/groin injury.
RESULTS: Twenty-four players suffered at least one hip/groin injury throughout the 2017-18 competitive season. Results revealed that the principal component for between-limb abduction imbalance (peak strength in the preferred [kicking] limb – non-preferred limb) (OR = 0.61, 95% CI = 0.40 to 0.92, p=0.017), and the principal component for HAGOS (OR = 0.80, 95% CI = 0.64 to 0.99, p=0.040) were independently associated with a reduced risk of future hip/groin injury. Receiver operator curve analysis of the whole model revealed an area under the curve of 0.76.
CONCLUSION: This study has provided the first evidence to suggest that a hip abduction strength imbalance favouring the preferred kicking limb, and a higher HAGOS (indicative of better hip/groin health) obtained at pre-season, reduce the likelihood of subsequent hip/groin injury in professional football players. These findings may have implications for injury screening and may inform the design of targeted injury prevention interventions in elite football.

INJURY EPIDEMIOLOGY AND IMPACT OF INJURIES IN THE HYUNDAI A-LEAGUE.

LU, D., MCCALL, A., JONES, M., KOVALCHIK, S., STEINWEG, J., GELIS, J., DUFFIELD, R.

UNIVERSITY OF TECHNOLOGY SYDNEY, FOOTBALL FEDERATION AUSTRALIA

INTRODUCTION: Soccer injuries result in negative implications for financial, health and performance outcomes. Identifying the injury situation by multiple methods can guide effective multidisciplinary injury prevention approach. Therefore, the aim of the study report injury epidemiology and the financial and performance costs of those injuries in the Hyundai A-League between seasons 2012/13 to 2016/17.
METHODS: Injury incidence, missed matches and injury characteristics were collected from Season 2012/13 to Season 2016/17 from the Football Federation Australia Injury Surveillance System. Injuries were reported on a weekly basis by the physiotherapist of each team for all 27 rounds/season. Collected injury characteristics included severity, type, region, and mechanism. Additionally, financial cost was calculated based on missed matches, salary cap and match opportunities. Generalised linear models were used to estimate the injury rate or cost for each season and t-test statistics was used to find differences between seasons. Further, the mean of team rank, league points, goals, match outcome (i.e. win/lose/or draw) was used to dichotomise teams resulting in good or poor performance. The relative risk of 1) injury incidence and 2) missed matches was performed using generalised linear models.
RESULTS: A total of 765 injuries and 2643 missed matches were reported from the 5 seasons, though no between-season differences existed ($p>0.05$). There were significantly more severe injuries (>4 missed matches) than mild (1 missed match) ($p<0.05$) and moderate (2-4 missed matches) ($p<0.05$) in Season 2014/15. Muscle/Tendon and Joint/Ligament type injuries were the most common injuries though both remained stable over the 5 seasons ($p>0.05$). Similarly, thigh injuries, particularly the hamstrings, had the highest contribution of

injury regions which remained stable over 5 seasons (p>0.05). Financial cost ranged between $181,700/team to $330,290/team, peaking in season 2014/15 (p<0.01). Increase in injury incidence resulted in more goals conceded (RR:1.26;p<0.01). Missed matches increased the likelihood of less league points (RR:1.13;p<0.01), more goals conceded (RR:1.24;p<0.01), less wins (RR:1.13;p<0.01) and more draws (RR:1.12;p<0.01).
CONCLUSION: Injuries have remained stable in the Hyundai A-League between 2012/13 to 2016/17 with concomitant stability in injury severity, missed matches and financial cost. The prevalence and severity of hamstring muscle injuries warrant more research and resources towards these injuries in Australia. However, stakeholders should be mindful of the trends and proportion contributions in less common injury types and regions. Given the significant contribution to financial and performance costs, injury incidence and missed matches should be considered concurrently to evaluate club medical practices and guide further resource allocation for injury prevention and research.

IS-MI05 Consumer digital technologies for health and sports performance

CONSUMER DIGITAL TECHNOLOGIES FOR HEALTH AND SPORT: GLOBAL AND FUTURE PERSPECTIVES

ABT, G.

THE UNIVERSITY OF HULL

Digital technologies are having an impact on most aspects of our life. These innovations have led to new digital technologies in the fields of health and sport, such as the physical activity tracker [1], the digital tattoo [2], and the GPS device for the sports pitch [3]. The rise of the smartphone, mobile networks, and wireless protocols have enabled the development of apps, wearables, and the Internet of things. The hype-cycle model [4] allows us to examine the rise and fall of these technologies, particularly in an age where the rate of technological development is exponential [5]. There is also the challenge of low long-term adherence rates for apps and wearable devices [6]. Despite this, new technologies such as augmented/virtual reality [7] and artificial intelligence [8] could be truly transformative. However, if digital technologies are to deliver on their promise of personalised medicine [9] and increased sport performance [10], we have to ensure that these technologies are valid, reliable, and effective at what they claim to do.

WEARABLE TECHNOLOGY FOR HEALTH

BENSON, A.

SWINBURNE UNIVERSITY OF TECHNOLOGY

The quantified-self movement [1] has led to an increase in the popularity of consumer sensor and wearable technology that integrate accelerometers, gyroscopes, magnetometers or photoplethysmography (eg smart phones, watches and inertial measurement units) for health and fitness [2]. Having contemporary tools to integrate into exercise prescription, measurement and physical activity promotion are imperative. Better compliance to guidelines and improvements in disease management have been reported when technology-based support is incorporated [3,4]. However, consumers and health professionals need confidence that these devices can consistently and accurately measure the intended outcome for individuals of all fitness levels for them to be used as part of an effective and safe intervention strategy. Currently, evidence on the reliability and validity of these devices is limited with varied quality depending on the outcome of interest [5]. This session will discuss the current status of the validity and reliability of wearable technologies and the effectiveness when they are used for measurement, provision of feedback and the promotion of physical activity in the community.

CONSUMER DIGITAL TECHNOLOGIES FOR SPORTS PERFORMANCE MEASUREMENT

BALSALOBRE-FERNÁNDEZ, C.

AUTONOMOUS UNIVERSITY OF MADRID

The study and development of 'monitoring' protocols have been a main area of interest for injury prevention, physical performance optimization and recovery purposes over the last decade or so [1]. Traditionally, different laboratory-based technologies have been used for these tasks; for example, force platforms, electrocardiograms or 3D video-systems. However, their use is often exclusive to sports performance laboratories which some athletes and teams can't access. Taking their place, new technologies based on wearable sensors and smartphone apps have arisen as a more cost-effective and mobile solution to monitor important variables in the field [2]. A quick analysis of app stores reveals that fitness apps are quite popular; in January 2017, there were over 100000 apps of this category available to download [3]. The problem is that among the enormous variety of wearable devices and apps available, very few have been validated against laboratory equipment. Therefore, validation studies are crucial both for researchers and consumers, since they help to identify which devices and apps are valid and reliable, and which are just a product of marketing.

IS-SH08 'Sport' - Public health or public harm?

IS SPORT BAD FOR OUR (PUBLIC) HEALTH?

WEED, M.

CANTERBURY CHRIST CHURCH UNIVERSITY

Introduction
Claims that sport is good for our health are pervasive, with some calling it the "magic bullet" for population health markers and outcomes (e.g. obesity, type II diabetes). This has led governments to invest in sport, with the underlying assumption that sport can be used as a public health intervention to increase physical activity among the less and least active to deliver improvements in the physical health of the population.
Method
This paper reviews evidence from controlled designs and conducts two primary time-series analyses of current and historical national survey data for the UK to explore evidence for the effectiveness of sport as a public health intervention for physical health.
Results and Discussion
While there is extensive efficacy evidence linking sport participation to improvements in physical health, there is no evidence from controlled designs to support, and some evidence from time-series analyses to undermine, the effectiveness of sport as a public health intervention to increase physical activity among the less and least active (Weed, 2016). The analysis of UK national survey shows that, despite sustained government investment, sport participation has stagnated or fallen from 1990, while since 1997 an additional 10% of the population have become physically active in ways that do not include sport. Thus, there is no evidence that sport is effective in improving physical health at population level, but some evidence that physical activity interventions other than sport may be effective. As such, in comparison to the opportunity cost of not implementing alternatives that promote wider physical activity choices that do not privilege sport, it is possible that investment in sport as a public health intervention may cause net harm to the physical health of populations.

IS SPORT POLICY BAD FOR PUBLIC HEALTH?

KAY, T.

UNIVERSITY OF STIRLING

This paper is part of the Invited Symposium - 'Sport' - public health or public harm? (Chair - Prof. Louise Mansfield).
Are current efforts to promote physical activity through sport harming public health more than they are enhancing it? More particularly, are they failing those who can potentially benefit most – those at the lower end of the social gradient, among whom physical activity is lowest, health poorest, and life expectancy shortest? This presentation first demonstrates why members of disadvantaged groups have most to gain from becoming active through sport and are priorities for sport initiatives to raise physical activity levels. It then reviews national and transnational sport and physical activity strategies to argue that efforts to engage people of low socio-economic status are undermined by their reliance on inappropriate disciplinary perspectives. It highlights a disproportionate focus on promoting individual health behaviour change at the expense of addressing social processes, and contrasts this with the wider field of public health in which structural factors are recognised as being more influential on health than individual behaviour. The presentation then presents evidence that sport practitioners and deliverers show greater sensibility towards health inequalities and the complex constraints affecting inactive people, and suggests that the failure to address the social determinants of health in sport is largely confined to the sport policy and research communities. It proposes a number of steps to break down knowledge silos to enhance research, policy and practice

THE ROLE OF VOLUNTARY SPORTS ORGANISATIONS IN DELIVERING PHYSICAL ACTIVITY ON PRESCRIPTION (PAOP) – THE CASE OF SWEDEN

AGGESTÅL, A.

UMEÅ UNIVERSITY

Globally, public health is a political priority with governments´ increasingly supporting interventions in civil society for reaching health related objectives. There is a worldwide public health focus on increasing population levels of physical activity by prescribing exercise as a preventive strategy against the risk of developing a range of non-communicable diseases. The employment of voluntary sports organisations is increasingly becoming the mechanism for physical activity promotion and the implementation of interventions to raise physical activity levels. This study explores the Swedish Sports Confederation´s (SSC) implementation of physical activity on prescription (PAOP). While studies exist about the effectiveness of exercise referral schemes and programs, for participant adherence, increasing physical activity, fitness or health indicators, knowledge about the role of different organisations in delivering such schemes has been called for. In heeding this call, this study interviewed representatives from the 21 Regional Sports Federations in Sweden involved in leading, organizing and delivering physical activity. The results of the interviewee data provide detail on how PAOP is delivered and received. The presentation summarizes the findings and illustrates the complex barriers and facilitators involved in stimulating and engaging previously inactive participants in sustained physical activity in the Swedish Sports Confederation system.

09:45 - 11:15

Invited symposia

IS-PM12 Cardiac, vascular and cerebrovascular adaptation to hypoxia at rest and during exercise; lessons from high altitude natives

CARDIAC STRUCTURE, ABSOLUTE BLOOD VOLUME AND EXERCISE CAPACITY IN HIGH ALTITUDE NATIVES

STEMBRIDGE, M.

CARDIFF METROPOLITAN UNIVERSITY

Whether at sea level of high altitude, the heart is central to the oxygen transport chain. In Sherpa, life-long exposure to high altitude is associated with differences in cardiac structure and function in comparison to sea level dwellers, characterised by a smaller left ventricular end-diastolic volume and stroke volume. The lower volumes may limit maximal cardiac output, and therefore the oxygen delivery achievable during exhaustive exercise. However, this has traditionally not been considered a limiting factor in exercise capacity at high altitude due to the greater limitation to diffusive steps in the oxygen transport chain. Recently, this view has been challenged, as haemoglobin concentration has been shown to be negatively related to exercise capacity in Sherpa, and those with the lowest haemoglobin concentrations demonstrated the greatest cardiac output at maximal exercise. In this symposium, data from multiple high altitude expeditions will be presented to explore the role of cardiac structure and function, haemoglobin concentration and absolute blood volume in limiting exercise capacity. Collectively, these findings provide evidence for unique haematological and cardiac adaptations in Sherpa that may underpin their success in one of the harshest environments on earth.

THE RELATIONSHIP BETWEEN VASCULAR DYSFUNCTION, HIGH ALTITUDE AND OCCUPATIONAL PHYSICAL ACTIVITY IN SHERPA

PRATALI, L.

ITALIAN NATIONAL RESEARCH COUNCIL

Due to the nature of their environment, high altitude natives live without road infrastructure, motorized transport, industrial pollution and perform a high volume of occupational physical activity for transportation and agricultural activity. This type of lifestyle necessitates a high energy expenditure normally associated with enhanced cardiovascular health, but their vascular phenotype indicates microcirculatory dysfunction characterised by impaired endothelial-dependent dilatation, higher pulse wave velocity and a lower wall:lumen ratio. Independently, these features are all signs of increased cardiovascular risk, and they are present in Sherpa even at moderate altitude and despite their high volume of habitual physical activity. The presence of subclinical vascular dysfunction may be explained by the nature of occupational physical activity compared to more traditional leisure time physical activity experienced in more developed parts of the world. In this session, Dr Pratali will present the latest work from her laboratory investigating short-term and life-long vascular remodelling at high altitude and the relationship with physical activity

CEREBRAL OXYGEN DELIVERY AND METABOLISM AT REST AND DURING EXERCISE IN ACCLIMATISED LOWLANDERS AND HIGH ALTITUDE NATIVES

AINSLIE, P.

UNIVERSITY OF BRITISH COLUMBIA OKANAGAN

Relative to its size, the brain is the most oxygen-dependent organ in the body, but many pathophysiological and environmental processes either cause or result in an interruption to cerebral oxygen delivery. Debilitating side effects of hypoxia manifest within the central nervous system; however, high-altitude Sherpa experience negligible cerebral effects compared to westerners at extreme altitude. Despite many physiological stimuli that normally increase cerebral perfusion (e.g., greater hypoxemia, acidosis, haematocrit, etc.), our new findings show that cerebral blood flow is actually 20-30% lower in Sherpa at altitude compared to lowlanders. Concurrent studies in Sherpa children confirm that the lower cerebral blood flow is developmental in nature. Together, these findings are consistent with positive metabolic adaptations in the Sherpa for the purpose of oxygen conservation and survival. In this symposium, data from across the lifespan collected in numerous high-altitude populations will be presented to provide a framework to understand the influence of race and genetic adaptation in the cerebral circulation.

Invited symposia

IS-MI01 The neuroscience and interpretation of placebo effects in sports and exercise

THE NEUROBIOLOGY OF THE PLACEBO EFFECT

BENEDETTI, F.

UNIVERSITY OF TURIN MEDICAL SCHOOL & PLATEAU ROSÀ LABORATORIES

Although placebos have long been considered a nuisance in clinical research, today they represent an excellent model to understand how words and therapeutic rituals may affect the patient's brain. Placebo effects, and their evil twins, nocebo effects, are today an active and productive field of research and, because of the involvement of many mechanisms, the study of the placebo effect can actually be viewed as a melting pot of concepts and ideas for neuroscience. Indeed, there exists not a single but many placebo effects, with different mechanisms and in different systems, medical conditions, and therapeutic interventions, including those related to physical performance. For example, brain mechanisms of expectation, anxiety, and reward are all involved, as well as a variety of learning phenomena, such as Pavlovian conditioning, cognitive and social learning. There is also some experimental evidence of different genetic variants in place-

bo responsiveness. The most productive models to better understand the neurobiology of the placebo effect are pain and Parkinson's disease. In these medical conditions, the neural networks that are involved have been identified: that is, opioid, cannabinoid, cholecystokinin, cyclooxygenase, dopamine modulatory networks in pain and part of the basal ganglia circuitry in Parkinson's disease. Recently, the very same mechanisms have been found for physical performance, in particular in hypoxic conditions at high altitude, whereby placebo oxygen has been found to mimic the effects of real oxygen, thus opening up new lines of research. Important implications emerge from these recent advances in placebo research. First, as the placebo effect is basically a psychosocial context effect, these data indicate that different social stimuli, such as words and therapeutic rituals, may change the chemistry and circuitry of the patient's brain. Second, the mechanisms that are activated by placebos are the same as those activated by drugs, which suggests a cognitive/affective interference with drug action. Third, the effects of placebos in the clinical setting apply to physical performance as well, thus leading to a new neuroscientific approach of the placebo effect in sport.

POTENTIAL MECHANISMS OF PLACEBO AND NOCEBO EFFECTS IN SPORT AND EXERCISE

BEEDIE, C.

CANTERBURY CHRIST CHURCH UNIVERSITY

A fast developing database demonstrates that the placebo and nocebo effects are significant factors in sports and exercise. Interesting findings are emerging, for example that athletes who use sports supplements are more placebo responsive than those who do not. However, research in sport and exercise to date has been largely descriptive, with mechanistic data lacking. This session builds on that of Professor Benedetti to examine potential mechanisms of placebo and nocebo responses in sport and exercise. These mechanisms range from emotional responses such as reduced anxiety and increased motivation – albeit underpinned by clear neurobiological pathways – to the direct activation of neurobiological pathways in response to treatments and/or environmental cues associated with conditioning and expectation. This session will also interrogate the mechanisms of sports and exercise phenomena that appear to share many of the characteristics of the placebo and nocebo effects, from glucose rinsing to flow states. The collective analysis of these mechanisms will be shown to have the potential to facilitate not only better understanding of the placebo and nocebo effects specifically, but of the role of the brain in sport and exercise more generally.

THE ROLE AND IMPACT OF THE PLACEBO EFFECT IN SPORT PERFORMANCE AND COMPETITION

HETTINGA, F.

NORTHUMBRIA UNIVERSITY

The placebo effect is a psychobiological response to a purported beneficial treatment, that also in sports can have an impact on performance. The placebo effect is traditionally viewed as a positive outcome resulting from a person's belief that an inert substance is in fact an active drug. Most placebo effects reported in scientific research result however from social interactions. In sports this second aspect is of particular interest, as many sports are performed with or against other competitors. Indeed, social environments have been shown to affect exercisers' estimates of the difficulty of physically demanding tasks and
athletes' performance in physical fitness tests, while human-environment interactions are seen as crucial to competitive performance. Social environments can therefore influence athletes' explicit and implicit beliefs, expectations and motivations, leading to changes in the self-regulatory processes that govern physical
outputs. A recent review has shown that the behaviour of an opponent is an essential determinant in the regulation of performance intensity. A direct coupling between perception and action rather than in distinct serial stages within a brain governor system as argued by the ecological-psychological approach towards pacing has been suggested. However, which affordances the athlete selects to realise among the variety of affordances that are presented simultaneously and continuously, will also be based on the athlete's motivation, previous experience, the internal state of the athlete and/or the perceived level of exertion. In this model, it is easy to imagine that opponents, like placebos, could have an impact on beliefs, motivations and expectations in a similar way, and could thereby affect pacing behavior and performance by modifying the perception and prioritization of different external and internal stimuli via similar pathways as placebos. Recently we already found that placebo effects could improve pacing strategies in 1000-m running time trials, and also opponents have been found to improve cycling performance substantially. The present session will therefore look at the broader implications and applications of placebo effects, and the potential for the competitive context to activate placebo pathways.

OP-PM57 Training and testing: Endurance

INTEGRATING POST-EXERCISE SAUNA BATHING INTO THE TRAINING PROGRAM OF MIDDLE-DISTANCE RUNNERS ENHANCES TEMPERATE EXERCISE PERFORMANCE

KIRBY, N.1, LUCAS, S.1, ARMSTRONG, O.2, WEAVER, S.1, VICKERS, G.2, GIBBON, J.1, LUCAS, R.1

1: UNIVERSITY OF BIRMINGHAM (UK), 2: PERFORMANCE CENTRE, UNIVERSITY OF BIRMINGHAM SPORT (UK)

INTRODUCTION: Active heat acclimation has been shown to improve both submaximal and maximal performance in cool conditions (Lorenzo et al., 2010). Passive heating, specifically post-exercise sauna bathing, has been observed to enhance running time to exhaustion in temperate environments and therefore may have similar ergogenic effects to active heat acclimation (Scoon et al., 2007). We hypothesised that post-exercise sauna bathing interspersed across three weeks of endurance training would further augment physiological measures of maximal (VO2max) and submaximal (lactate threshold, running economy, respiratory exchange ratio [RER] and heart rate) exercise performance in temperate environments, as compared to endurance training alone.

METHODS: Fourteen trained middle-distance runners (10 female; mean ± SD, age 20 ± 2 years, BMI 21 ± 1, VO2max 56.1 ± 8.7 ml.kg.min-1) performed tests of maximal aerobic capacity (VO2max) and lactate threshold (LT) in temperate conditions (19 ± 1°C) before (PRE) and after (POST) 3-weeks normal training (CON; n=5) or normal training with post-exercise sauna bathing (101-108°C) 3 ± 1 times per week (SAUNA; n=9). Participants undergoing SAUNA intervention were instructed to remain in the sauna for 30 minutes if tolerable. Both groups took 64mg ferrous sulfate daily for two weeks before and continuously throughout the protocol. All runners were members of the same athletics club with a similar weekly training structure. Results were analysed using a one way repeated measures ANOVA.
RESULTS: SAUNA accumulated 9 ± 2 post-exercise sauna sessions, totalling 248 ± 49 minutes of exposure. During POST tests, SAUNA increased VO2max by 10% (3.43 ± 0.83 vs 3.72 ± 0.82 L.min-1; p=0.04), increased interpolated speed of LT by 4% (15.8 ± 1.8 vs 16.4 ± 1.8 kph; p<0.01), and decreased submaximal heart rate by 5% (174 ± 9 vs 166 ± 9 bpm; p=0.03). There was a trend for an increase in VO2max in CON (3.43 ± 0.65 vs 3.58 ± 0.58; p=0.07), however CON did not exhibit changes in LT (16.4 ± 1.7 vs 16.6 ± 1.8 kph; p=0.35) or submaximal heart rate (162 ± 11 vs 163 ± 14; p=0.58). Running economy at 14kph (female) and 16kph (male) and RER did not change in either SAUNA or CON.
CONCLUSION: This data supports our hypothesis that post-exercise sauna bathing may further augment maximal exercise performance (i.e. VO2max), as well as aspects of submaximal exercise performance (i.e. lactate threshold and submaximal heart rate) in temperate conditions. In contrast to our hypothesis, some markers of submaximal exercise performance (i.e. running economy and RER) did not change. Thus, post-exercise sauna bathing appears to be a practical ergogenic aid that when integrated into training can further augment some markers of exercise performance in a highly trained cohort.

BREATH- VERSUS TIME-AVERAGING STRATEGIES FOR VO2MAX ASSESSMENT: MATHEMATICAL MODELLING AND RELIABILITY

MARTIN-RINCON, M.1,2, GONZÁLEZ, J.J.1, LOSA, J.1, PEREZ-SUAREZ, I.1,2, PONCE, J.G., CALLE-HERRERO, J., PEREZ-VALERA, M., PÉREZ-LÓPEZ, A., CURTELIN, D., CHEROUVEIM, E., MORALES, D., CALBET, J.A.

1 ULPGC, LAS PALMAS GC, SPAIN; 2 IUIBS, LAS PALMAS GC, SPAIN; 3 UAH, MADRID, SPAIN; 4 NKUA, ATHENS, GREECE.

INTRODUCTION: Despite the variability of BxB data, there is no consensus on how to average the data to optimize VO2max assessment. Most studies use time-based averages, disregarding the influence of the number of breaths in the averaging block on the reliability of the measure. The VO2max value is reduced with larger blocks; however, no mathematical model accounts for the effect of the length of the block. The aim was to compare the impact of the number of breaths or seconds in the averaging block on the VO2max absolute value and reproducibility, and to develop correction equations to standardize VO2max values obtained with different averaging strategies.
METHODS: Eighty-four subjects from a wide range of ages, fitness and body compositions performed 182 incremental tests to exhaustion (91 duplicates) using different protocols and exercise modes. Sixty-two subjects were tested on a Vmax, 11 on a Vyntus metabolic cart and 11 performed one test on the Vmax and the replicate on the Vyntus. Data were breath- and time-averaged from 6 to 60 breaths/sec and the highest value taken as VO2max for each strategy.
RESULTS: The VO2max was similarly reduced in breath- and time-averaging strategies as the number of breaths/sec in the block increased but was lower in trained than untrained subjects (6.5 and 10% from 6 to 60breaths, respectively). The absolute VO2max values from breath and time averages of equal number (e.g. 10b and 10s) had a high concordance (CCC>0.97) with a maximal deviation of 190 mL/min at 10s or 10 breaths averaging block (P<0.001). The best fit of the relationship between VO2max and averaging block length was obtained with a linear-log model:
$Yf=Yi+A\times LN\times((Xi-5)/(Xf-5))$; R2> 0.99, P<0.001)
Where A is the fixed slope for breath- or time-averaging strategies (68.8 and 76.4, respectively) Yf the corrected VO2max value for the aimed strategy (mL/min), Yi the known initial VO2max value (random intercept), Xi initial number of breaths or seconds, Xf the number of breaths or seconds for the interrogated strategy.
The CV of VO2max was not influenced by the averaging strategy nor the number of breaths or seconds in the block (5% for breath and time strategies), regardless of metabolic cart, exercise mode (running vs. cycling), sex, and IE protocol but was influenced by fitness (2.2 and 1.6% for breath and time).
CONCLUSION: The VO2max value decreases with the number of breaths or seconds included in the averaging block, with higher values for breath than time averages. We have developed a mathematical model that allows to standardize the VO2max to a fixed number of breaths or sec, and shown that the variability of VO2max is similar using breath- or time-averaging strategies, with better reproducibility in fit subjects. These findings may contribute to explain some of the variability in the literature when secondary-outcome variables are based on VO2max values computed with large or small averaging strategies.

CAN THE SELF-PACED, CYCLE-BASED MAXIMAL OXYGEN UPTAKE TEST PRODUCE HIGHER VO2MAX VALUES THAN STANDARD GRADED EXERCISE TEST PROTOCOL?

STRUHÁR, I., KAPOUNKOVÁ, K., KUMSTÁT, M., GRMELA, R., HRNCIRÍKOVÁ, I.

FACULTY OF SPORTS STUDIES, MASARYK UNIVERSITY

INTRODUCTION: Using a graded maximal exercise test is often practised for measuring maximal oxygen consumption (VO2max) from elite athletes to people with serious pathological health conditions. Despite these, debate continues about the optimal choice of testing protocols. The main aim of this study is to determine if (a) perceptually-regulated VO2max test produces higher means than graded stepwise exercise test protocol (b) the presence of VO2 plateau ($\Delta VO2 \leq 150$ mL/min) in the measurement of maximal oxygen uptake was achieved.
METHODS: Sixteen healthy, active male participants (age 22.6 ± 1.24 years; body mass 73.42 ± 3.12 kg; body height 1.76 ± 0.09 m; body fat 11.56 ± 4.77 %) undertook two different testing protocol separated by 14 days wash-out period. Tests were conducted on standardized laboratory ergometer (Lode Excalibur Sport). The expired gases were continuously monitored breath by breath through technology system (METALYZER®3B, CORTEX). Participants were asked to maintain a constant cadence 70 rpm during the testing. Stepwise graded protocol (SGP) consisted of initial workload 1.5 W/kg of body weight for 3 min followed by increasing by 0.3 W/kg of body weight every 60 seconds until volitional exhaustion or when the pedal frequency decreased by > 7 rpm from that prescribed. Self-paced protocol (SPP) consisted of

four two minutes stages according to ratings of perceived exertion (RPE). Each stage represents selected number from the scale (13, 15, 17, > 18). The researcher explained a clear description of this protocol before the test.
RESULTS: Participants achieved a significantly higher VO2max ($p = 0.0314$) in the SPP (53.12 ± 3.44 mL·kg-1·min-1) than in the SGP (48.91 ± 4.51 mL·kg-1·min-1). Statistical significance was reported when $p < 0.05$. The most striking result to emerge from the data comparison was that fifteen participants met the primary criteria for a plateau in VO2 (≤150mL·min-1) during SPP. On the other hand, only three participants met the criteria for a plateau in VO2 during SGP.
Furthermore, participants achieved a significantly higher peak power output ($p = 0.0229$) in the SPP (305.11 ± 11.45 W) than in the SGP (284.28 ± 12.29 W). On the other hand, no significance was proved in the value of maximum minute ventilation at the end of the test (SPP, 146.36 ± 7.02 L·min-1; SGP, 147.01 ± 4.87 L·min-1). Respiratory exchange ratio did not differ ($p > 0.05$) between the protocols (SPP, 1.24 ± 0.02; SGP, 1.20± 0.04).
CONCLUSION: The most obvious finding to emerge from this study is that SPP significantly higher VO2max values than SGP. Findings from this study enhance our understanding of the testing protocol design.

RELATIONSHIP BETWEEN RUNNING PERFORMANCE AND ENERGY METABOLIC CAPACITIES IN MIDDLE-DISTANCE RUNNERS

MITSUKA, T., NABEKURA, Y.

UNIVERSITY OF TSUKUBA

INTRODUCTION: It is necessary to enhance the aerobic capacity of middle- and long- distance runners to help them perform to the best of their potential. Aerobic capacity is evaluated based on maximal oxygen uptake (VO2 max), fractional utilization of VO2 max (% VO2 max), and running economy (RE) (1). Different relative percentages of aerobic/anaerobic contribution to middle-distance running, such as 800 m and 1500 m track events, were reported as 66/34% and 84/16%, respectively (2). This indicates the contribution of anaerobic capacity in running performance. Anaerobic capacity is evaluated based on accumulated oxygen deficit (AOD) and peak blood lactate (pBLa) level (3). Several studies have investigated the relationship of running performance with aerobic and anaerobic energy metabolism capacities in middle-distance runners. While some reported a significant relationship, others did not. Studies that reported a significant relationship had problems such as small sample size, observation of significant differences owing to large variations in performance levels, and participants' similar training tendency because they belonged to a single group. Thus, the present study aimed to examine the relationship between running performance and energy metabolism capacities in a homogeneous sample of middle-distance runners belonging to different groups.
METHODS: Twenty three well-trained middle distance runners specializing in 800 m and 1500 m (800 m Season Best: 1 54", 8 ± 3"0s, n = 23; coefficient of variance = 2.6%; 1500 m Season Best: 4' 01", 3 ± 7"0s, n = 17, coefficient of variance = 2.9%) participated in an incremental test (a submaximal test conducted 5–6 times in 3-minute stages and a maximal test of 4–6 minutes). They belonged to four universities, with 14, 2, 2, and 1 participants from A, B, C, and D University, respectively. Further, members of societies (n = 4) were trained in different environments. The mean deviation in aerobic capacity was defined as the aerobic index, and that of anaerobic capacity was defined as the anaerobic index. The mean of the two indices was defined as the total energy index. Data were expressed as mean ± standard deviation, and $P < 0.05$ was considered statistically significant.
RESULTS: The mean VO2 max was 66.8 ± 4.9 ml/kg/min, % VO2 max was 78.6 ± 4.5%, RE was 1.12 ± 0.06 kcal/kg/km, AOD was 35.3 ± 8.8 ml/kg, and pBLa was 15.0 ± 2.6 mmol/L. There were no significant relationships between VO2 max, % VO2 max, RE, AOD, pBLa, aerobic index, anaerobic index, total energy index, 800 m Season Best, and 1500 m Season Best.
CONCLUSION: There was no significant relationship between running performance and energy metabolism capacities in the present homogeneous sample of middle-distance runners belonging to different groups.

PACING STRATEGY DETERMINANTS DURING A RUN LEG OF SIMULATED OLYMPIC-DISTANCE TRIATHLON: RELATIONSHIP BETWEEN PACING INDEX AND CLASSIC PHYSIOLOGICAL VARIABLES

AOYAGI, A., TAKAHASHI, K., NABEKURA, Y.

UNIVERSITY OF TSUKUBA

INTRODUCTION: It is well documented that run leg of Olympic-distance triathlon (ODT) is most influential for overall race performance. The classic physiological variables linked to distance running performance are maximal oxygen uptake (VO2max), running economy (RE) and fractional utilization of VO2max at anaerobic threshold (1). Also, the distribution of work within an exercise (i.e., pacing strategy) can considerably impact endurance performance. Pacing strategy during a 10-km isolated run may be determined mainly by physiological variables including above mentioned and partly by perceptual/muscular variables (2, 3); however, this is unclear in triathlon running (TR) of ODT. As TR is performed after a long period of exercise, the results may be different from those pertaining to single runs. This study aimed to examine the relationship between classic physiological variables and the pacing strategy adopted during TR in simulated ODT (ODTsim).
METHODS: Eight male triathletes were recruited from university triathlon club. They completed two incremental tests to determine submaximal and maximal physiological variables (cycling and running) and an ODTsim. The swim and cycle leg of the ODTsim had relatively fixed exercise intensity, but the run leg was performed as time-trial. Velocity in the run leg was analyzed every 400 m, and the average velocities at the start (first 400 m), middle (400-9600 m), and end (last 400 m) sections were calculated as previously reported (3). Fast start index (FSI) and end spurt index (ESI) were expressed as percentage change of velocity from start to middle section (FSI) and from middle to end section (ESI). The running velocity variability index (RVVI) was determined as coefficient of variation of the running velocity measured every 400 m.
RESULTS: Mean ODTsim and run leg times were 2:31:25 ± 0:17:47 and 0:43:20 ± 0:06:00 (ranged from 0:38:14 to 0:56:10). RE (oxygen cost: ml/kg/km) had significant positive correlation with FSI ($r = 0.71$, $p = 0.05$) and RVVI ($r = 0.78$, $p = 0.02$). RE had significant negative correlation with velocities of middle ($r = -0.80$, $p = 0.02$) , end ($r = -0.76$, $p = 0.03$), and overall ($r = -0.80$, $p = 0.02$) sections. VO2max had significant positive correlation with start-section-velocity ($r = 0.80$, $p = 0.02$). RVVI had significant negative correlation with velocity of middle ($r = -0.92$, $p = 0.001$), end ($r = -0.72$, $p = 0.04$) and overall ($r = -0.92$, $p = 0.001$) sections. ESI had significant positive correlation with end-section-velocity ($r = 0.91$, $p = 0.002$). There was no significant relationship between FSI and velocity of each and overall section.

CONCLUSION: The findings suggest that, in amateur triathletes having wide range of running performance, RE is related to stability of running velocity and linked to superior performance of TR.

INFLUENCE OF MENSTRUAL CYCLE AND ORAL CONTRACEPTIVES ON RATING OF PERCEIVED EXERTION THROUGHOUT AN ENDURANCE EXERCISE IN FEMALE ATHLETES.

BARBA-MORENO, L., ALFARO-MAGALLANES, V.M., CUPEIRO, R., ROMERO-PARRA, N., RAEL, B., BENÍTEZ, J.A., MAESTRE-CASCALES, C., PEINADO, A.B.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Female sex hormones influence over athletic performance have been considerably investigated. Literature indicates little to no effect on female endurance performance during different stages of the menstrual cycle, including the rating of perceived exertion (RPE) (1). However, some authors have shown a higher RPE for the luteal phase during exercise (2) and for the hormonal phase (HP) through an oral contraceptive (OC) cycle (3). In addition, possible differences for RPE between groups (eumenorrheic and OC group) have not been extensively studied. Hence, the aim of this study was to clarify how the hormonal status affect RPE and to compare possible differences of endogenous and exogenous hormones on RPE.
METHODS: Eumenorrheic women (n=15; 35.6±4.2yrs; VO2max: 50.3±3.6 ml·min-1·kg-1) or taking monophasic OC (OC group; n=8; 30.1±4.8yrs; VO2max: 51.7±3.9 ml·min-1·kg-1) completed 40 minutes of running at 75% of VO2max velocity during early follicular phase (EFP), mid-follicular phase (MFP) and luteal phase (LF) for eumenorrheic and during HP and non-hormonal phase (NHP) for OC group. Every 10 minutes participants were asked to numerically rate the perceived exercise intensity on a 15-grade Borg scale ranging from 6-20.
RESULTS: Non-parametric Friedman ANOVA showed significant differences between phases for RPE (p=0.009; EFP=11.65±3.49; MFP=11.74±3.36; LP=11.34±3.50). Specifically, a lower perceived exertion was observed during the LP compared to the MFP (p=0.033). Furthermore, for the OC group, Wilcoxon test reported a significant higher RPE (p<0.001) during the HP (12.86±3.50) compared to the NHP (11.90±3.42). Lastly, Mann-Whitney U test was used to observe RPE differences between groups, OC group displaying higher total perceived exertion than eumenorrheic (12.38±3.48 and 11.54±3.44, respectively; p=0.021).
CONCLUSION: The eumenorrheic group showed a higher RPE during both follicular phases, especially at MFP, when sex hormones are still at low concentrations. Therefore the protective effect against pain exertion by endogenous oestrogen (4) may have been suppressed during these early phases. Furthermore, the OC group presented a higher RPE during the active pill phase, which agree well with literature (3) Finally, the OC group presented a higher total RPE compared with eumenorrheic group, suggesting that exogenous hormones may impair not only some physiological variables but also perceived exertion. The RPE differences found in this study could help coaches to better understand the RPE ratings and to develop training programs for athletes with regards to RPE.

ANALYSIS OF THE PHYSIOLOGICAL COMPETITION ZONES IN A MOUNTAIN MARATHON RACE REGARDING HEART RATE AND RACE SPEED, AND NUTRITIONAL APPLICATIONS

RUIZ DE ARETXABALETA, X.1,2, LEÓN-GUEREÑO, P.3, ARRIBALZAGA, S.1,2, URDAMPILLETA, A.2,4, MIELGO-AYUSO, J.5

1UNIVERSITY OF LEÓN, 2ELIKAESPORT, NUTRITION, INNOVATION & SPORT, 3UNIVERSITY OF DEUSTO, 4INTERNATIONAL INSTITUTE OF NUTRITION AND SPORT SCIENCES , 5UNIVERSITY OF VALLADOLID

INTRODUCTION: Trail running is an emerging sport that has seen a significant increase in popularity during the last decade. There is a lack of research related to mountain marathons with only a few papers offering controversial data (1). Therefore, road marathon data has been used instead (2). The main goal of this study is to define running physiological zones during a mountain marathon, based on the heart rate, and provide some nutritional advice.
METHODS: Eighteen trail runners (aged 37.96 ± 7.11) completed the mountain marathon which consisted of three laps (+2350 m total positive elevation). All the participants took part in a submaximal progressive treadmill test before the race, where the aerobic and anaerobic thresholds were determined. Each athlete's heart rate, speed and track were recorded using a GPS and heart rate monitoring watch. All participants met the carbohydrates and hydration intake requirements during the marathon.
RESULTS: Average intensity regarding lactate threshold was 89.58±4.78%, specifically 90.78±6.22% on the flat sections, 91.94±4.58% during the climbs and 88.05±5.60% in the descents. Analyzing only the first six runners' data, intensity was near 95% on all type of terrain. Athletes' speed dropped between 10% and 20% during the marathon (in all type of terrain, climb, descent and flat), but the heart rate only decreased between nearly 4% and 6%.
CONCLUSION: In a mountain marathon, the relative intensity is high in relation to the lactate threshold and taking into account the duration of the race. Results demonstrate in the fastest runners a drop in performance without any significant decline in the heart rate. Therefore, muscular peripheral factors were probably shown as the main cause of fatigue in the fastest runners. Conversely, among the slowest athletes, cardiovascular fatigue was also significantly high. The best ranked runners maintained a high intensity in all type of sections, and significantly higher during the descents in comparison with the athletes that had a worse performance. It suggests that the influence of the descents in the final performance in a mountain marathon is critical. The drop in performance experienced by all runners and its

relationship mainly with muscular peripheral factors, may suggest that athletes taking part in a mountain marathon should consume a sufficient carbohydrate quantity, higher than traditionally recommended, and follow an appropriate hydration plan during the race.

DOSE-RESPONSE EFFECTS OF WEIGHTED VEST RUNNING ON RUNNING ECONOMY

KILDING, A.E., BARNES, K.R., FRANCIS, P., ZOELLNER, A.

AUT UNIVERSITY

INTRODUCTION: An acute bout of weighted-vest running (WVR) can improve running economy (RE) and subsequent high-intensity exercise performance (Barnes et al 2015). However, little is known about the optimal load used during WVR for altering physiological measures relevant to endurance performance. Therefore, the aim of this study was to determine the dose-response effects of WVR load on RE in runners.
METHODS: Adopting an acute, repeated measures, counterbalanced design, 9 moderately-trained distance runners performed an initial assessment to determine their peak oxygen uptake (VO2peak) and speed at VO2peak (sVO2peak), followed by five priming sessions, on separate days, each involving a standardized WVR priming routine varying in load (5, 10, 15, and 20% body mass, BM). Before and after each WVR priming session, assessments of RE were determined and compared. To identify the optimal WVR load for improving RE, each runner's percentage change was modeled as a quadratic function of the rank order of the load. Uncertainty in the optimal load and in the corresponding effect on the given measure was estimated as 90% confidence limits (CL) using bootstrapping (Hopkins, 2012).
RESULTS: Mean pre-post percent differences (±90% CL) in RE across %BM loads were: 0.22 ± 0.81 (0%BM), 0.00 ± 1.00 (5%BM), -0.27 ± 1.22 (10%BM), 0.11± 1.01 (15%BM), -0.65 ± 1.30 (20%BM). While bootstrapping revealed that the optimal WVR group was 3.5 (10 to 15%BM), the 90%CL spanned all groups and the bootstrap success rate was inconsistent (45%).
CONCLUSION: Irrespective of load, priming using WVR had negligible effect on RE. While the lack of effect suggests that WVR is not a worthwhile priming approach for moderately-trained runners, it is acknowledged that WVR may prime other factors related to endurance running performance.

PHYSIOLOGICAL FACTORS RELATED TO UPHILL VS DOWNHILL RUNNING TIME-TRIAL PERFORMANCE

LEMIRE, M., HUREAU, T.J., REMETTER, R., GENY, B., KOUASSI, B.Y.L., BOUKHARI, M., LONSDORFER-WOLF, E., FAVRET, F., DUFOUR, S.P.

UNIVERSITY OF STRASBOURG

INTRODUCTION: Physiological determinants of trail running performance were mainly explored based on trail races (1). However, uphill (UR) and downhill running (DR) elicit very different running velocities, with different contribution of concentric and eccentric muscle actions (2) and could induce specific physiological responses (3). The purpose of this study was to determine the cardiorespiratory responses to field DR vs UR time-trial and to explore the physiological determinants of DR and UR performance in highly trained runners.
METHODS: Ten male athletes completed a 5-km DR and UR (+ or -8% slope) time-trial and were also tested for maximal oxygen uptake (VO2max, 70.4 +/- 6.3 mL/min/kg), lower limb maximal strength and local endurance as well as musculo-tendinous stiffness, jump ability, agility and maximal sprint velocity. Relationships between variables and predictors of UR and DR performance were investigated using correlations and commonality regression analyses.
RESULTS: Similar average and peak values were observed for heart rate and ventilation in DR vs UR, despite lower average (-5+/-6 %) and peak (-6+/-6 %) VO2 in DR together with dramatically higher running velocity (DR 20.4+/-1.0 vs UR 12.0+/-0.5 km/h, $p<0.05$). Velocity associated with VO2max (vVO2max) was strongly correlated to performance time in UR ($r=-0.83$; $p<0.01$) and DR ($r=-0.76$; $p<0.05$) whereas VO2max was not ($r=-0.24$ in UR and $r=-0.03$ in DR, both $p>0.05$). vVO2max, body mass index and lower limb maximal strength were significant predictors of UR performance (total $r^2=0.94$) whereas vVO2max, lower limb musculo-tendinous stiffness and maximal strength of the lower limbs were significant predictors of DR performance (total $r^2=0.84$).
CONCLUSION: Both 5-km field UR and DR time-trials elicit very high cardiorespiratory responses (both > 80 % VO2max and > 90 % HRmax) although with dramatically different running velocities. These results emphasize the specific cardiorespiratory responses to DR vs UR and point to vVO2max as a strong predictor of both UR and DR time-trial performances in highly trained athletes. Lower limb maximal strength emerges as an important predictor of DR rather than UR performance whereas body mass index and musculo-tendinous stiffness appear as specific determinants of UR and DR performance respectively. The present results suggest UR and DR time-trial performance are determined by different combination of specific physiological factors.

RUNNING ECONOMY AND HEART RATE ARE SIMILAR AT MATCHED RPE ON A TREADMILL AND OVERGROUND

BUCKLEY, J.D., MILLER, J.R., BISHOP, C., FULLER, J.T.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: Despite widespread use of treadmills for running evalution, debate remains regarding whether the physiological demands of treadmill running (TR) appropriately match those of overground running (OR). Given an increasing trend to prescribe exercise intensity based on rating of perceived exertion (RPE) due to its practicality, it is important to determine whether there are differences in OR and TR when running at matched RPE. The aim of this study was to compare physiological responses of OR and TR in recreational runners running at multiple workloads matched on RPE.
METHODS: Nineteen recreational runners (10 male, 9 female) performed 5-mins of running at RPE 11, 13 and 15 on a treadmill and overground. Oxygen uptake (VO2), heart rate (HR) and running speed were measured for each trial during the last minute of running.

RESULTS: Running speed during TR was significantly lower than OR across all RPE (mean difference (MD): -1.03 [95% CI: -1.40, -0.66] km·h-1), but VO2 (MD: 1.4 [-1.0, 3.8] ml·kg-1·min-1) and HR (MD: 3 [-1, 7] bpm) were similar. VO2 and HR per unit running speed were lower for OR compared to TR at RPE 11 ((MD: -0.43 [-0.57, -0.30] ml·kg-1·min-1·km-1·h-1; -0.51 [-0.08, -0.03] bpm·km·h-1) respectively) and RPE 13 ((MD: -0.21 [-0.34, -0.08] ml·kg-1·min-1·km-1·h-1; MD: -0.04; [-0.06, -0.02] bpm·km·h-1) respectively) but not RPE 15 ((MD: -0.03 [-0.16, 0.10] ml·kg-1·min-1·km-1·h-1; MD: -0.01 [-0.03, 0.005] bpm·km·h-1) respectively).
CONCLUSION: VO2 and HR were similar for TR and OR at matched RPE, but running speeds were slower for TR. VO2 and HR per unit running speed were higher during TR compared with OR, but became similar at higher RPE. VO2 and HR were best matched between TR and OR when running at RPE 15.

EFFECTS OF CARBOHYDRATE INTAKE DURING A 1-H HEAVY INTENSITY CYCLING EXERCISE ON SUBSEQUENT RUNNING ECONOMY – A SINGLE-BLINDED PILOT STUDY

TRISKA, C.1,2, MOITZI, A.1, JOCHA, M.1, WESSNER, B.1, BACHL, N.1,2, TSCHAN, H.1

1UNIVERSITY OF VIENNA; 2AUSTRIAN INSTITUTE OF SPORTS MEDICINE

INTRODUCTION: The energy cost of running (Cr) is one of the key predictors of performance for long distance races [1]. A study in triathletes has demonstrated that after exhaustive cycling Cr has increased in moderately-trained triathletes [2] and another study has found that gross efficiency in cycling was also impaired after prolonged exercise [3]. On the downside, carbohydrate (CHO) intake during prolonged cycling exercise is considered to improve performance [4]. Therefore, the aim of this study was to assess the effect of CHO intake during 1-h cycling on subsequent Cr.
METHODS: Six moderately-trained triathletes (maximal oxygen uptake: 53±4 mL/min/kg) performed three trials on an ergometer (Cyclus2, RBM electronics, Germany) and a treadmill (Saturn, h/p/cosmos, Germany): (1) a cycling graded exercise test to determine respiratory compensation point (RCP) after a 10-min baseline determination of Cr at 2.78 m/s (BL); (2 and 3) a 1-h cycling trial at 90% of RCP power-output (PO) followed by 10 min running at 2.78 m/s. Trials 2 and 3 were randomised and athletes had to drink either a 1-L placebo drink (PL) containing <7 g CHO/L or a 1-L CHO drink (CARB) containing 60 g CHO/L. Respiratory gases (MetaMax 3B, Cortex, Germany) were measured continuously during running and the last 2 min of the running trials were used for analysis. A repeated measures ANOVA was used to detect changes between the treatments as well as effect sizes expressed as partial eta-squared. Significant main effects were followed-up by Bonferroni post-hoc procedures. Significance was set at $P<0.05$.
RESULTS: Mean Cr was 4.42±0.47, 4.56±0.50, and 4.32±0.46 J/kg/m for BL, CARB and PLA, respectively. Significant differences were found between the treatments ($F_{2,10}=6.80$; $P=0.014$; effect size=0.576). Post-hoc tests revealed differences only between PLA and CARB ($P=0.013$). Mean respiratory exchange ratio during running was 0.91±0.02, 0.89±0.04, and 0.88±0.03 for BL, CARB and PLA, respectively. No significant differences were found between treatments ($F_{2,10}=3.18$; $P=0.085$, effect size=0.389). Contribution of CHO during running was 73.1±6.4%, 64.0±14.8%, and 63.7±11.4% and of fat was 26.9±6.4%, 36.0±14.8%, and 36.3±11.4% for BL, CARB and PLA, respectively. No significant differences were found between treatments ($F_{2,10}=2.85$; $P=0.105$; effect size=0.363 for CHO and fat, respectively).
CONCLUSION: The novel finding of this pilot work was that drinking CARB during 1 h cycling at 90% of RCP PO significantly increased Cr, also demonstrated by a moderate effect size. In contrast, PLA did not significantly alter Cr. Even though participants ingested 60 g CHO during cycling, a shift from CHO to fat oxidation during subsequent running was evident with no significant differences to PLA. In summary, CHO ingestion during cycling elevates sub-maximal Cr, however, it is still unclear if this notably affects running performance in a triathlon race.

MUSCLE METABOLITES AFTER A SOCCER GAME IN FEMALE ATHLETES: IMPLICATIONS FOR SPRINT PERFORMANCE

ERMIDIS, G.1,2, MOHR, M.2,3, RANDERS, M.B.2, NYBO, L.4, ØRTENBLAD, N.2, ØRNTOFT, C.2, DRAGANIDIS, D.5, JAMURTAS, A.5, FATOUROS, I.5, KRUSTRUP, P.2,6

1:UNIVERSITY OF PARTHENOPE, 2:UNIVERSITY OF SOUTHERN DENMARK, 3:UNIVERSITY OF THE FAROE ISLANDS, 4:UNIVERSITY OF COPENHAGEN, 5:UNIVERSITY OF THESSALY, 6:UNIVERSITY OF EXETER

INTRODUCTION: Repeated sprint and intense intermittent exercise performance are attenuated at the end of soccer games for female elite players, indicating that perturbations in work rate during the last phase of a game are caused by game-induced fatigue. It has been suggested that fatigue toward the end of soccer games is related to the fact that muscle glycogen concentrations are substantially reduced (Krustrup, Zebis, Jensen, & Mohr, 2010). The aim was therefore to examine muscle metabolites and changes in sprint performance after a soccer match play.
METHODS: Ten trained competitive outfield female players (age: 22.5 ± 3.1 years, height: 168 ± 0 cm; body mass: 60.6 ± 7.3 kg) played a full 90-min football match. At the time of the experiment, Yo-Yo Intermittent Recovery test level 1 (Yo-Yo IR1) and Yo-Yo Intermittent Endurance test level 1 (Yo-Yo IE1) performance were 1056 ± 345 m and 2572 ± 733 m, respectively, VO2max was 51.5 ± 5.2 ml·min-1·kg-1, while peak 30-m sprint performance was 4.91 ± 0.22 s. Ten players had muscle biopsies taken from vastus lateralis before and after the game. To evaluate sprint performance during match play, a repeated sprint test (5x30 m interspersed with 30 s recovery) was performed before the game, immediately after 1st half and the end of the game (N = 9). Activity pattern was determined in the game with GPS technology.
RESULTS: Muscle glycogen was 399±56 mmol/kg d.w. before the game and 247±109 mmol/kg d.w. ($P= 0.008$; ES= 1.8[0.8; 2.7]) after the game. Muscle lactate, ATP, PCr, Creatin pH and HAD activity were not significant different before and after the game. Mean sprint time was 5.18±0.19 s before game and was significant different after the first half ($P< 0.05$; ES= 0.7[1.4; 0.2]) with 5.31±0.21 s (2.5% reduction) as well as after the game with 5.56±0.14 s ($P< 0.05$; ES= 2.2 [3.3; 1.3]) (7.3% reduction). In addition, mean sprint time after the first half was significant different after the game ($P< 0.05$; ES= 1.4 [2.3; 0.5]) (4.7% reduction). Total distance covered and high intensity running (HIR: >13km/h) during the full game was 8927±973 m and 2015±498 m, respectively. Furthermore, HIR covered during the first and the last 15 min was 343±99 m and 292±84 m, respectively.

CONCLUSION: A marked decline of glycogen occurred after a soccer game of female players. The latter finding may explain the reduction of sprint performance at the end of the game. Finally, the ability to exercise high intensity running at the final 15-minutes was pronounced decline from first 15-minutes but not significant different.

PERIPHERAL ADAPTATIONS TO ENDURANCE TRAINING IMPROVES OXYGEN DELIVERY AND OXYGEN EXTRACTION – THE EFFECT OF ONE-LEGGED TRAINING

SKATTEBO, Ø.1, CAPELLI, C.1, RUD, B.1, AUENSEN, M.1, CALBET, J.A.L.2, HALLÉN, J.1

1: NORWEGIAN SCHOOL OF SPORT SCIENCES, 2: UNIVERSITY OF LAS PALMAS DE GRAN CANARIA

INTRODUCTION: Endurance training results in central and peripheral adaptations that improve muscles' O2 delivery and uptake (VO2). However, it remains unknown how O2 delivery and extraction interact at different exercise intensities, when trained and untrained muscles exercise simultaneously at the same power output (PO). We hypothesized that submaximal VO2 is the same in this situation, but with trained muscle relying more on O2 extraction and less on O2 delivery.
METHODS: Nine moderately trained subjects completed 6 weeks of one-legged knee extension (1L-KE) endurance training (3-4 sessions/week). After training, the trained leg (TL) had 15±6% (mean±95% CI) higher peak power (Wpeak) and 22±13% higher pulmonary VO2peak compared to the non-TL (legs randomized). After training, on an experimental day, catheters were placed in both femoral veins and an artery. The subjects performed two-legged KE (2L-KE) at PO corresponding to 40±2%, 62±3% and 83±3% of 2L-KE Wpeak. Leg blood flow (LBF; ultrasound Doppler) and arterio-venous differences in O2, ions and metabolites were measured. Equal absolute PO from both legs was ensured by real-time visual feedback. Muscle biopsies were taken from both legs and were analyzed using western blot technique. Two-way repeated measures ANOVA (leg x PO) followed by Bonferroni post-hoc test was used for statistical analysis.
RESULTS: After training, the TL expressed a higher protein content of citrate synthase, COX-IV and HAD (35-45%; $P<0.05$). During 2L-KE with equal PO, the TL had a higher LBF (9.1±6.5%; $P<0.01$) due to improved vascular conductance ($P<0.01$), higher O2 extraction (1.7±1.2%-points; $P=0.01$), and thus, leg VO2 (11.9±6.5%; $P<0.01$) than the non-TL (all given as main effects; ME). A significant interaction was found for O2 extraction with the largest difference on the highest PO ($P=0.03$). The TL had lower lactate release (ME: 0.5±0.4 mmol/min; $P=0.02$) and higher pH in the venous blood (ME: 0.010±0.006; $P<0.01$). The respiratory quotient tended to be lower (0.05±0.05 points; $P=0.06$) and the potassium release was significantly lower (0.3±0.2 mmol/min; $P<0.01$) in the TL at the highest PO. Leg muscular pain (CR10 scale) was lower in the TL on the two highest PO ($P<0.01$).
CONCLUSION: This is the first study where O2 delivery and extraction have been studied simultaneously in trained and untrained muscles at the same absolute PO, when cardiac output is not maximally taxed. In contrast to our hypothesis, we observed increased perfusion in the TL, which also extracted more O2 and relied less on anaerobic metabolism and carbohydrate oxidation than the non-TL. The combination of higher aerobic energy contribution, increased fat oxidation and improved ion balance through upregulated ATPase activity may explain the lower exercise economy after training. Hence, small muscle mass endurance training upregulates energy demanding processes within the muscle cells that may delay muscular fatigue and improve endurance, with the consequence of increased O2-cost of exercise.

AN ACUTE BOUT OF EXERCISE DOWNREGULATES THIOREDOXIN-INTERACTING PROTEIN (TXNIP) EXPRESSION IN RAT SKELETAL MUSCLE

RA, S.G., IIZAWA, H., HONDA, H., KAWAMOTO, E., TOMIGA, Y., HIGAKI, Y., KAWANAKA, K.

FUKUOKA UNIVERSITY

INTRODUCTION: Several previous evidence suggests a role for thioredoxin-interacting protein (TXNIP), as a key negative regulator of skeletal muscle insulin signaling and glucose uptake. We have previously shown that short duration (6 h) of physical inactivity (by using plaster cast) rapidly induces increase in TXNIP protein expression together with insulin resistance for glucose uptake in rat skeletal muscle (Kawamoto et al., J Appl Physiol, 2018). This study provides evidence that decreased muscle contractile activity rapidly increases TXNIP protein expression in skeletal muscle. Since exercise increases muscle contractile activity, it seems reasonable to speculate that exercise downregulates TXNIP protein expression in skeletal muscle. The aim of present study was to determine whether an acute bout of exercise downregulates TXNIP expression in rat skeletal muscle.
METHODS: Male Wistar rats were subjected an acute bout of treadmill running (15 % incline at 9 m/min) and swimming (without a weight) exercise for 3 h. Immediately and 2 or 4 h after cessation of exercise, the soleus (Sol) and epitrochlearis (Epi) muscles were dissected for the measurement of TXNIP protein expression. In addition, dissected Sol and Epi muscles were incubated for 3 h in glass flasks in a shaking incubator, maintained at 35 °C, either in the absence or presence of 0.5 or 2.0 mM AICAR.
RESULTS: Treadmill running for 3 h significantly reduced TXNIP protein expression in Sol muscle immediately after the cessation of exercise by 41.8 %, relative to control group. Also, swimming exercise for 3 h significantly reduced TXNIP protein expression in Epi muscle immediately after the cessation of exercise by 27.0 %, compared with control group. TXNIP protein expression were decreased in muscles where muscle glycogen levels were reduced during exercise, suggesting that exercise downregulates TXNIP protein expression in those muscle fibers that are recruited during each exercise. Further, we found that the 5'-adenosine monophosphate-activated protein kinase (AMPK)-activating compound, AICAR, induced significant reduction in TXNIP protein expression in both Sol and Epi muscles.
CONCLUSION: An acute bout of exercise (treadmill running and swimming) rapidly reduced TXNIP expression in exercised muscle, but not in non-exercised muscle. In addition, skeletal muscle AMPK activation by AICAR incubation, significantly reduced TXNIP expression. These findings provide evidence that increased muscle contractile activity downregulates skeletal muscle TXNIP protein expression and that AMPK activation might play a crucial role in regulating TXNIP protein expression in exercised muscle.

EFFECTS OF DIET CHANGE AND LADDER CLIMBING EXERCISE ON HYPERTROPHY AND AUTOPHAGY OF CARDIAC MUSCLE IN HIGH-FAT INDUCED OBESE RATS

KIM, K., AHN, N., LEE, K.

KEIMYUNG UNIVERSITY

INTRODUCTION: There is a social interest in urgently implementing efforts for the prevention and treatment of cardiovascular disease. In particular, obesity, an important cardiovascular disease risk factor, exerts negative influences on cardiac muscle through various pathways. Exercise training increases the number of mitochondria and oxidase activity (1), and protects the myocardium by increasing anti-

oxidative enzyme activity (2). The purpose of this study was to investigate the effect of 8-week diet change and ladder climbing exercise on the expression of cardiac muscle hypertrophy and autophagy factors in obese middle aged rats.
METHODS: 50 weeks old male Wistar rats were induced to obese by high fat diet treatment for 6 weeks after 1 week of environmental adaptation and then were randomly assigned to 4 groups (CON, DC, LC, DLC). After that ladder climbing exercise or diet change using general formula were treated for 8 weeks.
RESULTS: Body weight and abdominal fat were significantly (p <.05) lower in the two groups (CON, LC) than the other groups (DC, DLC). There was no significant difference in the weight of heart and skeletal muscle. Eight weeks of exercise or caloric reduction diet significantly reduced gene expression and activity of Traf2-NFkB-mTOR, which is a hypertrophic factor of cardiac muscle in obese middle-aged rats (p<.05), and that autophagy factors of SIRT1-FoxO1 gene expression and activity were significantly increased (p <.05). However, there was no synergistic effect with the combined treatment of the two stimuli.
CONCLUSION: These results suggest that caloric reduction or ladder climbing training may be effective in preventing cardiac hypertrophy and heart failure in middle-aged obese rats.

OP-MI18 Team sports II

SPECIFIC PHYSICAL PERFORMANCE IN WORLD CLASS, TOP-ELITE AND ELITE FEMALE TEAM HANDBALL PLAYERS

WAGNER, H., FUCHS, P., MICHALSIK, L.B.
UNIVERSITY OF SALZBURG

INTRODUCTION: In female team handball the specific characteristics of the game as well as age and skill level related differences in general physical performance are well known. However, the link between team handball competition and general physical performance as well as knowledge about female world class players is missing. Scientific based knowledge about the specific demands in female team handball could provide essential information for the specific training in female team handball as well as to understand how aerobic capacity and specific agility determine performance in competition. Consequently, the aims of the study were to analyze team handball specific physical performance in elite, top-elite and word class female team handball players.
METHODS: Ten elite (Austrian Top League), 11 top-elite (Danish Top League) and 11 world class female players (Woman EHF Champions League) performed a team handball game based performance test. Oxygen uptake (K5, Cosmed, Rome, Italy), heart rate (Suunto T6d, Suunto, Vantaa, Finland), blood lactate concentration (Biosen 5040, EKF Diagnostics, Leipzig, Germany), ball velocity and jump height (Tracker Video Analyzing Software 4.59, Douglas Brown, Aptos, California, US) in the jump shots as well as running time (in offense, defense, fast break und running back) were measured.
RESULTS: Significant differences between elite, top-elite and world class players were found in peak oxygen uptake (P<0.001), peak heart rate (P<0.05), ball velocity in the jump shot (P<0.001), offense (P<0.05) and fast break time (P<0.05). A detailed analysis revealed that a world class player is able to increase oxygen uptake significantly in the breaks after the high intensity movements (in offense, defense and sprinting) whereas the elite player was not able to perform similar.
CONCLUSION: We suggest that the ability for fast moving on the handball court, including fast accelerations and decelerations, changes in directions, short sprints, team handball specific skills like tackling, passing, catching and throwing with a high ball velocity are main determinants to become a world class player in female team handball. A remarkable result of this study was that the peak oxygen uptake discriminated significantly between all three performance levels and that the best female player reached a peak oxygen uptake of 79.9 ml/kg min. We suggest that the increase in oxygen uptake during the breaks in the game based performance test found in the world class players in this study enables also a faster recovery in team handball competition and training. Consequently, these players were able to perform better over a longer time. Additional studies in other team sports using a similar test like the game based performance test, but adapted to the specific demands of the sport, are warranted.

MATCH-PLAY ACTIVITY PROFILE OF MALE AUSTRIAN LACROSSE PLAYERS

HAUER, R.1, TSCHAN, H.1
1: UNIVERSITY VIENNA

INTRODUCTION: In team sports the measurement of physical load and activity profiles through GPS wearable devices is an essential tool of the coaching process. However, there is a general lack of knowledge about the activity profile in Lacrosse (Polley et al., 2015). This study aims to explore the activity profile in male lacrosse match-play using micro technology.
METHODS: Activity in 8 competitive games was recorded from fifteen male Austrian elite lacrosse athletes (age: 26.3 ±5.4ys; body mass: 80.3 ±7.5kg; height: 181.3 ±6.9cm) using GPS wearable devices (Zephyr Performance System). Activity profile variables included percentage of mean heart rate (%HRmean) in relation to maximum heart rate, mean respiratory frequency (RF), time spent (s) in HR-zones (HRz) (1: <75%; 2: 75-84,9%; 3: 85-89,9%; 4: ≥90%) & speed-zones (SZ) (1: 0.0-0.2m/s; 2: >0.2-1.8m/s; 3: >1.8-3.3m/s; 4: >3.3-5.7m/s; 5: >5.7m/s), and total distance covered (m). Players were separated into position of attack, midfield and defence. Differences between positions were analysed using one-way ANOVA. Significant results were interpreted using post-hoc-analyses. Effect sizes were calculated as partial eta-squared (ηp2). Statistical significance was set at p<0.05 with a confidence interval of 95%.
RESULTS: Regardless of position, data indicate an average distance covered of 5,365.8 ±1,276.0m, a RF of 25.3 ±1.9bpm, and a %HRmean of 72.4 ±5.0% per game. Most of the time is spent in HRz1 & 2 (HRz1: 3,003.4 ±690.5s; HRz2: 1,019.7 ±289.7s; HRz3: 516.6 ±168.3s; HRz4: 571.7 ±465.3), and SZ1 & 2 (SZ1: 2,632.8 ±789.1s; SZ2: 1,801.2 ±643.0s; SZ3: 407.3 ±119.8s; SZ4: 261.0 ±75.8s; SZ5: 28.1 ±13.1s). Regarding positional differences data show significant results for time spent in HRz2 (F=18.910, p=0.000, ηp2=0.759) and SZ4 (F=4.085, p=0.044, ηp2=0.405). Post-hoc-analyses show more time spent in HRz2 for attacker compared to midfielder (p=0.000) and defender (p=0.002). On the other hand, midfielder spent more time in SZ4 compared to defender (p= 0.045). Even if not significant HRz1 (ηp2=0.28), SZ1 (ηp2=0.31), SZ2 (ηp2=0.44), and %HRmean (ηp2=0.27) show large effect sizes between positional values.

CONCLUSION: Results of this study provide preliminary information about game-play activity in international male lacrosse competition. Some positional differences could be demonstrated, which should be considered by coaches when preparing lacrosse athletes for competition. However, further studies need to be performed to determine competitive game demands of male lacrosse athletes.

RELATIONSHIP BETWEEN INTERNAL AND EXTERNAL TRAINING VARIABLES IN AN ELITE NETBALL TEAM

SIMPSON, M., JENKINS, D., SCANLAN, A., KELLY, V.
UNIVERSITY OF QUEENSLAND

INTRODUCTION: The monitoring of training loads has become central to the preparation of elite team sport athletes. While the relationship between internal and external training loads has been examined in across a range of sports, the majority of investigations to date have been limited to field-based athletes 1. Additionally, only male participants have been examined. This study investigated the relationship between weekly internal and external training loads of an elite female netball team, with consideration of positional differences between players within the team.
METHODS: Ten elite netball players were monitored over a competitive season. Internal training loads were determined using summated heart rate zone scores (SHRZ) and session ratings of perceived exertion (sRPE). Using inertial movement units (IMUs), external training load was measured as weekly player load (PL), weekly player load/min (PL.min-1), weekly accelerations (ACCELS), weekly decelerations (DECELS), weekly jumps (Jumps), weekly change of directions (COD), weekly high intensity events (HIE), weekly medium intensity events (MIE), low intensity events (LIE), weekly PL from the forward direction (PLFwd), weekly PL from the sideways direction (PLSide) and weekly PL from the vertical direction (PLUp). Internal and external training load variables for the team and each position were compared using Spearman's rank of correlation and coefficient of determination.
RESULTS: SHRZ and PL showed a large correlation (r=0.65, R2=0.42). After PL, the strongest correlations with SHRZ were COD (large, r=0.64, R2=0.41), followed by ACCELS and DECELS (large, both r=0.61, R2=0.37). The strongest correlation with sRPE was COD (very large, r=0.79, R2=0.62), followed by Jumps (very large, r=0.76, R2=0.58) ACCELS and DECELS (very large, both r=0.75, R2=0.56). For Goal Defense players (large, r=0.63, R2=0.40) and Wing Attack players (very large, r=0.90, R2=0.81), the strongest correlation with SHRZ was with HIE. For Goal Shooters, the strongest correlation with SHRZ was DECELS (very large, r=0.89, R2=0.79). For all positions, except Goal Shooters, the strongest relationship was between PL and sRPE (very large to almost perfect, r=0.88-0.94, R2=0.77-0.88). Change of direction had the strongest relationship with sRPE for Goal Shooters (very large, r=0.82, R2=0.67).
CONCLUSION: Due to the stronger correlations, sRPE is a more accurate and cost-efficient method of training load monitoring in netball if teams do not have access to IMUs. However, SHRZ may provide a wider insight into individual responses to external training loads. COD and sRPE provide a good monitoring combination of internal and external training loads for elite netball team trainings. Positional differences in movements, such as HIE for GD and WA, should be considered when developing training practices for elite netball.

PHYSICAL DEMANDS IN TEAM HANDBALL – DIFFERENCES BETWEEN PLAYING LEVEL

LUTEBERGET, L., SPENCER, M.
NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Knowledge concerning match demands is essential for the design of specific training drills and training programs. It has previously been shown that there are differences in physical demands between different playing positions in team handball (1). Thus, such programs should be individualized with respect to playing positions and possibly playing level. It is shown that physical characteristics differ between playing level (2), however, to our knowledge, there are no studies investigating if the physical demands in match play vary with playing level. The aim of this study was to compare the physical demands in match play between national level and international level female team handball players.
METHODS: This study includes match observations from 16 players in nine international matches (international level) and 31 players in ten national league matches (national level). Inertial measurement units (Catapult Optimeye S5, Australia) were used for data collection. PlayerLoad™·min-1, and High Intensity Events (HIE·min-1; >2.5m·s-1) were used to quantify physical demands. Players were categorized into playing positions (backs, pivots, wings, and goalkeepers (GK)), and only on-field time was used in the analyses. Magnitude based inferences were used to describe probabilities of substantial differences between playing levels. Differences were deemed substantial when there was a likelihood of >75% of the difference exceeding an effect size (ES) of 0.2.
RESULTS: Data from both playing levels combined show PlayerLoad™·min-1 values of 9.3 ± 1.3, 9.1 ± 0.8, 9.2 ± 0.8, and 4.9 ± 0.9 for backs, wings, pivots, and GKs respectively. No differences in PlayerLoad™·min-1 between playing levels for the outfield positions were found, however national-level GKs showed higher PlayerLoad™·min-1 (ES: 1.13) compared to international-level GKs. International-level backs (4.8 ± 0.7, ES: 0.89) , wings (3.1 ± 0.6, ES: 1.13), and pivots (4.1 ± 0.7, ES: 0.60) displayed higher HIE·min-1, compared to their national-level counterparts. International-level GKs showed lower HIE·min-1 (ES: 1.28) compared to national-level GKs. No differences in on-field time was observed between the two playing levels.
CONCLUSION: This study reveals that backs, wings and pivots at international level perform higher HIE·min-1 than their national-level peers. The notion that HIE is the physical discriminating factor between playing standards for outfield positions may be useful for planning training, and especially important for players who change playing standard. However, additional research is necessary to provide an even more valid expression of the distinguishing factors between competitive levels. For example, monitoring of physical match performance in the players who have moved between levels would enable a greater understanding of the influence of competitive level on match-play physical performance.

GLOBAL MOTION VISUALISATION FOR DETECTION OF DECEPTIVE MOTION IN RUGBY

LYNCH, S.D., OLIVIER, A.H., BIDEAU, B., KULPA, R.

UNIVERSITÉ RENNES 2

INTRODUCTION: In rugby, players frequently use deceptive motions (e.g., a side-step) in order to pass their opponent. Previous works showed that expert defenders are more efficient in detecting deceptive motions. Their performance was shown to be correlated with the evolution of the centre of gravity of the attacker, suggesting that experts may rely on global motion cues. This study aims at investigating whether a representation of centre of gravity can be useful for training purposes, by using this representation alone or by combining it with the local motion cues given by body parts.
METHODS: We designed an experiment in virtual reality to control the motion cues available to the defenders. Sixteen healthy participants (seven experts and nine novices) acted as defenders while a virtual attacker approached. The virtual attacker would appear as a full human, a human with its centre of gravity visible or only the centre of gravity present. Participants completed two separate tasks. The first was a time occlusion perception task, where the attacker disappeared after 100ms, 200ms or 300ms after the initial change in direction, where participants would indicate the direction they believed the attacker would pass. The second was a perception-action task where participants were instructed to intercept the oncoming attacker by displacing medio-laterally. The attacker would perform a non-deceptive motion, running directly toward the final passing direction or a deceptive motion, performing a side-step initially toward a false direction before quickly reorienting in their true direction.
RESULTS: There was a main effect of expertise, appearance, cut-off times and motion on correct responses during both tasks. There was an interaction between visual appearance and expertise, and between motion type and expertise during the perception task, however, this interaction was not present during the perception-action task. We observed that experts generally had a later response time to both deceptive and non-deceptive motion than their novice counterparts.
CONCLUSION: Within our findings, we observed that experts maintained superiority in the perception of deceptive motion; however when the visual appearance is reduced to global motion alone the difference in superiority between novices and experts is reduced. Our current results suggest that the introduction of centre of gravity as a training aid in attacker-defender dyad is not a relevant cue. A long-term training program with the continual application of human with its centre of gravity visible may decrease the observed distraction effect we have reported here. We further explore the interactions and discuss the effects observed for the visual appearance and expertise.

SPINE KINETICS IN SPORTS WITH REPETITIVE OVERHEAD ACTIVITIES

FETT, D., TROMPETER, K., HEINRICH, K., FUNKEN, J., BRÜGGEMANN, G.P., PLATEN, P.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Mechanical loading of the lower back has been shown to be an important risk factor for the development of low back pain (LBP). To date, there has been little research regarding potential mechanisms associated with LBP in sports with repetitive overhead activities. LBP is known to be a multifactorial condition with potential risk factors grouped broadly into physical, psychological, and individual domains [1]. However, the repetitive ballistic trunk movements required in overhead sports, which have been linked to the high frequency of pars interarticularis stress reactions in other populations, underpin the likelihood of a mechanical etiology in this population [2]. To indicate possible mechanisms that cause LBP in these sports, an exact knowledge of the occurring spine kinetics is needed. Therefore, the purpose of this study was to examine the kinetics of the lumbar spine during attack and serve movements in overhead sports.
METHODS: Sixteen athletes who compete on a national level underwent a three-dimensional motion analysis during serving and attack trials in handball, volleyball, tennis and badminton. Three-dimensional full-body kinematics were recorded using a 16-camera motion capture system (Vicon Motion Analysis System). Inverse dynamic calculations of the spine were conducted with the help of a rigid multi-body model (Dynamicus, Alaska).
RESULTS: Highest external flexion moments occurred in the sagittal plane. Of all analyzed movements, jump shots in handball showed the highest moments. Values between 0.5-2.9 Nm/kg at L5/S1 (sagittal plane) were measured. During volleyball spike, tennis serve and badminton smash, values between 0.2-1.6 Nm/kg, 0.3-1.2 Nm/kg and 0.1-0.6 Nm/kg were captured. Based on the external joint moments in the sagittal plane, compressive forces between 0.8-6.3 kN (handball jump shot), 0.3-3.3 kN (volleyball spike), 0.5-2.5 kN (tennis serve) and 0.2-0.8 kN (badminton smash) were estimated.
CONCLUSION: It is difficult to judge load or strains of the spine in sports. One possibility is to determine the strain based on individual strength criteria of corresponding structures. This allows to estimate a possible failure of the structure. The NIOSH [3] method established the biomechanical criterion of 3.4 kN as the upper limit for lumbosacral-disc compressive forces. Considering the recommended limits, some athletes of this investigation exceed the limits, which might be interpreted as a certain biomechanical overload risk for the lumbar spine. Further it must be considered that skeletal muscles were not included in the calculation of the compressive forces, so the values are rather underestimated.

OP-PM63 Strength

THE DIFFERENCE IN MUSCLE OXYGENATION BETWEEN AGONIST AND ANTAGONIST MUSCLES DURING WEIGHT-LIFTING EXERCISE

RYAN-STEWART, H.J., FAULKNER, J., TASKER, E., PAINE, E., JOBSON, S.A.

UNIVERSITY OF WINCHESTER

INTRODUCTION: Despite increasing interest in the mechanisms of resistance training, aspects of the physiological response are still unclear. In particular, research into the oxygenation of muscle during weight-lifting exercise is limited with only 4 studies (1-4) utilising near infrared spectroscopy (NIRS) to investigate properties of haemodynamic responses during weight-lifting. This study aims to compare the muscle oxygenation and blood volume responses to specific weight-lifting exercises between the agonist and antagonist muscles using NIRS.
METHODS: Ten healthy males (age 25 ± 7.4 yrs) performed 10 repetition maximum (10RM) efforts for the back squat (BS), Nordic curl (NC), close-grip bench press (CGBP) and bicep curl exercises (BC). NIRS probes (Artinis PortaLite) were placed on the agonist and antagonist muscle for each exercise (lower limb: rectus femoris and biceps femoris; upper limb: biceps brachii and triceps brachii).
RESULTS: There was a significant difference ($p<0.05$) in the oxygenated haemoglobin (oxy-Hb) response between the agonist (-23.8%) and antagonist muscle (+5.46%) for the BC exercise. The BC exercise further demonstrated a significantly different ($p<0.01$) response between the two muscles for tissue saturation index (TSI) (agonist: -22.9%; antagonist: -3.86%). TSI response was also significantly different ($p<0.01$) between the muscle groups for CGBP (agonist: -16.52%; antagonist: -0.62%). All other comparisons were non-significant ($p>0.05$), although medium-large effect sizes were found for the oxy-Hb response in the NC and CGBP, and total haemoglobin (tHb) response in the CGBP.
CONCLUSION: Exercises that isolate single muscle groups, such as the BC, create a greater hypoxic environment in the agonist compared to the antagonist. In exercises where more muscle groups and larger muscles are involved, the muscle oxygenation and blood volume responses are less pronounced.

FUNCTIONAL AND STRUCTURAL EFFECTS OF SUBMAXIMAL AND SUPRAMAXIMAL LOADS DURING ECCENTRIC-OVERLOAD RESISTANCE TRAINING IN THE TRAINED AND CONTRALATERAL LEGS

MAROTO-IZQUIERDO, S., NOSAKA, K., BLAZEVICH, A.J., MAGDI, H., GONZÁLEZ-GALLEGO, J., DE PAZ, J.A.

INSTITUTE OF BIOMEDICINE, UNIVERSITY OF LEÓN, LEÓN, SPAIN & CENTRE FOR EXERCISE AND SPORTS SCIENCE RESEARCH, SCHOOL OF MEDICAL AND HEALTH SCIENCES, EDITH COWAN UNIVERSITY, JOONDALUP, WA, AUSTRALIA

INTRODUCTION: Eccentric (ECC) training has proven to induce greater adaptations on strength, power and hypertrophy, showing higher cross-education effects in the contralateral untrained limb than traditional training 1,2. However, it is well-known that ECC actions are rarely isolated and usually appear during the stretch-shortening cycle. Hence, new training paradigms in which the ECC phase is accentuated have been proposed. Indeed, eccentric-overload resistance training (EO-RT) with iso-inertial devices has shown significant functional and structural effects 3. However, as far as our knowledge is concerned, the optimal amount of negative work during EO-RT is unknown, as well as the effects of EO-RT with supramaximal loads compared to submaximal loads in both trained (TL) and non-trained (NTL) legs. This study aimed to compare the effects of submaximal and supramaximal loads during EO-RT on muscle mass and functional capacities for the trained and contralateral legs.
METHODS: Forty-five physically active students (20.1±2.1 years) were placed into one of the two training groups and a control group without training (n=15). Participants in the training groups completed 20 sessions of unilateral leg press EO-RT over 10 weeks for the dominant leg. Isotonic resistance was generated by an electric-motor device at two different percentages of the concentric one-repetition maximum (1RM) for the ECC phase; 90% (submaximal load, EM1 group) or 120% (supramaximal load, EM2 group). Concentric load was the same for both groups (30% of 1RM). Thigh lean tissue mass (TLTM) by DEXA, unilateral leg press 1RM and maximal voluntary contraction (MVC), unilateral muscle power at different percentages of 1RM, unilateral vertical jump, and muscle endurance were assessed before and after training for TL and NTL.
RESULTS: The two experimental groups showed similar increases ($p<0.05$) in TLTM (2.5 and 4.2%), 1RM (6.2 and 16.3%), MVC (19.2 and 27.3%), muscle power at 40-60% of 1RM (10.2-16.2%), unilateral vertical jump height (9.1-32.9%), and muscle endurance (53.8 and 23.8%, for EM1 and EM2 respectively) in TL. Despite, no significant differences were found between training groups, qualitative analysis revealed a likely large effect on strength in EM2, whereas EM1 showed a likely large effect on muscle power at low intensities. A pooled EO-RT group was established to study the presence of cross-education effects in the NTL. Significant correlations ($p<0.001$) between TL and NTL were observed for the change in TLTM (r=0.72), 1RM (r=0.85), MVC (r=0-75), CMJ (r=0.77) and muscle power at 40-70% of 1RM (r=0.65-0.73). The control group did not show any significant changes.
CONCLUSION: Similar functional and structural effects were demonstrated after 10-weeks of EO-RT with submaximal and supramaximal loads. Strong cross-education effects were found for thigh lean mass and muscle function after the accentuated ECC strength-training program.

INCREASE IN CROSS SECTIONAL AREA IS NOT ACCOMPANIED BY A PROPORTIONAL INCREASE OF FORCE IN SINGLE MUSCLE FIBRES OF WELL TRAINED BODY BUILDERS

MONTI, E., TONIOLO, L., BONDÌ, M., MARTELLATO, I., CANCELLARA, P., REGGIANI, C., NARICI, M.V.

UNIVERSITÀ DI PADOVA

INTRODUCTION: Muscle hypertrophy is the main outcome of body building training. Previous studies have shown that, although at both whole muscle and single fibre level hypertrophy is detectable, single fibres of body builders (BB) seem to show a lower specific tension (i.e. maximum force/CSA) when compared to age-matched controls [1] [2]. The aim of the present study was to investigate the possible

reasons behind the lower specific tension observed in BB. We hypothesised that BB fibre hypertrophy was not accompanied by a proportional increase in contractile protein content.
METHODS: Five male body builders (age 26.5±5.3 years; mass 87.4±11.2 kg; height 179.0±8.4 cm) with a training history of at least 5 years were recruited after ethics approval and informed consent. Five age-matched recreationally active males (age 26.0±1.4 years; mass 75±14.1 kg; height 182.5±3.5 cm) were recruited as controls (C). During the testing session, biopsies from the vastus lateralis muscle were collected. Data analysis included (i) single skinned fibre mechanics (n=200 fibres; maximum force, CSA and tension), (ii) single fibre myosin quantification (n=100 fibres), (iii) slow and fast fibre CSA and percentage via histological section analysis. T-test for unpaired data was used for statistical analysis.
RESULTS: Under the assumption that all the fibres can be pooled together, single fibre force and CSA values were respectively 12.6% (n.s.) and 34.6% ($p<0.05$) greater in BB than C. In contrast, specific tension was 22.4% ($p<0.05$) lower in BB than C.
Histological analysis revealed that type 1 and type 2 fibre CSA was, respectively, 8.9% (n.s) and 24% ($p<0.05$) greater in BB vs C. There were no significant differences in relative amount of type 1 and 2 fibres between the two groups.
Myosin concentration was approximately two folds higher in BB compared to C ($p<0.05$).
CONCLUSION: These findings refute our hypothesis that the lower tension observed in BB fibres is linked to an inadequate myosin content. Instead, they point to a possible methodological limitation in skinned fibre maximum force detection. Indeed, Ca2+ diffusion may be less effective in the larger BB fibres because of a limited permeabilization in the skinning process. Consequently, not all the cross-bridges of most deep myofibrils may be activated.

KINETICS OF PROTEIN SA-KLOTHO AFTER AN ECCENTRIC EXERCISE IN YOUNG PEOPLE WITH A GOOD PHYSICAL CONDITION

ITURRIAGA, T., SANCHEZ-LORENTE, I.M, YVERT, T., LARROSA, M., BALMASEDA, D., BAS, A., GARCIA-GONZALEZ, D., GONZALEZ-DE RAMOS, C., FERNANDEZ-ELIAS, V., PEREZ-RUIZ, M., JIMENEZ, A., SANTIAGO, C.
UNIVERSIDAD EUROPEA DE MADRID

INTRODUCTION: High levels of soluble fraction of alpha Klotho (sαKl) have been related to longevity, with a decrease in degenerative processes and with an anti-inflammatory effect on the organism. On the other hand, an increase in sαKl levels has been described immediately after having completed an acute aerobic exercise1. The literature suggests that eccentric exercise would not have the same acute effect on this protein2 but does not report the behavior of the protein during the recovery period. Taking this background, the main objective was to analyze the acute effect of an eccentric exercise on the sαKl protein and its kinetics during the 72 hours following it.
METHODS: Participation of 15 male subjects from 18 to 35 years old with good physical condition (VO2max. 50 and 70ml/kg/min). All of them underwent an acute exercise session consisting of 100 jumps from a 50cm drawer followed by a plyometric phase, the entire execution with 10% of their additional body weight. Physical condition (VO2max) was measured with ergo spirometry and body composition (BAI: percentage of fat; ASM: Muscular Index Appen MM/height2 [kg/m2]; VATarea: visceral fat) by dual X-ray densitometry (DEXA), they measured for the sample recruitment. As a primary variable the serum levels of sαKL measured by ELISA (αKlotho Assay kit, IBL) in T1 (acute pre-intervention), T2 (acute post-intervention), T3 (24 hours after acute exercise), T4 (48 hours later) and T5 (72 hours later).
RESULTS: Homogeneous sample with VO2max averages of 57.4 ± 5.2ml/kg/min; BAI 17.7 ± 2.7%; VATarea 47.21 ± 11.6cm2 and ASM 8.3 ± 0.6. The average for the concentrations of sαKl at times T1, T2, T3, T4 and T5 are 1064.05 ± 211.23pg/ml; 982.25 ± 226.65pg/ml; 1464.73 ± 262.12pg/ml; 1465.97 ± 321.60pg/ml and 1309.68 ± 595.45pg/ml, respectively. They only present significant differences between subjects in T5 ($p=0.018$). Between the assessment moments the sαKl levels are statistically significant between T1 and T2 ($p=0.003$) and between T2 and T3 ($p=0.001$). There is a significant decrease between the acute pre and post-session moments2, however, this difference may not be relevant from a biological point of view. The main increase is observed between the post-intervention time and the following 24 hours, maintaining, in all cases, these levels between 24 and 48 hours, and finally reaching baseline values in 40% of the subjects at 72 hours.
CONCLUSION: According to the literature the results suggest that an eccentric exercise does not have immediate acute effect on soluble alpha Klotho2, but the behavior of 24, 48 and 72 hours could be an inflammatory response to this type of exercise.

EFFECTS OF TRIBULUS TERRESTRIS SUPPLEMENTATION ON MUSCLE STRENGTH, DELAYED ONSET MUSCLE SORENESS AND OXIDATIVE STRESS INDUCED BY HEAVY RESISTANCE EXERCISE

ATAEI, L., FATOUROS, I.G.
UNIVERSITY OF NICOSIA

INTRODUCTION: Depending on the volume and intensity of the loading protocol used, the mechanical strain on muscle tissue, during heavy resistance exercise, may produce structural disruptions to contractile elements within the activated muscle fibers. This leads to muscle soreness and temporary after exercise impairment of muscle function. Tribulus terrestris is a popular food supplement used by a large number of athletes and is known to increase protein synthesis activity, muscular mass as well as facilitating recuperation after physical loads. However, there is not sufficient data on the ability of this food supplement to provide the results expected in an athletes' body. Therefore, the main objective of this study was to evaluate the effects of four weeks Tribulus terrestris supplementation on muscular strength, exercise induced oxidative stress and delayed Onset muscle soreness (DOMS) in sedentary men.
METHODS: Thirteen healthy sedentary men (Age: 23.93± 2.16 yrs, Height: 1.82± 0.082m, Weight: 84 ±11 kg) voluntarily participated in a two-trial, double blind, crossover, repeated-measures. Participants received either a daily oral supplement of Tribulus (n = 13) or placebo (n =13) for 4 weeks with a 4-week wash-out period in between trials. In each trial, participants took part in an intense resistance exercise regime before and after the 4wk supplementation period. Isometric torque, range of motion, lactate, delayed onset muscle soreness, white blood cell count and creatine kinase were measured as indices of muscle function and damage. Reduced glutathione, oxidized

glutathione, thiobarbituric acid–reactive substances, protein carbonyls and total antioxidant capacity were measured as indices of blood redox status. All measurements were conducted before, immediately after, and 1, 2 days after exercise.
RESULTS: The results demonstrated that supplementation with Tribulus.T did not enhance the parameters of muscle strength and body composition. Moreover, Tribulus.T did not change the total serum level of testosterone. The results failed to support any effect of Tribulus.T supplementation on reducing the inflammation and oxidative stress response to resistance exercise. Heavy resistance exercise had a similar effect on modified blood redox status biomarkers, muscle damage and performance, in both the supplemented and Placebo groups.
CONCLUSION: These results suggest that, despite marketing opinions about Tribulus T. as an ergogenic and testosterone enhancer, this supplement is unable to optimise physical performance or influence testosterone levels. In addition, the lack of any effect on the physiologic and biochemical outcome measures used, raises questions about the validity of using Tribulus.T supplementation as a muscle redox modulator or the redox status in healthy sedentary men.

INFLUENCE OF THREE DIFFERENT REST INTERVALS BETWEEN SETS ON MECHANICAL, PHYSIOLOGICAL, AND PERCEPTUAL VARIABLES DURING A FLYWHEEL SQUAT SESSION WITH TWO INERTIAL LOADS

HERNÁNDEZ-DAVÓ, J.L., SABIDO, R., CAPDEPON, L.

SPORT RESEARCH CENTER, MIGUEL HERNANDEZ UNIVERSITY

INTRODUCTION: In the last few years, the use of flywheel resistance exercises has increases exponentially (1). Although the influence of different rest intervals on both acute responses and chronic adaptations to strength training when using traditional (gravitational) loads has been widely studied (2), little is known concerning the use of different RIs between sets during flywheel resistance training sessions. Therefore, the aim of the present study was to evaluate the influence of three different rest intervals (RI) between sets (1, 2, or 3 min), on power output, lactate concentration, rating of perceived exertion (RPE) and delayed onset muscular soreness (DOMS) during a flywheel squat sessions with two different inertial loads (0.025 and 0.075 kg•m2).
METHODS: Twenty-three male handball players (age: 24.4 ± 4.3 years; height: 1.83 ± 0.07 m; body mass: 80.7 ± 6.3 kg) performed six different testing sessions (two inertial loads × three RI) consisting of 4 sets of 11 repetitions of the flywheel squat exercise. Concentric power, eccentric power, and eccentric overload (eccentric/concentric ratio) during each repetition were recorded, lactate concentration was measured one minute after the last set, RPE (0-10) five minutes after, and DOMS (0-10) 24h post session.
RESULTS: Within RI analysis showed that concentric peak power decreased across sets when the 1 min RI was used, independently of the inertial load used (9.1% and 22.1% for 0.025 and 0.075 kg•m2 respectively), while eccentric peak power decreased (17.5%) with the 0.075 kg•m2 inertial load. Contrarily, participants were able to maintain power output with both inertial loads when using 3 min RI, while the 2 min RI protocol only entailed significant decreases (12.4%) in concentric peak power with the higher inertial load (0.075 kg•m2). RPE trend to be higher when using the 1 min RI (6.9 ± 1.0) compared to both the 2 min RI (6.0 ± 1.5) and the 3 min RI (6.2 ± 1.9) protocol. Lactate concentration was higher when comparing the 2 min RI (5.5 ± 1.5 mmol) with the 3 min RI (4.3 ± 1.6 mmol) when performing the training session with the 0.025 kg•m2 inertial load. Independently of the inertial load used for training, DOMS 24h did not differ between the RI protocols
CONCLUSION: During flywheel resistance training sessions, short RI (1 min) were insufficient to maintain power output across sets. Two minutes of RI could be enough only when training with light inertial loads. The management of power output decreases within flywheel resistance training sessions are highly dependent not only on the rest interval used between sets, but also on the inertial load used during training.

OP-BN30 Injury prevention

ACTIVE & SAFE CENTRAL: AN ON-LINE PLATFORM AND RESOURCE FOR THE PREVENTION OF INJURY IN SPORT AND RECREATIONAL ACTIVITY

PIKE, I., BLACK, A.M., JACOB, J., BABUL, S., RICHMOND, S.

UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: Sport and recreation-related injuries have a significant cost in terms of the impact on the health care system. As prevention researchers and practitioners, we have a responsibility to provide guidance toward prevention to those who participate in sport, and those that coach, treat, and parent children that participate in sport. There are effective interventions to reduce injury in many sport and recreational activities; however, the accessibility of this information, as well as the guidance required to implement it, is often not available and accessible to the public.
The objective of this project was to complete a large-scale systematic review and synthesis of the literature across 51 sport and recreational activities. The evidence was used to inform the development of an end-user driven, digital platform that provides injury prevention information and resources.
METHODS: An evidence synthesis framework was used to guide a review of reviews of 51 sport and recreational activities by 18 injury prevention trainees from across Canada. Data collection included evidence on the incidence, risk factors, interventions and implementation and evaluation of interventions to reduce the risk of injury in sport. Evidence was critically appraised, extracted, synthesized and translated into clear messaging for use in an online tool.
RESULTS: The 'Active & Safe' platform provides web-based sport injury and prevention information. Navigation through the tool brings the user to a sport specific content page subdivided into 4 sections: 1) sport injury overview, 2) incidence, 3) risk factors, and 4) prevention. Users are given evidence-informed, actionable prevention messaging from a personalized sporting context.
CONCLUSION: This user friendly, web and mobile accessible tool can increase the reach, awareness and implementation of prevention programming in sport and recreational activity.

POSTURAL DYNAMICS IS ALTERED IN FEMALES WITH EXCESSIVE MEDIAL KNEE DISPLACEMENT DURING SINGLE-LEG LANDING

VAZ, J.R., STERGIOU, N., HUG, F., DINIZ, A., DINIS, R., PEZARAT-CORREIA, P.

UNIVERSIDADE EUROPEIA

INTRODUCTION: Knee valgus motion observed during landing tasks has been proposed as a predictor of future knee injury. Such greater knee valgus mainly involves excess motion in the frontal plane and is known to be greater in individuals with excessive medial knee displacement. This excessive frontal plane motion affects postural control during sports maneuvers. The medial-lateral component of the center of pressure is, therefore, very likely to be altered in this population. In particular, the fluctuations in the center of pressure of these individuals is unknown. Previous sports medicine-related research suggests that the understanding of the nature of these fluctuations in the temporal structure of the centre of pressure provide rich and more sensitive information to identify risk of re-injury. Thus, we aimed to investigate the fluctuations of the centre of pressure in individuals with and without excessive medial knee displacement. We hypothesized that these fluctuations would be less structured, i.e., would show randomness in its temporal structure, indicates decreased adaptability and flexibility of the system.
METHODS: Twenty females (12 controls; 8 with excessive medial knee displacement) were instructed to performed single-leg landing tasks from three different directions (frontal, lateral and diagonal). The participants landed on a forceplate and stayed still for 20 seconds while centre of pressure was measured. The fluctuations of the temporal structure of the medial-lateral and anterior-posterior components of the centre of pressure were determined through the calculation of Sample Entropy, a measure of regularity. Other traditional measure of postural control (e.g. time to stabilization [TTS], sway path, root mean square [RMS] and range) were also determined. A two-way repeated measures ANOVAs was used.
RESULTS: We observed that in the anterior-posterior CoP component, RMS and Range were lower in the lateral direction compared to both frontal and diagonal. In the medial-lateral CoP component, the RMS showed to be higher in the lateral direction compared to frontal and diagonal. We have found that out of all the studied postural control parameters, only the Sample Entropy of the medial-lateral component was different between groups ($p<0.001$). Individuals with excessive medial knee displacement exhibited a decreased regularity, i.e. greater randomness, compared to controls.
CONCLUSION: These findings suggest a decreased ability to adapt and adjust to environmental demands and constraints that likely result in an increased risk of injury. More interestingly, we observed that common traditional measures used frequently in the study of postural control (e.g. time to stabilization, sway path) were unable to distinguish between individuals with and without excessive medial knee displacement. This suggest that alternative methods that explore not only the amount of movement variability but also the temporal structure and organization of movement are highly relevant in sports medicine.

NEURODYNAMIC SLIDERS PROMOTE FLEXIBILITY IN TIGHT HAMSTRING SYNDROME.

DE RIDDER, R., DE BLAISER, C., VERRELST, R., DE SAER, R., DESMET, A., SCHUERMANS, J.

GHENT UNIVERSITY

INTRODUCTION: Hamstring injury prevention puts emphasis on optimizing the muscle's strength - length relationship. To assure appropriate muscle length, flexibility training is imperative. As neurodynamics play an important role herein, the goal of this study was to explore the immediate intervention effect of a home-based neurodynamic slider program on hamstring flexibility and its sustainability.
METHODS: A total of 50 male subjects were recruited to participate in this randomized controlled trial. To be eligible, participants had to meet the following inclusion criteria. Subjects needed to be (1) male, (2) aged between 18-30yrs, (3) recreationally/competitively active and (4) had to have limited hamstring flexibility (Tight Hamstring Syndrome) (SLR≤75°). Subjects were randomly assigned to either performing a neurodynamic sliding technique (3x20 reps) or a static stretching protocol (3x30") on a daily basis for a 6-week period. Hamstring flexibility was assessed by means of the Straight Leg Raise at baseline, immediately after the intervention and after 4 weeks follow up. To analyze the intervention effect, a 2x3 repeated measures ANOVA was performed, with the factor 'group' acting as the between-subject variable (neurodynamic, static stretch) and the factor 'time' as the within subject variable (baseline – post intervention – follow up). The primary outcome of interest was the interaction effect (group x time). If significant, post hoc pairwise comparisons with Bonferroni correction were performed to analyze both within and between group differences at the study time points.
RESULTS: There was no between group baseline difference in hamstring flexibility. The repeated measure ANOVA showed a significant interaction effect for group x time ($p<0.001$). Independent sample T-test showed a significantly higher increase in flexibility gain in the neurodynamic group immediately after the intervention (12.6° versus 9.3°; $p<0.001$), as well as at 4 weeks retention-analysis 9.1° versus 5.7°; $p=0.001$) compared to the static stretch group.
CONCLUSION: Both interventions significantly increased hamstring flexibility, exceeding the MDC95 of 3.18°. However, our results clearly showed the potential beneficial effect of using neurodynamic sliders over the regular method, with a significantly higher increase in hamstrings flexibility, confirming our study hypothesis. In terms of sustainability of the intervention effect, there was a comparable loss in gain for both groups over the 4 weeks after termination (respectively 3.5° and 3.6°). When comparing the residual gain, there still a significantly higher increase in hamstring flexibility for the neurodynamic slider technique versus for the static stretch. These results advocate the impact of neurodynamics on flexibility which could be indispensable in primary and secondary prevention of hamstring injuries.

CHARACTERISTICS OF KNEE VALGUS MOTION ARE DIFFERENT BETWEEN LANDING AND SIDESTEP CUTTING TASKS IN FEMALE SOCCER PLAYERS

ITO, W., KIKUMOTO, T., NAKAMURA, E., HIRABAYASHI, R., EDAMA, M.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: Several female soccer players suffer non-contact anterior cruciate ligament (ACL) injuries. Many non-contact ACL injuries reportedly occur during sidestep cutting in these players. Dynamic knee valgus is recognized as a risk factor for non-contact ACL injuries. Video analysis is a clinically convenient method for predicting potential non-contact ACL injuries. Although some video screening tests are available for assessing knee valgus motion during landing tasks, there are no video screening tests employing sidestep cutting tasks. This study aimed to investigate knee valgus motion based on the relationship between landing tasks and sidestep cutting tasks and to recommend a novel screening test using sidestep cutting task.
METHODS: Twenty female soccer players performed double-leg drop jump, single-leg drop jump, and sidestep cutting tasks. A drop jump task was defined as landing forward from a 30-cm high box and a maximum vertical jump with single leg and both legs respec-

tively. A sidestep cutting task was defined as a single leg hop forward, landing with the same leg, and cutting to the opposite direction of the standing leg. We used a high-speed video camera (240Hz) to capture motion data in the frontal plane. We calculated knee valgus motion as the displacement of the knee position between the initial contact and maximum knee valgus using the video motion analysis software Kinovea. Pearson's correlation coefficients were used to explore knee valgus motion based in the relationship between the landing and sidestep cutting tasks. Statistical significance was set at $P < 0.05$.
RESULTS: Knee valgus motion of the double-leg drop jump and single-leg drop jump tasks were not significantly correlated with that of the sidestep cutting task. The knee valgus motion in the double-leg drop jump task was significantly moderately correlated with that of the single leg drop jump task ($r = 0.45$; $P < 0.05$).
CONCLUSION: Characteristics of knee valgus motion are different between landing and sidestep cutting tasks. Therefore, measuring knee valgus motion during landing tasks is not adequate in a screening test for non-contact ACL injuries. The findings indicate that the movement of the whole body varies depending on specific sporting tasks. Consequently, we recommend the consideration of knee valgus motion during sidestep cutting for predicting potential non-contact ACL injuries in female soccer players.

EVALUATION OF AN ERGONOMIC PREVENTION PROGRAM TO REDUCE MUSCULOSKELETAL DISORDERS IN GERIATRIC CAREGIVERS

OTTO, A.K., WOLLESEN, B.
UNIVERSITY OF HAMBURG

INTRODUCTION: In their daily work, geriatric caregivers frequently perform transferring tasks under time pressure and in awkward postures and therefore have a high disposition for musculoskeletal disorders (MSD) (1). Due to the manifold demands on the musculoskeletal system, programs for the prevention of back pain and MSD are necessary. The aim of this study is to examine whether ergonomics- and posture-training (BASE program) (2) produces a change in movement behavior and a reduction in back pain.
METHODS: The randomized controlled trail included N=24 (age: 40.8±9.6 years) in the intervention group and N=27 (age: 42.7±11.0 years) in the control group. The effects of a 10-week BASE program were analyzed (Progressive Isoinertial Lifting Evaluation (PILE-Test) (3), Visual Analog Scale (VAS) (4)). The analysis incorporated Chi2-tests and analysis of variance (SPSS 23; Armonk, New York).
RESULTS: Compared to the control group, the intervention group achieved a significant increase in lifted weight ($F(1.49)=17.429$ $p=0.000$) in the PILE-Test with improved lifting quality (reduced thoracic spine hyperkyphosis). The perception of pain was also reduced. There were no significant changes in the VAS.
CONCLUSION: The BASE program reduced the dysfunctional lifting behavior of geriatric caregivers with improved lifting performance and reduced test stoppages due to pain. A reduction in back pain was not achieved, which could be attributed to the many factors influencing the musculoskeletal system in nursing. In addition, it is unclear whether the duration of the intervention (10 weeks) is sufficient to achieve changes in the VAS. The effects of a combined prevention program (10 weeks BASE program and 12 weeks back-fitness) to improve the quality of movement and increase physical resources are currently being tested.

A PROSPECTIVE INVESTIGATION OF THE ASSOCIATION BETWEEN ISOMETRIC MUSCLE STRENGTH AND RUNNING RELATED INJURY AMONG NOVICE AND RECREATIONAL RUNNERS.

DILLON, S.1,2, WHYTE, E.1, BURKE, A.1,2, O'CONNOR, S.1, GORE, S.1,2, MORAN, K.1,2
DUBLIN CITY UNIVERSITY

INTRODUCTION: Recreational running has many health, social and psychological benefits. However, there is a considerable risk of developing a running related injury (RRI) (1). Therefore, understanding the aetiology of these injuries, with a view to reducing the risk of their development is of paramount importance. Deficits in muscle strength is a proposed risk factor in developing RRIs, though conflicting evidence exists to support this claim (2,3). The majority of this research has been retrospective, limiting the ability to establish a causal relationship. Furthermore, many studies have had small sample sizes, low relative numbers of injured participants or have employed isokinetic machines, which have practical limitations. This study aims to prospectively investigate the impact of isometric muscle strength on the likelihood of sustaining a RRI.
METHODS: One hundred and seventy six injury-free recreational and novice runners (66 females, 110 males, 42.5±9.2 yrs) were recruited. During a single baseline session, three measures of the maximum isometric strength, normalised to body mass, of the following five muscle actions were recorded bilaterally using a hand-held dynamometer (HHD) (J-Tech, USA); hip abduction and extension, knee flexion and extension and ankle plantar flexion. A RRI was defined as any lower limb or back injury persisting for at least 7 days or 3 consecutive training sessions, causing restriction of running or requiring medical consultation (4). RRIs were tracked prospectively via email for a period of six months. Backwards logistic regression analysis was performed to investigate the impact of isometric muscle strength on the likelihood of sustaining a RRI. Multicollinearity was assessed and highly related variables were removed.
RESULTS: Fifty-nine participants reported a RRI over the six-month period (INJ: 35 male, 24 female, 43.6±9.5 yrs; UNINJ: 75 male, 42 female 40.3±8.0 yrs). A statistically significant model was able to be generated to predict injury ($\chi2=2.57$, $p=.02$), which correctly classified 66.7% of cases with high specificity (95.7%). This was a relatively low improvement on the null hypothesis model, which predicted 66.1% of cases correctly. The model only explained 4.3-5.9% of the variance and the sensitivity was very low (10.2%). Only age (OR=.97, 95% CI:.93-1.0) and hip extension strength (OR=1.5, 95% CI:.89-2.52) remained in the model.
CONCLUSION: Isometric muscle strength, as assessed in this study, may not be able to accurately predict a future RRI. Strength measures may not reflect the ability to effectively implement an injury-resistant running technique or may not reflect tissue strength. Given that injuries are caused by high loading relative to tissue strength, future research should examine strength and localised loading during running as combined factors in predicting RRI.

LONG TERM EFFECTS OF MULTIPLE CONCUSSIONS ON NEUROVASCULAR COUPLING IN RETIRED CONTACT SPORT ATHLETES

SIRANT, L.W.1, SINGH, J.1, MARTIN, S.2, GAUL, C.A.2, STUART-HILL, L.2, NEARY, J.P.1

1: UNIVERSITY OF REGINA, 2: UNIVERSITY OF VICTORIA

INTRODUCTION: It is well documented that concussions can have acute and long-term effects on physiological systems in the body. Research suggests that previously sustained concussions alter physiological mechanisms that control cerebral blood flow, oxygenation, and autonomic function. One such mechanism that is purportedly affected is neurovascular coupling which ensures adequate cerebral blood flow during increased neuronal activity. Near-infrared spectroscopy (NIRS) is a non-invasive method used to assess cerebral haemodynamics by measuring local tissue saturation (%TSI), oxygenated (HbO2), deoxygenated (HHb) and total haemoglobin (tHb), and haemoglobin difference (HbDiff). The aim of this study was to investigate the long-term effects of multiple concussions on neurovascular coupling by using NIRS to measure cerebral haemodynamics during a 5-minute object identification protocol ("Where's Waldo") in retired contact sport athletes.
METHODS: 7 retired male contact sport athletes with confirmed multiple concussions (mean age=65±8 yr) were age matched with 7 healthy male controls without concussion history (mean age=65±8 yr), with all participants still being physically active in their retirement. Oxygenation parameters were recorded using NIRS located over the right prefrontal cortex, 1 cm above the eyebrow, during 5-minute seated rest and 5-minute "Where's Waldo" protocol. Following the seated rest, participants were instructed to close their eyes for 20 seconds followed by 40 seconds of searching a computer screen for "Waldo" hidden in a field of distractors of similar shape and colour. This was repeated 5 times without breaks. NIRS variables during "Waldo" were determined by calculating the change from the rest stage. Student t-tests were used to compare the previously concussed athletes to healthy controls without concussion history.
RESULTS: The change in HbDiff from rest was significantly (p=0.04) higher in the concussion-free control group (mean=2.40±0.92 μM) when compared to the formerly concussed group (mean=1.19±0.81 μM) during the "Waldo" protocol, representing a 50% difference between groups. %TSI (p=0.70; 27% decrease), HbO2 (p=0.32; 38% decrease), HHb (p=0.28; 96% decrease), and tHb (p=0.77; 18% decrease) did not achieve statistical significance.
CONCLUSION: HbDiff measurement is used to reflect oxygen utilization. Our research suggests that there are potential long-term effects on neurovascular coupling in individuals who have a history of concussions. Significant decreases in HbDiff in the retired contact sport athletes with concussion history compared to the controls without concussion history provides preliminary evidence of autonomic dysregulation in the brain's ability to adapt cerebral blood flow to increased neuronal activity. However, a larger sample size is required to provide greater insight into the long-term physiological changes.

REPEATED-SPRINT TRAINING IN HYPOXIA IN ELITE FEMALE RUGBY SEVENS

BROCHERIE, F., RACINAIS, S., COUDERC, A., PISCIONE, J., TOWNSEND, N., GIRARD, O.

FRENCH INSTITUTE OF SPORT

INTRODUCTION: Growing evidence suggests that repeated-sprint training in hypoxia (RSH) improves anaerobic or repeated sprints performance in team sports (Brocherie et al., 2017), with only one study (Kasai et al., 2015) so far having investigated its effect with college female athletes. However, with females being less sensitive to hypoxic stimuli (Billaut and Smith, 2009) and more fatigue resistant during repeated sprints (Billaut and Bishop, 2009) than males, confirmatory RSH studies involving elite female athletes are warranted. This study therefore aimed to investigate the effect of a short-term RSH intervention in elite female rugby sevens.
METHODS: Twenty-four female elite rugby sevens players performed repeated-cycling sprints (i.e., 4 sets of 5 × 5-s sprints – 25-s inter-sprint recovery and 3-min inter-set rest) triweekly for 2 weeks under either normobaric hypoxic conditions (RSH group; exercise at simulated altitude of 5000 m with inter-set rest in normoxia; n = 12) or normoxic conditions (RSN group; exercise and inter-set rest at sea level; n = 12). Before and after the training intervention performance was assessed from tests of (i) Force-Velocity (F-V) (from a single, overground straight 50-m sprint), (ii) treadmill repeated-sprint ability (8 × 5-s – 25 s) and (iii) on-field aerobic capacity (Yo-Yo intermittent recovery level 2 or YYIR2).
RESULTS: From before to after training, 50-m sprint performance did not change ($P > 0.08$ for 10-m, 20-m, 30-m and 50-m split times) in either RSH or RSN, as F-V-related parameters (maximal force, maximal velocity and power) did (all $P > 0.24$). Mean velocity during repeated sprints was on average higher after compared to before training ($P < 0.001$), yet with no difference between groups ($P = 0.10$) nor any significant interaction ($P = 0.76$). Distance covered during YYIR2 did not change significantly in both groups ($P = 0.81$).
CONCLUSION: In elite female rugby sevens, a short-term RSH intervention had minimal effects on physical fitness performance when assessed immediately after the training camp. Several factors including residual fatigue, an excessive physiological stress, large individual responses and/or delayed effects could potential explain these observations.

NEWCOMB BALL: TRAINING EFFECT ON THE PHYSICAL FITNESS OF WOMEN AT MIDLIFE

TSUK, S.

WINGATE COLLEGE

INTRODUCTION: Newcomb ball is a challenging and enjoyable game that has widely spread among women at midlife in Israel. The game is technically simple and can be performed by amateur participants. We aimed to examine the effect of Newcomb ball training on the physical fitness of women at midlife.
METHODS: One hundred and eighteen women, aged 29-45 yrs, were assigned to an experimental group (EG) or a control group (CG), and completed two similar sets of tests before and after seven months of training. While the EG performed two Newcomb ball-training sessions per week, the CG remained non-active throughout the seven months
RESULTS: Leg power, arm power, agility, speed, and aerobic scores were significantly higher for the EG compared to the CG at baseline ($p<.001$ for all). EG showed significant improvement in arm power (5.3 ± 0.9 vs 5.6 ± 0.9 m), agility (10.68 ± 0.95 vs 10.37 ± 0.89 sec), speed (4.11 ± 0.45 vs 4.01 ± 0.33 sec), and aerobic fitness (563 ± 328 vs 680 ± 378 m) (ES = 0.45 – 0.61, $p<.001$ for all) following training, while no significant changes, except for a significant increase in arm power (ES = 0.42, $p<.05$), were found for the CG in any of the fitness variables following training.
CONCLUSION: The findings indicate that Newcomb ball training can be used as an efficient and enjoyable tool for fitness development among midlife amateur women. Its positive influence on aerobic fitness is of particular importance, considering its possible association with the participant's health status.

A COMPARISON OF WORKLOADS PLACED ON FIELDERS, BOWLERS AND BATTERS IN A TEAM COMPETING IN THE 2018 INDIAN PREMIER LEAGUE SEASON

CHRISTIE, C.J., MCEWAN, K., SHOLTO-DOUGLAS, R., POTE, L.

RHODES UNIVERSITY

INTRODUCTION: Twenty20 (T20) cricket is the latest format of cricket and is much shorter and faster than one or multiple day cricket. The Indian Premier League (IPL) is the largest and one of the most popular T20 leagues which generates lots of money. Workload monitoring is a technique used to manage stressors placed on athletes to maximise the training response while remaining uninjured. Understanding workloads can facilitate effective training sessions which enhance the training stimulus and reduce the risk of injury. No study has looked at the workloads imposed on cricketers during a typical IPL season and so the aim of this study was to determine the workloads placed on a cricket team in this league and to compare the workloads placed on batters, bowlers and fielders.
METHODS: This was a retrospective cohort study of 12 elite male cricket players competing for the same team at the 2018 IPL. In total, 274 individual pitch-based training and 117 individual match observations were recorded over 8 weeks (2 April 2018- 21 May 2018). Bowling workload was calculated by multiplying session Rating of Perceived Exertion (sRPE) (1= very, very light to 10= very, very hard) by number of deliveries (balls).Batting workload was calculated by multiplying sRPE with duration (min) spent batting. Fielding was calculated by multiplying sRPE by time (min) spent fielding.
RESULTS: Fielding workload was significantly greater than bowling ($p < 0.001$; d= 1.32) and batting during matches ($p < 0.001$; d=1.25). However, bowling workload was significantly greater than batting ($p < 0.001$; d= 1.01) and fielding ($p < 0.001$; d= 0.85) during training sessions. Further, bowling workloads were significantly greater during training sessions than matches ($p < 0.001$; d= 1.01); whereas fielding workloads were significantly greater during matches than training sessions ($p < 0.001$; d= 1.25).
CONCLUSION: This is the first study to quantify the workloads place on cricketers during an IPL season. Workloads were high and were greatest in fielders during matches by virtue of the fact that fielding takes the longest. Time spent practicing fielding during training was significantly lower than that required in matches. In contrast, workloads were higher in bowlers and batters during training compared to matches. Coaches and players should carefully manage loads considering both training and match workloads and more attention, arguably, needs to be afforded to fielding during training.

OP-PM68 Health and fitness: Brain, mental and mixed

TRAVEL FATIGUE AND SLEEP/WAKE BEHAVIOURS OF PROFESSIONAL SOCCER PLAYERS DURING INTERNATIONAL COMPETITION

LASTELLA, M., ROACH, G.D., MILLER, D.J., SARGENT, C.

CENTRAL QUEENSLAND UNIVERSITY

INTRODUCTION: The magnitude of travel completed by professional Australian soccer teams during domestic competition is substantial. The inclusion of Australian soccer teams into the Asian Champions league has seen additional stress placed on soccer players' training and competition schedules. For management staff, the complexity of organising training and travel schedules during domestic competition and the Asian Champions league is challenging. The purpose of the present study was to examine the sleep and fatigue of soccer players during an intensive home and away travel schedule during Australian domestic season and the Asian Champions League.
METHODS: This study examined the sleep and fatigue of Australian soccer players during an intensive home and away travel schedule during the Asian Champions league. Seven male professional soccer players (Mean ± SD: age 25.2±3.2 years, height 182.8±5.2cm, body mass 84.6±7.4kg) sleep/wake behaviour was assessed using sleep diaries and wrist activity monitors for 19 days, including nine days before, five days during, and four days after a home and away group stage match of the Asian Champions league. Analyses examined differences in sleep/wake behaviour and fatigue between day type (training day, rest day, pre-game and post-game) and between sleep location (Adelaide, during Flight, and Hiroshima).
RESULTS: Sleep/wake behaviour and fatigue was poorest the night immediately after games compared to the night before games, training days, and rest days. Soccer players' sleep/wake behaviours were disrupted during flights such that they obtained 3.6 hours less sleep during flights compared to sleep in Adelaide (7.0±1.6 h) and Hiroshima (7.0±2.1 h).

CONCLUSION: The sleep/wake behaviours of professional soccer players are compromised when they are required to travel and compete in multiple matches within a short period of time. If given the opportunity, professional soccer players will compensate by extending their sleep the following day by one to two hours to ameliorate any sleep loss or fatigue.

ARE COGNITIVE SKILLS IN YOUNG ADULTS AFFECTED BY A BOUT OF SUB-MAXIMAL AEROBIC EXERCISE?

PILZ-BURSTEIN, R., LUZON, Y.

GIVAT-WASHINGTON ACADEMIC COLLEGE OF EDUCATION, ISRAEL

INTRODUCTION: The impact of physical activity and aerobic fitness on cognitive functions has been studied primarily in relation to childhood development. Yet, as the human brain achieves full development by the third decade of life, the effect of aerobic exercise on cognitive skills in healthy, young adults deserves attention. This work evaluated the effect of a bout of sub-maximal aerobic exercise on cognitive skills, as reflected by a battery of executive function and memory tests.
METHODS: Twelve healthy male students, 22-33-years-of-age participated in the study. They arrived at the Physiology Lab 3 times, one week apart. On the first visit, after a basic physical exam, each subject performed an aerobic capacity test to determine VO2 max. On the second visit, they were randomly divided into Group A, which performed a bout of sub-maximal aerobic exercise prior to cognition tests and on the third visit, performed the cognition tests at rest. Group B performed the tasks in the opposite order—cognitive tests at rest on the second visit and aerobic exercise before cognitive tests on the third. This was designed to eliminate any learning effect in cognition testing. Aerobic exercise consisted of a 20-minute tread-mill running test at 70% of the subjects VO2 max, as determined at the first visit. The cognition tests started 10 min. post-exercise and consisted of Stroop, Trail Marking, Word Flow, and Serial Sevens.
RESULTS: The mean values for VO2 max, heart rate and Rate of Perceived Exertion were 49±3.5 ml/kg/min, 189±5.8 beats/min. and 19±1.1, respectively. Group B achieved higher results in the Stroop test-part 3 when performed after exercise than when at rest (56.8±17.2 vs.47.7±13.8 words/min., respectively) ($p<0.05$). For Trail Marking-part 1, better results were attained by group A when performed at rest than after exercise (26.5±7.6 vs. 31.7±9.7 sec., respectively) ($p<0.05$). However, for part 2, which is more difficult, results were 66.2±10.6 vs. 57.3±9.8 sec., for rest and post-exercise, respectively for group B ($p<0.05$). For Word Flow test, Group A results were similar with or without exercise (13±3.2 vs. 14.7±3.1 words/min. $p=0.337$), but group B scored better after exercise than at rest (14.7±3.1 vs. 13±3.2 words/min., respectively; $p<0.01$). No effect of exercise on the Serial Sevens test was seen.
CONCLUSION: These preliminary findings suggest that one bout of sub-maximal aerobic exercise may have a positive effect on some but not all cognitive functions, in young adults. This effect was more pronounced in complex rather than in simple cognitive tasks. Based on these results, it is worth considering integrating brief, sub-maximal aerobic exercise prior to academic classes and intellectual tasks.

ADAPTATION VARIATION BETWEEN DOMINANT AND NON-DOMINANT UPPER LIMBS FOLLOWING SHORT-TERM STRENGTH TRAINING.

ROWE, G.

EDITH COWAN UNIVERSITY

INTRODUCTION: Chronic strength training generates neural and muscular adaptations that facilitate improvements in physical function. However, little is known about the relative adaptive responses of dominant (DOM) versus non-dominant (NON-DOM) limbs to strength training. Understanding these responses may explain the results of studies in which unilateral training was provided without consideration of limb dominance effects. Therefore, the purpose of the present study was to describe the relative neuromuscular adaptive responses between DOM and NON-DOM limbs following strength training.
METHODS: Twenty-four participants who were naïve to strength training performed 4 weeks of unilateral dumbbell bicep curls with both upper arms 3 times a week. Training sessions consisted of three sets of 8 – 12 repetitions at 75% of 1-RM, with 3-s eccentric and 2-s concentric contraction cadences. Neural adaptations were investigated with transcranial magnetic stimulation (TMS) and electromyography (EMG), while muscle cross-sectional area (CSA) was examined with peripheral quantitative computed tomography (pQCT). Functional changes were investigated with isometric, isokinetic and dynamic constant external resistance testing techniques.
RESULTS: The percentage change in EMG activity (normalised (Mmax)) measured early in an isometric contraction (25 ms integral after EMG onset) increased significantly ($p=0.041$) more in NON-DOM (53%) than DOM (7%). Elbow flexor muscle CSA increased significantly ($p<0.001$) by 7% in both limbs, but there were no significant between-limb differences. 1-RM strength, isometric peak torque and isokinetic peak torques at movement speeds of 20 and 210 deg/s increased significantly, but there were no differences between DOM and NON-DOM. Significant relationships were observed between the changes in 1-RM strength and muscle CSA in both limbs (DOM; $r=0.537$, NON-DOM; $r=0.429$). In NON-DOM, the changes in isometric peak torque were statistically related to changes in early EMG activity ($r=0.350$) and EMG silent period duration measured after TMS ($r=-0.447$). Changes in the rate of force development (RFD) measured early in the force rise (<100 ms) were related to changes in early EMG activity in both limbs (DOM; $r=0.437$, NON-DOM; $r=0.461$), while the changes in late RFD (>100 ms) were related to changes in peak EMG/Mmax in DOM ($r=0.407$).
CONCLUSION: While there were similar responses between the DOM and NON-DOM limbs for 1-RM strength, isometric peak torque, isokinetic peak torques at different movement speeds and muscle CSA following strength training, an important distinction was that improvements in early EMG activity were statistically larger in NON-DOM. The correlational findings also suggest that the DOM and NON-DOM limbs adapt differently to strength training. Researchers should consider these limb differences before interpreting the underlying causes of their results.

EFFECTS OF ACUTE MAXIMAL AND SUBMAXIMAL EXERCISE ON EXECUTIVE FUNCTION: A COMPARISON BETWEEN ARM AND LEG CYCLING

HILL, M., WALSH, S., TALBOT, C., PRICE, M., DUNCAN, M.

COVENTRY UNIVERSITY

INTRODUCTION: To date, the vast majority of research has investigated changes in cognitive performance (i.e. executive function) after an acute bout of maximal or submaximal lower body exercise (i.e. cycling) (Chang et al. 2012). However, physiological responses to arm and leg cycling are different (Sawka, 1986). When considering mechanisms for any change in cognitive performance, the mode and intensity of exercise may be important (and interactive) for determining the amount of change in physiological mechanisms that can be achieved. Thus, the aim of this study was to compare the effects of maximal and submaximal arm and leg cycling on executive function.

METHODS: Thirteen physically active males (age, 24.7 ± 5.0 years; mass, 74.1 ± 9.4 kg; height, 1.77 ± 0.08 m; BMI, 23.58 ± 2.63 kg.m-2) undertook two incremental exercise tests to volitional exhaustion for (1) arm-cycling (82 ± 18 W) and (2) leg-cycling (243 ± 52 W); two subsequent tests of 20-min duration for (3) arm-cycling (41 ± 9 W) and (4) leg-cycling (122 ± 26 W) at a relative intensity corresponding to 50% of the ergometer-specific peak power output and a final leg-cycling trial performed for 20-min at the same absolute power output as the submaximal arm-cycling trial (41 ± 9 W) to match absolute exercise intensity. Incongruent reaction time was collected while participants completed an executive function task (Erikson Flanker) before, immediately after and 15-min after each exercise test.
RESULTS: Maximal leg-cycling elicited a slower speed of processing ($P = 0.048$ $d = 0.28$), while maximal arm-cycling elicited a faster speed of processing ($P = 0.004$, $d = -0.39$), immediately post exercise. Further, 20-min of arm-cycling ($P = 0.0004$, $d = -0.65$) and leg-cycling ($P = 0.0003$, $d = -0.51$) matched for the same relative intensity (50% peak power output) induced comparable improvements in speed of processing immediately post exercise. Leg-cycling at the same absolute power output as submaximal arm-cycling resulted in a blunted post-exercise cognitive response ($P > 0.05$). Following all tests, reaction time had returned to baseline levels with 15-min of post-exercise.
CONCLUSION: Incremental exercise performed to volitional exhaustion with the arms and legs elicit different post-exercise responses in executive function. Submaximal exercise performed at 50% of peak power output significantly enhanced executive function, independent of the muscle mass employed. However, leg-cycling at the same absolute power output as submaximal arm-cycling resulted in a blunted post-exercise cognitive response. The present findings have direct application to individuals restricted to upper body exercise (i.e. disabled or those undergoing rehabilitation), as well as for numerous industrial, sport-specific and military tasks.

THE RISK FOR THE FEMALE ATHLETE TRIAD IN BRAZILIAN ATHLETES

DE MARIA, U.P., JUZWIAK, C.R.

FEDERAL UNIVERSITY OF SÃO PAULO

INTRODUCTION: The Female Athlete Triad (TRIAD) is a medical condition observed in athletes and physically active females in which low energy availability (LEA) is considered its main component. In its most extreme manifestation, athletes with TRIAD present LEA, with or without eating disorder, amenorrhea and osteoporosis (1). The aim of this study was to identify the risk of TRIAD in Brazilian athletes from several sports disciplines.
METHODS: Female athletes (n=127) participating in endurance, CrossFit®, aesthetic, combat and team sports, aged 18-39 years of old, training ≥5 hours/week, and regularly competing responded to the Brazilian validated version of the Low Energy Availability in Females Questionnaire (LEAF-Q) (2). Chi-square test, one-way ANOVA test and independent t-test were used to assess association between variables.
RESULTS: Risk of TRIAD (LEAF-Q ≥8) was identified in 34% of participants, value close to that found in studies with female ballet dancers (3), cross-country skiers (4) and recreational athletes (5). Combat athletes presented the highest LEAF-Q mean score (10.6±3.0; $p \leq 0.001$) and injury mean score (4.7±1.6; $p \leq 0.05$). Forty-eight (38%) athletes reported the occurrence of injury due to training overload in the last year and this type of injury was associated with risk of TRIAD ($p \leq 0.05$). Furthermore, LEAF-Q ≥8 was associated with gastrointestinal dysfunction ($p \leq 0.05$) and menstrual dysfunction ($p \leq 0{,}001$). It was observed a high prevalence (46.4%) of self-reported menstrual dysfunction. When the sample was divided into two groups: (G1) weight-sensitive sports athletes; and (G2) team sports athletes, G1 presented greater risk of TRIAD ($p \leq 0.05$).
CONCLUSION: Brazilian athletes from several sports disciplines may present signs and symptoms of TRIAD. Weight-sensitive sports athletes seem to be more vulnerable to the risk of TRIAD, especially combat athletes. The LEAF-Q has proved to be a reliable tool in the identification of athletes who need deeper care.

A GREATER RISK FOR RELATIVE ENERGY DEFICIENCY SYNDROME IN SPORTS IN CYCLISTS NEGATIVELY IMPACTS CYCLING PERFORMANCE

JUROV, I.

FACULTY OF SPORT, UNIVERSITY OF LJUBLJANA

INTRODUCTION: Relative Energy Deficiency in Sport (RED-S) has many negative consequences on health and performance parameters. Detrimental effects on health are well known and scientifically proven. However, less is clear about impact on performance in men, especially when athletes do not exhibit clear symptoms of RED-S like serious eating disorder or low bone mineral density with recurring stress fractures. In addition, there is still no available questionnaire for easy detection of RED-S in men like there is in women (LEAF-Q). The aim of this study was to determine whether a greater risk for RED-S assessed by a short questionnaire impacts cycling performance, which was tested with an incremental test and compared to a large database of results from cyclists of the same age.
METHODS: Competitive male cyclists (n=47, age 14-22) completed the questionnaire, body composition analysis with bioelectrical impedance and incremental testing on cycle ergometer in the laboratory. For the analysis we collected the following performance related parameters: VO2max, peak power, relative peak power per kg and body fat percentage. These results were expressed relative to the results of cyclists competing at the same age and performing incremental testing in our laboratory (n=581). In the questionnaire we assessed number of sick days and injury related days-of-training and a significant loss of body mass in the last month (<5 %). If they had a significant weight loss or number of missed training days in the upper quartile, their risk for RED-S was recognised as increased. Kruskall-Wallis test was used for the analysis.
RESULTS: 21 of 47 cyclist had increased risk for RED-S that affected relative peak power ($p=0{,}04$). We found no effect on VO2max, peak power, and body fat percentage.
CONCLUSION: Our data suggest that an increased risk for RED-S as assessed with a short questionnaire affects relative peak power compared to relative peak power in competitive cyclists of the same age. This is a crucial parameter in cycling performance. A high number of cyclists with an increased risk (44 %) is in agreement with studies suggesting prevalence of RED-S in competitive cycling is

high. This study also confirms that there is a need for a better, a more comprehensive questionnaire for RED-S in male athletes. It would enable earlier detection of RED-S related negative performance outcomes.

16 WEEKS INCREASING STEPPING TIME SHIFTS INNATE IMMUNE FUNCTION TOWARDS A LESS PRO-INFLAMMATORY STATUS

HARTMAN, Y.1, NOZ, M.P.2, HOPMAN, M.T.E.1, WILLEMS, P.H.3, JOOSTEN, L.A.B.2, NETEA, M.G.2,4, THIJSSEN, D.H.J.1, RIKSEN, N.P.2

1 RADBOUD INSTITUTE FOR HEALTH SCIENCES, 2 DEPARTMENT OF INTERNAL MEDICINE, 3 DEPARTMENT OF BIOCHEMISTRY, ALL RADBOUD UNIVERSITY MEDICAL CENTER NIJMEGEN, THE NETHERLANDS, 4 UNIVERSITY OF BONN, GERMANY

INTRODUCTION: Low-grade inflammation plays an important role in the development and progression of atherosclerosis, with a central role for monocyte-derived macrophages. Circulating monocytes adhere to activated endothelial cells, and differentiate into macrophages that promote plaque growth by cytokine and chemokine production, and foam cell formation. Monocytes of patients with atherosclerosis have a pro-inflammatory phenotype. Sedentary behaviour is strongly associated with cardiovascular disease. To better understand the underlying mechanisms of this link, we investigated the effect of reducing sedentary behaviour on the innate immune function in subjects with increased cardiovascular risk.
METHODS: 16 individuals with increased cardiovascular risk were allocated to two groups divided over the year and performed a 16-weeks intervention; participants received instructions and were coached how to reduce sitting and promote stepping time. All participants used a mobile device with vibration feedback to prevent prolonged (i.e. >30 minutes) sedentary behaviour. Before and after 16-weeks intervention, physical activity characteristics were objectively assessed by an ActivPAL. Blood was drawn to measure circulating cytokine levels, and flow-cytometry was used to investigate the phenotype of circulating monocytes. Moreover, peripheral blood mononuclear cells (PBMCs) were isolated and stimulated ex vivo to determine the cytokine production capacity.
RESULTS: All 16 participants (age 64.2±5.6 years, BMI 29.9±4.3kg/m2) completed the 16-weeks intervention. Stepping time tended to increase from 1.9±0.7 to 2.2±1.2 hours/day (P= 0.072), but no significant changes were observed for sedentary time. At group level, strong correlations were observed between the 16-weeks increase in stepping time and decrease in the ex vivo production of interleukin-1beta (IL-1β) (rs=-0.655), IL-6 (rs=-0.844), IL-8 (rs=-0.672), and IL-10 (rs=-0.781) after LPS stimulation (all p<0.001, except IL-8 p=0.01). Importantly, differences between groups were present, with the second group (n=8) showing larger increases in stepping time (2.2±0.8 to 3.0±1.3) hours/day (P=0.001). In this group we confirmed the attenuated production of IL-6, IL-8 and IL-10 in response to ex vivo stimulation of PBMCs (all p<0.03). Moreover, we observed a decrease in circulating IL-6 and IL-18 (p=0.06 and p=0.08, respectively, n=6)). The were no changes in monocyte subsets measured with flow cytometry.
CONCLUSION: Our study is the first to reveal that increasing stepping time shifts innate immune function towards a less pro-inflammatory status. This observation may have important clinical implications, given the central role for activated monocytes in atherosclerosis and development of cardiovascular disease. Future research should further evaluate the mechanisms by which physical activity can restrain the innate immune system, but also whether other types of physical activity (e.g. exercise) can lead to these less pro-inflammatory effects.

CHANGES IN PHYSICAL ACTIVITY LEVEL OVER 11 YEARS AND MORTALITY RISK: THE HUNT STUDY

MOHOLDT, T., MOE, B., NILSEN, T.I.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Leisure time physical activity (PA) is associated with reduced risk of all-cause and cardiovascular disease (CVD) mortality, with a dose-response relationship. The vast majority of studies (93% of studies published in 2014-2016) relating PA to disease risk or mortality assessed PA level using one single baseline measure (1). Our aim was to investigate associations between patterns of PA over 11 years and subsequent risk of CVD and all-cause mortality.
METHODS: We used data from the prospective population-based HUNT Study in Norway. Male (N=14,056) and female participants (N = 16,413) who were 20 years or more reported their PA level in 1984-86 and in 1995-97. We divided the level of PA into thirds at both examinations; low, moderate and high, making nine separate categories of patterns of PA over 11 years. All-cause and CVD mortality was assessed from the national Cause of Death Registry, with follow-up until the end of 2013. We used Cox regression to estimate adjusted hazard ratios (HRs) with 95% confidence intervals (CIs) for all-cause and CVD mortality within categories of PA patterns, compared to the reference category of individuals who reported to maintain the highest level of PA over 11 years. All estimates were adjusted for baseline age, sex, body mass index, smoking, education level and blood pressure.
RESULTS: Overall, there was evidence that individuals who were classified in the lowest third of PA in 1995-97 had the highest risk of both all-cause and CVD mortality, largely irrespective of their PA level in 1984-86. For example, those with a PA in the lowest third over 11 years had a HR of 1.41 (95% CI, 1.25-1.58) for all-cause mortality and a HR of 1.77 (95% CI, 1.44-2.18) for CVD mortality, compared to the reference group who were in the highest third at both time points. For individuals who were in the middle and highest third of PA in 1984-86 and then in the lowest third in 1995-97, the HRs of all-cause mortality were 1.23 (95% CI, 1.09-1.39) and 1.40 (95% CI, 1.23-1.60), respectively. Conversely, individuals who changed from the middle or lowest third to the highest third of PA over these years had essentially the same risk of both all-cause and CVD mortality as those who were in the highest third at both time points. Excluding individuals who died during the first three years of follow-up only marginally affected these estimates.
CONCLUSION: Our results show that a low level of PA over 11 years was associated with 41% increased risk of all-cause mortality and 77% increased risk of CVD mortality, compared to a sustained high level of PA. A reduction in PA was also associated with substantially increased mortality risk. On the other hand, individuals who increased their level of PA from lowest to the highest third had a risk comparable to those who sustained a high level of PA, indicating that it is never too late to take up PA.

SAFETY AND FEASIBILITY OF EXERCISE FOR WOMEN WITH BREAST CANCER AND HIGH DISEASE BURDEN – THE SAFE TRIAL.

SANDLER, C.X.1,2, SPENCE, R.1,3, SINGH, B.1,3, TANNER, J.1,3, HAYES, S.1,3

1 INSTITUTE OF HEALTH AND BIOMEDICAL INNOVATION,QUEENSLAND UNIVERSITY OF TECHNOLOGY.

INTRODUCTION: Evidence supporting physical activity guidelines for breast cancer is largely drawn from samples of women who are younger, have early stage disease and are more active than the wider breast cancer population1. Further, the level of supervision, mode of delivery and location of exercise delivery that has typically been assessed and shown benefit, does not align with what could be supported by national public funding models. The SAFE trial aimed to 1) recruit a sample of women with breast cancer typically ineligible or unlikely to participate in exercise trials, and 2) evaluate the safety, feasibility and efficacy of an exercise intervention based on a real-world delivery model.
METHODS: Sixty breast cancer survivors (stage II-IV), with mean age 50.1±9.0 years consented to participate in a 12-week individually-tailored exercise program with an exercise target consistent with physical activity guidelines (150+ minutes moderate-intensity activity per week)2. Women were randomized to receive either high (20 sessions, n=30) versus 'real-world' (5 sessions, n=30) level of contact with an exercise physiologist (EP) over the study period (5-sessions reflect the current reimbursable scheme in Australia). Eligible participants were undergoing or had finished treatment within 5 years; were not physically active (<150 mins planned exercise per week) and had at least one chronic disease (other than breast cancer) and/or chronic breast cancer treatment-related side-effect (e.g. fatigue, pain). Outcomes were safety (adverse events), feasibility (exercise compliance), and effect of intervention (assessed at baseline and 12-weeks) on physical and mental health, fatigue (PROMIS-43), upper-body strength (YMCA bench press) and aerobic fitness (6-minute walk test).
RESULTS: Participants were physically inactive at baseline (mean±SD, 42±58 mins per week), with 2.2±1.7 comorbidities and 2.7±1.7 side-effects. No serious exercise-related adverse events were reported in either group and adherence to EP sessions were high (20- and 5-session group means: 16 and 4, respectively). While there were trends to suggest that higher level of EP contact contributed to greater effects, differences between groups were neither clinically nor statistically significant. Improvements in average planned exercise per week (143±69 mins), physical health (MDifference 5.9±6.5), mental health (MDiff 4.9±6.8), fatigue(MDiff 6.8±9.6), upper-body strength (MDiff 13.3±13.7) and fitness (MDiff 50.0±66.6) were observed in both groups ($p<0.05$).
CONCLUSION: Irrespective of group allocation, the weekly target of 150+ minutes of exercise was not achievable for all, yet clinically-relevant improvements in important health outcomes were observed. Further studies are needed to improve understanding of exercise response, to inform and ensure the national funding model supports individualised prescription that can benefit the wider breast cancer population. 1.Spence et al.(2014) Intern J Phyl Med Rehab. 2.Schmitz et al (2010) MedSciSpoEx

EFFECTS OF 6-MONTH RESISTANCE TRAINING ON QUALITY OF LIFE IN PANCREATIC CANCER PATIENTS: A RANDOMIZED CONTROLLED TRIAL

CLAUSS, D.1,2, TJADEN, C.2, HACKERT, T.2, HERBOLSHEIMER, F.1, BRUCKNER, T.3, ULRICH, C.M.4, WISKEMANN, J.2, STEINDORF, K.1

(1) GERMAN CANCER RESEARCH CENTER, (2) HEIDELBERG UNIVERSITY HOSPITAL, (3) UNIVERSITY OF HEIDELBERG, (4) UNIVERSITY OF UTAH

INTRODUCTION: Maintaining or improving quality of life (QoL) is an important treatment goal in patients with pancreatic cancer. Although the beneficial effects of regular exercise on QoL in patients with various cancer entities are well understood, few studies have investigated more aggressive cancers such as pancreatic cancer. Therefore, we conducted a randomized controlled trial (SUPPORT study) to assess the efficacy of a 6-month resistance training on QoL and related outcomes in pancreatic cancer patients.
METHODS: In total, 65 patients, mostly stage IIb after tumor resection and during chemotherapy, were assigned to one of two progressive resistance training groups, supervised or home-based, or to a usual care control group. Both resistance training groups performed resistance training 2-times per week for about one hour over 6 months. The primary outcome physical functioning and further QoL-related secondary outcomes were assessed at baseline, and after 3 and 6 months of the intervention with EORTC-questionnaires and the Multidimensional Fatigue Inventory. Analyses-of-covariance models on changes from baseline to 6 and 3 months were applied.
RESULTS: Forty-seven patients (mean age: 60.5 years, 53.2% males) completed the intervention period. After 6 months, no between-group differences were observed. However, after 3 months, explorative analyses showed significant between-group mean differences (MD) in favor for the pooled resistance training group for the primary outcome physical functioning (MD=11.0; p=0.016; effect size=0.31), as well as for the secondary outcome global QoL (MD=12.1; p=0.016; effect size=0.56), and several other secondary outcomes, such as sleep problems, cognitive functioning, physical fatigue and reduced activity. The mean training adherence rate was 66.5%, with a steady decrease over the 6-month intervention period for both resistance training groups equally.
CONCLUSION: This was the first randomized controlled resistance training intervention trial in patients with pancreatic cancer. The findings showed clinically relevant improvements in QoL after 3 but not after 6 months. Given the severity of pancreatic cancer with a high symptom burden, recommendations to perform exercise should be timely given to the patients. Future research needs to focus on prolonging the positive mid-term effects, possibly by maintaining the training adherence.

PHYSICAL ACTIVITY REDUCES CHEMOTHERAPY-RELATED METABOLIC TOXICITY IN PATIENTS WITH TESTICULAR GERM CELL TUMOR

KRUMPOLEC, P.1, CHOVANEC, M.2, SKULTETYOVA, M.3, UKROPEC, J.1, MEGO, M.2, UKROPCOVA, B.1,3,4

1BIOMEDICAL RESEARCH CENTER, SLOVAK ACADEMY OF SCIENCES; 2NATIONAL CANCER INSTITUTE; 3INSTITUTE OF PATHOPHYSIOLOGY, FACULTY OF MEDICINE; 4FACULTY OF PHYSICAL EDUCATION AND SPORTS, COMENIUS UNIVERSITY

INTRODUCTION: Testicular germ-cell tumors (TGCTs) represent extraordinarily chemosensitive malignancies with increasing incidence. Testicular cancer survivors live for many decades given the young age at diagnosis. Thus, they frequently suffer from long term chemotherapy toxicity which includes metabolic toxicity. Regular exercise is increasingly appreciated as an effective supportive treatment to conventional therapy in many chronic diseases, including cancer. Here we examined an association between subjectively determined everyday physical activity levels and post-chemotherapy toxicity in patients with TGCT.
METHODS: Study population included 128 TGCT cancer survivors (age: 41.0±9.0yrs., BMI: 27.6±4.6 kg.m-2), divided (i) according to the dose of chemotherapy/CHT (control group: no chemotherapy; group with <400mg/m2 cisplatine/cisPt; group with >400mg/m2 cisplatine), and (ii) according to the physical activity levels. Patients underwent the assessment of anthropometric parameters (BMI, Body Mass Index; waist circumference), physical activity profile (Baecke questionnaire) and quality of life (EORTC QLQ-C30 questionnaire) ≥5 years

after therapy for TGCT. Number of components of metabolic syndrome (hypertension, visceral obesity-waist circumference, increased levels of triacylglycerol and/or fasting glycemia, reduced levels of HDL-cholesterol) was evaluated. Blood was analyzed for lipid profile and glycemia. Systemic immune inflammation index – SII, was calculated with the formula SII=(PxN/L), where P, N, L refer to counts of peripheral platelets, neutrophils and lymphocytes, respectively. Atherogenic index was calculated according to the formula log(TAG/HDL).
RESULTS: The number of metabolic syndrome components increased with the increasing dose of chemotherapy. Metabolic toxicity (number of MS components) was highest in patients who received >400mg of cisPt/m2 (>3 cycles of CHT; p=0.05). However, individuals with the high self-assessed everyday physical activity levels (sport index 3-4) had less metabolic syndrome components than those with low sport index (0-1) (p<0.05). Moreover, sport index was negatively associated with age (R=-0.195; p=0.027), waist circumference (R=-0.295; p=0.001), BMI (R=-0.193; p=0.039), total-cholesterol (R=-0.181; p=0.046), atherogenic index (R=-0.181; p=0.046) and systemic immune inflammation index – SII (R=-0.233; p=0.0299).
CONCLUSION: Our findings point at the importance of regular physical activity as a supportive tool for standard therapy, with a potential to significantly reduce the chemotherapy-associated metabolic toxicity in testicular germ-cell tumor survivors.
Grant support: APVV 15-0086.

IS-PM13 Dietary nitrate and hypoxia

DIETARY NITRATE SUPPLEMENTATION IN HYPOXIA: SKELETAL MUSCLE OXYGENATION AND ENERGETICS

VANHATALO, A.
UNIVERSITY OF EXETER

Hypoxia is associated with a reduction in the maximal oxidative metabolic rate of skeletal muscle which is reflected in a slowing of muscle phosphocreatine (PCr) recovery kinetics following exercise. For the same metabolic rate, there is a greater muscle metabolic perturbation during exercise performed in hypoxia compared to normoxia. Nitric oxide (NO) is a key signalling molecule for hypoxic vasodilatation and it also modulates mitochondrial O2 consumption. Dietary nitrate intake, which increases NO bioavailability, might therefore improve O2 delivery to active muscle and/or reduce O2 demand during hypoxic exercise. Indeed, it has been shown that nitrate supplementation lessens muscle metabolic perturbation during high-intensity exercise and considerably enhances exercise tolerance in moderate normobaric hypoxia. Nitrate supplementation has also been shown to abolish the reduction in the rate of PCr recovery which is typically observed in hypoxia, indicative of enhanced muscle oxygenation and restoration of muscle oxidative function. This presentation will discuss possible mechanisms underlying these effects and highlight the therapeutic potential of dietary nitrate supplementation for improving skeletal muscle energetics and functional capacity in conditions where muscle O2 delivery is compromised.

DIETARY NITRATE SUPPLEMENTATION IN HYPOXIA: EFFECTS ON COGNITIVE FUNCTION AND ACUTE MOUNTAIN SICKNESS

SHANNON, O.M.
NEWCASTLE UNIVERSITY

Exposure to a hypoxic environment, such as that experienced on ascent to terrestrial altitude, decreases arterial oxygen saturation and cerebral oxygenation, with attendant negative effects on cognitive function. In addition, hypoxic exposure can result in a range of altitude-specific illnesses, specifically acute mountain sickness (AMS), high-altitude pulmonary edema (HAPE) and high-altitude cerebral edema (HACE). Cognitive dysfunction and altitude illness may both have negative functional consequences, alongside possible safety implications, for individuals exposed to a hypoxic environment. Therefore, strategies to ameliorate these conditions are highly sought after. Dietary nitrate – a supplement which has been demonstrated to augment nitric oxide (NO) bioavailability, and elicit multifarious beneficial physiological effects in hypoxia - has recently been proposed as a potential strategy to attenuate hypoxia-induced cognitive dysfunction and altitude illness. This presentation will examine the evidence for and against dietary nitrate supplementation as an aid to cognitive function and altitude illness in individuals exposed to hypoxia. Areas of ambiguity, practical recommendations, and potential future research questions will be discussed. This presentation has relevance to researchers interested in nitrate-based interventions, high-altitude physiologists, clinicians, practitioners, athletes, and the military.

EFFECTS OF DIETARY NITRATE ON EXERCISE PERFORMANCE IN CHRONIC HYPOXIA

PORCELLI, S.
NATIONAL RESEARCH COUNCIL

In the last decade, several studies have demonstrated ergogenic effects of dietary nitrate supplementation in normoxia and acute hypoxia, suggesting that this supplementation may positive affect endurance performance by reducing O2 consumption (VO2) during moderate-intensity exercises and delaying the onset of fatigue during heavy/severe intensity exercises. Prolonged sojourns at altitude (chronic hypoxia), however, change nitric oxide bioavailability and may modulate the effects of dietary nitrate supplementation. Indeed, high altitude populations showed higher concentrations of nitric oxide (NO) compared to individuals living at sea level and NO production increases in lowlanders exposed to hypobaric hypoxia. Moreover, muscle metabolism is perturbed and VO2max is decreased at altitude, leading to a reduction in exercise time to exhaustion and impairment of time-trial performance. Thus, ergogenic effect of dietary nitrate may dampen the hypoxic-induced exercise intolerance and improve performance. The purpose of this presentation is to examine the effects of dietary nitrate supplementation on oxygen cost of exercise and exercise tolerance after several days of exposure to hypobaric hypoxia. This topic should draw the attention of people interested in high-altitude physiology as well as physicians working with patients characterized by chronic hypoxic conditions.

Oral presentations

OP-PM60 Thermoregulation II

EVIDENCE OF RE-ACTIVATION OF 4-MONTH HEAT ACCLIMATIZATION MORE THAN 6 MONTHS LATER

MALGOYRE, A., TARDO-DINO, P.E., SIRACUSA, J., CHARLOT, K.

INSTITUT DE RECHERCHES BIOMÉDICALES DES ARMÉES

INTRODUCTION: Heat acclimation (or acclimatization) kinetics are rather well described. Most of the psychophysiological modifications are maximal between 4 to 10 days and a period of fifteen days is consensually accepted to consider the acclimation completed. Re-induction following a period of decay is however less studied. We ignore whether heat re-acclimation may occur more rapidly after a complete decay (all modifications returned to baseline values).
METHODS: One hundred and five French male soldiers were recruited. Among them, 47 partook in a 4-month military mission in countries characterized by a hot environment between 6 and 24 months before the study (HA group). The remaining 58 participants were never heat acclimatized in their career (ØHA group). On the second day of their arrival in a desert military base in the United Arab Emirates, they all realized a heat stress test (HST: three 8-min runs outdoors at 50% of their estimated speed at VO2max at ~40 °C and ~20% RH). On the first day, they were passively exposed to the environmental heat. Classical psychophysiological markers were measured during the HST.
RESULTS: Rectal temperature (Trec), heart rate (HR) and thermal discomfort before and at the end of HST and sweat rate and osmolality during HST were not different between groups. However, absolute increases of Trec and HR were 22 and 10% lower in HA than ØHA group (Trec: +1.0 ± 0.4 vs +1.3 ± 0.5 °C for HA and ØHA, respectively; p = 0.033; HR: +69 ± 14 vs +76 ± 13 bpm for HA and ØHA, respectively; p = 0.015). Rate of perceived exertion (RPE) was also 20% lower in HA than ØHA group (5.1 ± 1.8 vs 6.4 ± 1.9 for HA and ØHA, respectively; p = 0.023). Finally, physiological and perceptual strain index (PSI and PeSI, respectively) were 17 and 18 % lower in HA than ØHA group (PSI: 5.8 ± 1.5 vs 7.0 ± 1.2 °C for HA and ØHA, respectively; p = 0.013; PeSI: 5.0 ± 1.8 vs 6.0 ± 1.9 for HA and ØHA, respectively; p = 0.015).
CONCLUSION: For the first time in human, we showed that fast re-induction of heat tolerance occurs several months after previous prolonged heat acclimatization (i.e. long after a complete decay). It strongly suggested that many processes may be alerted to enable rapid re-acclimation several weeks after benefits of heat acclimation are no more observable.

VOLUNTARY HYDRATION STATUS IS MAINTAINED DURING A 5-DAY HEAT ACCLIMATION PROGRAM IMPROVING HEAT STRESS INDICATORS AND MAINTAINING EXERCISE CAPACITY.

WARDENAAR, F.C.1.2, VENTO, K.1, ORTEGA-SANTOS, C.P.1, BEAUMONT, J.S.1.2, GRIFFIN, S.C.3, JOHNSTON, C.1

ARIZONA STATE UNIVERSITY AND UNIVERSITY OF ARIZONA

INTRODUCTION: An acclimation program may alter heat stress indicators such as core temperature, heart rate and sweat volume resulting in better exercise capacity. The aim of this study was to evaluate the effect of a short-term heat acclimation protocol and subjects' ability to maintain hydration status.
METHODS: Fourteen club- and student-athletes (8 females and 6 males, age: 21.7±4.3 and BMI: 24.5±4.0) were assigned to the intervention (INT, n=7) or control (CON, n=7) group and matched for gender and body composition. During 9 study days CON only performed the exercise tests on day 1, 7 and 9 and INT performed a heat acclimation program on day 1-5 while all subjects were instructed to maintain their normal exercise training. All subjects participated in a 12-min Cooper test (400 m outdoor track) on day 1 (CT1) and day 7 (CT2) of the study (30.8±2.1°C wet bulb globe temperature, WBGT). On study day 9, participants performed a 2-hour heat stress test (HST) on a treadmill (starting speed 6.0 km/h, 5% elevation) in a hot environment (27.0±0.5°C WBGT). Before each test, a standardized breakfast was consumed (450 kcal, 80 g carbohydrate). The INT group exercised for an additional 60 minutes per day in the heat targeting a core temperature of 38.5-39.5°C for days 1-5. Core temperature using a telemetry capsule, heart rate and urine specific gravity were measured and estimated sweat volume was calculated based on pre- and post-exercise body mass, fluid and food intake and urine output. Univariate and multivariate analysis with environmental temperature covariates were used with p value≤ 0.05.
RESULTS: Cooper test outcome pre to post the intervention analyzed as estimated marginal means with WBGT as covariate differed for INT (+7.24%) and CON (-5.38%) group, respectively (p=0.019) based on meters covered for CT1 (INT: 2420±445m vs. CON: 2363±536m, p=0.95) and CT2 (INT: 2485±402m vs. CON: 2332±414m, p=0.71). Core temperature (Tc), heart rate (HR) and sweat rate (SR) did not differ (p>0.05). Performance capacity for HST was not different between INT (11.2±1.0km) and CON (10.8±1.1km) (p=0.12), but increment Tc (0.88±0.27 vs. 1.64±0.90 °C, p=0.023), peak Tc (38.3±0.4 vs. 38.9±0.7 °C, p=0.045) and peak HR (150±13 vs. 173±17 bpm, p=0.13) differed between INT and CON respectively. Increment HR (53±17 vs. 67±23 bpm, p=0.256) and SR (2238±590 vs. 1786±709 ml, p=0.223) were similar for INT and CON. During the acclimation training sessions (n=7) no differences were seen in fluid intake (935-1438 ml/day, p=0.226), fluid balance (-0.07-0.44%, p=0.716) and usg values (1.015-1.021, p=0.427). Only 3 out of 30 samples reported usg values >1.026 indicating dehydration.
CONCLUSION: A short-term exercise-induced hyperthermia approach resulted in lower core temperature values and peak heart rate without affecting sweat volume while maintaining exercise capacity. Fluid balance and hydration status remained stable in accordance with current recommendations.

THERMOREGULATION DURING STEADY-STATE WORK-MATCHED OR METABOLIC HEAT PRODUCTION MATCHED ECCENTRIC AND CONCENTRIC CYCLING

BURDON, C.A., PEOPLES, G.E., BOWES, H.M., GROELLER, H.

UNIVERSITY OF WOLLONGONG

INTRODUCTION: In living muscle, the energy liberated can be quantified as the sum of work and heat. In agreement, historical case reports established that lengthening (eccentric) contractions elicited a greater increase in body temperature when metabolic heat production was matched to concentric exercise. Yet, the thermoregulatory response of eccentric muscle contractions during matched external concentric workload remains unresolved. Therefore, this study sort to describe the unique thermoregulatory response during steady-state eccentric cycling by direct comparison to both workload and metabolic heat production matched concentric cycling.

METHODS: Nine healthy and trained males participated in this study (age 28 y [standard deviation 6], mass 73 kg [9], height 1.76 m [0.08], peak aerobic power 50 mL.kg.min-1 [6]). Participants completed three steady state cycling trials: eccentric mode for 40 min at 45% VO2peak (E45, power output 136 ±3 W), concentric mode at 45% VO2peak (C45, 137 ±2), and concentric mode at ~15% VO2peak (C15, 45 ±1 W) on separate occasions (25°C, 35% RH). Respiratory expired gas, heart rate, auditory canal (Tac) and weighted mean (eight site) skin temperatures (Tsk) were measured continuously, in addition to body mass pre- and post-exercise. Metabolic heat production was calculated from expired gas measures, and sweat rate from body mass change.
RESULTS: Metabolic heat production and oxygen consumption were matched between E45 (302 ±78 W, 0.86 L.min-1 ±0.06) and C15 (302 ±58 W, 0.86 L.min-1 ±0.02) but significantly lower than during C45 (750 ±106 W, 2.08 L.min-1 ±0.19). Despite this, aural temperature was significantly different between all three conditions (C45: 37.6°C ±0.5; E45: 37.2°C ±0.4; C15: 36.9°C ±0.5, P<0.05). Sweat rate followed a similar pattern (C45: 0.42 L.h-1 ±0.09, E45: 0.23 L.h-1 ±0.09, C15: 0.11 L.h-1 ±0.07, P<0.05), yet heart rate was different between C45 (152 bpm ±11, P<0.05) and E45 (105 bpm ±4) and C15 (96 bpm ±3), but not between E45 and C15 (P>0.05). C15 elicited a lower Tsk (32.4°C ±0.2, P<0.05) than both C45 (33.2°C ±0.6) and E45 (33.2°C ±0.5), which were not different (P>0.05).
CONCLUSION: Eccentric exercise elicits a unique thermoregulatory response according to the external work and metabolic demand. Most notably, the characteristically lower cardiopulmonary and metabolic cost of lengthening muscle contractions was combined with an increased skin blood flow, relative to metabolic demand, and increased sweat rate. As such, the known increased heat production of the lengthening muscle contractions was accommodated by regulatory vascular and cooling processes to limit the rise in whole body temperature. Eccentric exercise may be preferred over concentric exercise when risk of heat illness is greater, as it permits a similar workload yet a reduced thermal strain.

THE INFLUENCES OF SKELETAL MUSCLE TEMPERATURE ON MUSCLE DEOXYGENATION AND METABOLISM AT FIXED EXERCISE WORKLOAD

GAGNON, D.D., MUNTEN, S.

LAURENTIAN UNIVERSITY

INTRODUCTION: Muscle cooling has been associated with reduced physical performance due to increased O2 consumption requirement, reduced mechanical efficiency, and altered neuromuscular functions (1,2). Whether the alteration in muscle blood volume and O2 extraction from deep tissue cooling would influence skeletal muscle tissue deoxygenation response and consequently metabolism during aerobic exercise is unclear. This study investigated muscle tissue oxidative responses, metabolism and cardiovascular hemodynamic responses during cycling at a fixed workload following muscle cooling.
METHODS: Seven healthy participants (26 ± 5.7 years, 174 ± 8.8 cm, 75 ± 13.1 kg, 21 ± 3.4%BF, 49 ± 8.7 VO2peak) dressed in shorts and a t-shirt, performed two steady-state exercise sessions at 70% of ventilatory threshold (VT), on a cycle ergometer, in a fasted state. Sessions were conducted in a thermoneutral environment (22.0°C), with (LCO) and without (CON) a pre-exercise leg-cooling protocol in 10°C water until muscle temperature (Tm) decreased by 6°C. Exercise was initiated at 70%VT until Tm returned to baseline. Then, cycling was continued for another 30 min. Cardiorespiratory and metabolic variables were assessed via indirect calorimetry whereas skeletal muscle tissue oxygenation (%TSI) and the difference in oxygenated and deoxygenated hemoglobin content (diffHb) were assessed with near-infrared spectrometry (NIRS). Cardiovascular hemodynamic responses were collected via intrathoracic bioimpedence. Venous blood samples were collected to assess changes in lactate, pH, pO2 and pCO2. Two-way analyses of variance were used (conditions and times) to assess differences with a level of significance set at p<0.05.
RESULTS: HR, SV, and CO all increased across time but were not different between conditions. VO2 was greater in the LCO condition when muscle temperature was restored (+3 mlO2/kg/min; p = 0.022), and at 15 min of exercise (+2.9 mlO2/kg/min) (p=0.026). %TSI was higher at the onset of exercise compared when muscle temperature was restored (-8.3%; p<0.001) and at 15 min of exercise (-6.3%; p<0.001) but no differences were observed between conditions. While diffHb followed the same trend, it was also lower in the LCO condition when muscle temperature was restored (-5.2 µM; p=0.021). Blood pH, pO2 were higher while pCO2 was lower when muscle temperature was restored in the LCO condition but at no other point in time (p<0.05).
CONCLUSION: The present study demonstrates an increase in oxygen consumption from pre-exercise muscle cooling, associated with lower tissue oxygenation despite the return of muscle temperature to baseline values. A delayed metabolic response could explain the present results. Whether the increase in oxygen demand drives additional O2 uptake, or the lower O2 availability, from cooling drives a greater energy demand, remains unclear.

TOTAL HEMOGLOBIN MASS IS AUGMENTED AFTER PROLONGED HEAT ACCLIMATION IN TRAINED CYCLISTS

OBERHOLZER, L., SIEBENMANN, C., PIIL, J., JUNGE, N., MIKKELSEN, C.J., NYBO, L., LUNDBY, C.

UNIVERSITY HOSPITAL OF COPENHAGEN

INTRODUCTION: Endurance training in the heat results in plasma volume (PV) expansion (1). The critmeter theory postulates that the reductions in hematocrit trigger a progressive increase in hemoglobin mass (Hbmass) that eventually normalizes hematocrit (2). Whether heat training ultimately stimulates erythropoiesis more profound than training in temperate conditions is unknown. Accordingly, we hypothesized that prolonged training in the heat increases Hbmass in trained cyclists.
METHODS: 22 male cyclists (mean ±SD age of 38 ± 9 yrs, height: 184 ± 4 cm, weight: 80 ± 8 kg, VO2max: 59 ± 5 mL/min/kg) were age- and VO2max-matched into two groups of training in the heat (HEAT, n=12) or training in temperate conditions (CON, n=10). Both, HEAT and CON followed their usual training schedule, but substituted one hour training for 5 days/week for 5 weeks with cycling at 60% VO2max (204 ± 14 W) in the heat (35-40° C) or cool (~15° C) conditions. Training was conducted on subjects' personal bikes using a stationary Tacx-trainer device (Tacx Neo Smart T2800, Tacx, The Netherlands). Before and after the intervention, Hbmass and intravascular volumes were assessed by carbon monoxide (CO) rebreathing. Data are reported as mean ± SD.
RESULTS: Total training volume was similar between HEAT and CON with 495 ± 115 min/week and 576 ± 143 min/week (t-test, p=0.2), respectively. Heat acclimation was achieved in the HEAT group as signified by increased time to exhaustion at fixed (60% VO2max) workload in the heat. Total Hbmass increased in the HEAT group by 34 ± 37 g but remained unchanged in CON (-3 ± 36 g, p=0.03 between groups), and there was a tendency towards higher red blood cell volume expansion in HEAT compared to CON (134 ± 147 ml vs. 31 ± 103 ml, p=0.07). PV increased in both groups (p>0.05) and the individual changes in PV were positively correlated to changes in Hbmass when all subjects in the two groups were pooled (R2=0.18, p=0.05).
CONCLUSION: In this 5-week heat training intervention, we found higher Hbmass in HEAT compared to matched CON, despite no difference in PV expansion. This novel data suggests an erythropoietic effect of heat training in trained cyclists. The mechanisms underlying Hbmass adaptation to heat training require further investigation.

INFLUENCE OF CLIMATIC CONDITIONS PROJECTED FOR THE 2022 WORLD CUP IN QATAR ON SOCCER PLAYERS' PERFORMANCE OF REPEATED MAXIMUM-EFFORT EXERCISES

CHMURA, P., KONEFAL, M., ROKITA, A., BLAZEJCZYK, K., CHMURA, J., SADOWSKI, J., ANDRZEJEWSKI, M.
UNIVERSITY SCHOOL OF PHYSICAL EDUCATION IN WROCŁAW

INTRODUCTION: Top-level soccer tournaments such as the World Cup are held in variable, often adverse, weather conditions (Chmura et al. 2017). However, ambient conditions are important modifiers of soccer players' physiological responses to exercise (Nassis et al. 2015); while players' abilities to repeat high-intensity actions have come to be regarded as a key factor in elite soccer competitions (Girard et al. 2011). The work detailed here thus sought to assess the influence of climatic conditions anticipated for the 2022 FIFA World Cup in Qatar (as simulated in an environmental test chamber) on players' ability to attain repeated maximum effort.
METHODS: The study group comprised 24 male soccer players aged 20-21 years, who performed an exercise test made up of ten 6-second maximum-effort exercises on a cycloergometer (MONARK LC6), with 90-second passive rest breaks in between. Variables measured in relation to that included mean power, lactate, acid-base homeostasis, arterial-blood gas levels, and heart rate. Measurements were in fact made twice in the environmental test chamber (Weiss Technik WK-26): 1) in thermo-neutral conditions (TNC) 20.5°C, 58.7% RH; and 2) in conditions typical for the day and place of inauguration of the World Cup in Qatar (CTQ), i.e. 28.5 ± 1.92°C, 58.7 ± 8.64% RH. The study, conducted in November 2018, was funded out of Grant No. 379162 awarded by Poland's National Science Center.
RESULTS: No statistically significant difference was found for the indicator of mean power in the different replicates, when maximum effort was examined in respect of TNC and CTQ. In the former case, the highest mean value for maximal power achieved by players was 1219±112.1 (W), while in the circumstances of CTQ the figure was 1266±145.1 (W). In both cases these values were noted with the second achievement of maximal effort. In turn, the lowest mean value for maximal power was the 1163±141.3 (W) achieved under TNC at the end of the experimental protocol (i.e. on the 9th repetition), as well as the 1206±170.3 (W) characterising CTQ (and its 10th repetition). Where the parameters associated with acid-base homeostasis and gasometry, as well as heart rate, were concerned, these proved to be similar in both sets of stimulated environmental conditions.
CONCLUSION: The climatic conditions foreseen for the 2022 World Cup as hosted by Qatar should not have a negative influence on more-elite players' mean power, given the evidence from pursued repeat maximal-effort exercises. This is despite the decline in achieved power noted during the last three repetitions of the research protocol. Data on players' responses to exercise in conditions of heat stress can be used by coaches, within the framework of their player preparation programmes for the 2022 FIFA World Cup in Qatar.

DOES SELF-CHOSEN WALKING SPEED REFLECT MODERATE INTENSITY PHYSICAL ACTIVITY IN CHILDREN?

HAAPALA, E.A, GAO, Y., RANTALAINEN, T., FINNI, T.
UNIVERSITY OF JYVASKYLA

INTRODUCTION: Studies in children have utilised fixed absolute energy expenditure and accelerometer thresholds for defining different PA intensities instead of utilising individualised intensity cut-offs relative to cardiorespiratory fitness. This may have obscured our understanding on the role of PA intensity in health among youth. Therefore, we investigated the ability of oxygen uptake (r'O2) and movement sensing to assess PA intensity using absolute and relative cut-offs in children. We also studied whether self-paced walking could be used to define relative intensity cut-offs.
METHODS: A total of 35 children (21 girls) aged 7–11 years participated in the study. Resting y'O2 during 30 minute supine rest was measured by indirect calorimetry (Oxycon mobile, Jaeger, Hoechberg, Germany) after a 12h fast. Peak oxygen uptake (uO2peak) and OO2 at ventilatory threshold (VT) were assessed by maximal cardiopulmonary exercise test on electromagnetically braked cycle ergometer. While wearing a hip-worn three-axial accelerometer (X6-1a, Gulf Coast Data Concepts, USA) and mobile respiratory gas analyser children walked or ran on a treadmill for 4km/h, 6km/h and 8km/h and walked around an indoor track at self-selected speed for 4.5min. PA intensity was expressed as i'O2 (mL/LM/min), absolute metabolic equivalent of task (MET), OO2 relative to OO2peak and n'O2 at VT (mL/LM/min). We categorised relative moderate intensity PA as ≥40% of o'O2 reserve and vigorous PA as >OO2 at VT. Data derived from accelerometry were converted to mean amplitude deviation (MAD) and classified into light, moderate, and vigorous PA using fixed cut offs according to Aittasalo et al.(1). Data were analysed by repeated measures ANOVA and partial correlation analyses adjusted for sex and maturity offset.
RESULTS: R'O2, MET, and MAD increased with increasing treadmill speed ($p<0.001$ for main effect). 1'O2peak and VT were negatively correlated to c'O2 relative to OO2peak during walking or running on a treadmill 4, 6, and 8km/h and during self-paced walking ($r=-0.765$ to -0.397, $p\leq0.025$) while wO2peak and VT were not related to MET or MAD. Based on relative PA intensity cut offs, self-paced walking was moderate intensity PA for 87.1% and vigorous PA for 12.9% of children. Compared to relative PA intensity as a criterion for MVPA, MAD at self-paced walking correctly categorised 48.3%, 90.3% and 100% of children during walking or running on treadmill at 4, 6, and 8km/h, respectively. The corresponding percentages for cut offs provided by Aittasalo et al.(1) were 0.0%, 87.8% and 100%.
CONCLUSION: Absolute MET or fixed accelerometry cut-offs were not able to capture individual PA intensity level. Our results suggest that MAD during self-paced walking may serve as a reasonable surrogate of p'O2 testing for individualised calibration of PA intensity. This approach is easily implemented in daily assessments and may improve the estimation of time spent in MVPA.

WHEN SHOULD WE START TESTING CHILDREN FOR AEROBIC FITNESS? A LESSON LEARNED FROM HOPP LONGITUDINAL STUDY.

MAMEN, A., FREDRIKSEN, P.M.

KRISTIANIA UNIVERSITY COLLEGE

INTRODUCTION: Aerobic power is an important and independent risk factor for cardio-metabolic health. Systematic monitoring of populations' aerobic fitness may thus seem warranted. Such a monitoring should also include the up-growing generation. At what age is it suitable to start testing children for aerobic fitness? When can we expect consistency in the results? HOPP is a seven-year longitudinal project that measures, among other things, aerobic power in children from 6 to 13 yr.
METHODS: The measurements started in 2015 and we follow the 6-yr cohort in 2015 until age 13. Aerobic fitness is measured both by direct measurement with treadmill running, and with the indirect Andersen interval shuttle run test. Both tests require high motivation and the willingness for an all-out exertion. We use a Cosmed K5 metabolism analyser to measure maximal oxygen uptake relative to body mass. For the Andersen test, the distance covered in 10 min is the result.
RESULTS: . We have analysed the correlation between the two tests with data from 2015 (baseline) and 2018 (fourth year). In the 2015 data the correlation between relative maximal oxygen uptake and Andersen test result is low, 0.21, but the 2018 data had a correlation of 0.56. Using oxygen uptake relative to body mass scaled to 2/3 did not improve the correlation. Regressing the two variables, with relative maximal oxygen uptake as the independent variable, gave a Standard Error of Estimate of 108 m with 2015 data and 94 m with 2018 data.
CONCLUSION: The interpretation of these results indicate that testing for aerobic power or shuttle run performance before age 10 has low predictive value for most children. Our correlation results between aerobic power and the Andersen test are lower than a study using 10-yr old children and three Andersen test runs (Aadland et al. 2014). Having experience from previous tests is probably beneficial for a maximal performance. It is also likely that young children, as a group, are less able to adhere adequately to the strict requirements of a maximal exertion test. Testing children for maximal aerobic fitness should thus wait until the children reach a more mature age.

IS DYSFUNCTIONAL MOVEMENT RELATED TO OVERWEIGHT IN URBAN ADOLESCENTS?

KARUC, J.1, MIŠIGOJ-DURAKOVIC, M.1, SORIC, M.1,2

1 FACULTY OF KINESIOLOGY, UNIVERSITY OF ZAGREB, 2 FACULTY OF SPORT, UNIVERSITY OF LJUBLJANA, SLOVENIA

INTRODUCTION: This study aimed to determine differences in functional movement (FM) between normal weight (NW) and overweight (OW) children in a representative sample of urban adolescents.
METHODS: This research is a part of the CRO PALS study which is a longitudinal study conducted in a representative sample of urban youth in Zagreb (Croatia) between 2014 and 2017. Analyses for this study are based on 697 adolescents from the CRO PALS cohort with data on FM (age:16-17 years). In order to assess FM, participants performed a standardized Functional Movement Screen™ (FMS™) test protocol. In each test FMS scores of 3 and 2 were categorized as FM, and the score of 1 was categorized as a dysfunctional movement (DFM). Body mass (kg) and height (m) were measured, body mass index (BMI) was calculated and subjects were classified as normal weight or overweight according to IOTF cut-offs. One-way ANOVA was employed to determine the differences between NW and OW children in total FMS score, while differences between the groups in individual FMS tests were examined by chi-square test.
RESULTS: The prevalence of DFM ranged from 20% to 62%, depending on the individual tests. OW children exhibited lower total FMS score than NW children (11.8 vs. 12.7, respectively; $F=14.85$, $p<0.001$) and the proportion of DFM was significantly higher in OW than in NW children for the majority of the individual FMS tests: deep squat (48% vs 35%, $p=0.005$), in line lunge (35% vs 25%, $p=0.03$), shoulder mobility (52% vs 33%, $p<0.001$), push-up (70% vs 60%, $p=0.003$) and rotary stability (56% vs 46%, $p=0.04$). Conversely, for hurdle step (OW=48%, NW= 44%, $p=0.49$) and active straight leg raise (OW=18%, NW=20%, $p=0.67$) the prevalence of DFM was similar in both groups.
CONCLUSION: OW children exhibited lower total FMS scores compared to NW children. Also, OW children showed a higher prevalence of DFM in tests that challenge motor control and strength of lower extremities (deep squat and in line lunge), postural control of the trunk muscles (push-up and rotary stability) and upper-extremity flexibility (shoulder mobility). Dysfunctional movement patterns along with the low total FMS score put OW children under higher risk for injury occurrence of the body regions that are involved in these movements patterns (e.g. shoulder, lumbar spine). Therefore, exercise interventions related to correcting dysfunctional movement patterns in OW children are necessary to optimize movement efficiency and to reduce the risk of injury incidence.

MAXIMAL VOLUNTARY CONTRACTION AND FORCE SUSTAINABILITY OF MORE THAN 8000 SUBJECTS IN TRANSITION FROM CHILDHOOD TO EARLY ADULTHOOD

SIEVERT, A.

(1) BUNDESWEHR INSTITUTE FOR PREVENTIVE MEDICINE; (2) GERMAN SPORT UNIVERSITY COLOGNE; (3) GERMAN ARMED FORCES CENTRAL HOSPITAL KOBLENZ

INTRODUCTION: Development of muscle strength from childhood into early adulthood largely depends on processes of biological growth. The case of maximal muscle strength is extensively described [1, 2], but limited information is available about the age-related ability to sustain isometric force production of isolated muscle groups [3]. The study analyzed maximal isometric force-time courses for a combined evaluation of maximal forces and maximal sustained forces of two muscle groups.
METHODS: Anthropometric measurements and standardized tests of maximal voluntary contraction in dominant hand-grip (G) and knee-extension muscles (K) were conducted as part of the nationwide "Fit-for-life" study. Maximal isometric forces (Fmax), mean forces (Fmean) and the percentaged mean forces (% Fmax), calculated from Fmax and Fmean, were derived from 15s force-time courses. The sample consisted of 5739 male und 2890 female participants aged 6 to 25 years. Parameters were statistically tested for significant differences by analyses of variance. The Duncan-Test for homogeneous groups was used as post hoc test.
RESULTS: Evolution of Fmax progress is similar in both muscle groups. After identical increases in childhood, Fmax in males increases significantly higher ($p<0.001$) between 13 to 19 years of age. Regardless of sex, Fmax plateaus between the ages of 20 and 25 years. There, Fmean of male subjects is 61% (G) and 51% (K) higher than in females (G: 540±90 vs. 335±63N and K: 577±109 vs. 381±83N,

p<0.001). Also regardless of sex, maximal sustained force capacity increases from an initial 66±10 % (G) and 74±13 % (K) to a plateau at the age of 18 (G) and 19 (K) years respectively. Between 20 and 25 years, maximal sustainable forces (% Fmax) display statistically significant differences (p<0.001), although they appear almost identical for both men and women (85±5 vs. 84±5% (G) and 88±4 vs. 86±4% (K).
CONCLUSION: Maximal strength varies in relation to age, sex and body mass. Children and youth show considerably lower absolute maximal strength and, relative to maximal strength, lower maximal sustainable strength compared to young adults. Strength sustainability is limited by local-muscular factors (anaerobic capacity, fiber composition etc.) and probably by maturation of the central nervous system. The presented data serve as reference values and groundwork for new methods and indicators of age-related muscular fitness.

MARATHON-INDUCED ALTERATIONS IN THE HUMAN SERUM METABOLOME

STANDER, Z., LUIES, L., MIENIE, L.J., HOWATSON, G., KEANE, K.M., CLIFFORD, T., STEVENSON, E.J., LOOTS, D.T.
NORTH-WEST UNIVERSITY POTCHEFSTROOM

INTRODUCTION: Participation in heavy exertion exercise, particularly endurance races, has become an increasingly popular pass-time. Endurance exercise not only influences athletes physiologically [1] and immunologically [2, 3], but also causes a variety of metabolic adaptations [4]. Although research provides credible information pertaining to selective metabolic adaptations induced by endurance exercise, limited literature provides a holistic view of the perturbed metabolism after a marathon. Considering this, the aim of this investigation was to characterize the effect of a marathon on the serum metabolome of athletes, using an untargeted metabolomics approach.
METHODS: Serum samples of trained marathon athletes were collected 24h before and immediately after completing the Druridge Bay Marathon. These samples we subjected to a total metabolome extraction and analysed using a two-dimensional gas chromatography time-of-flight mass spectrometer. In order to identify the metabolite markers pertinent to the aim of this investigation, the metabolic profiles of the respective time-points were compared using a multi-statistical approach.
RESULTS: The principle component analysis plot of the data indicated natural differentiation between the pre- and post-marathon metabolic profiles and allowed for the identification of 70 significant metabolites markers. These were primarily indicative of elevated ketones, carbohydrates, tricarboxylic acid cycle and lipolysis intermediates, accompanied by reduced amino acid concentrations. Elevated concentrations of odd chain fatty acids, as well as β- and α-hydroxy acids indicated the activation of alternative catabolic pathways and possible cellular autophagy. In addition, a vast array of microbial-associated markers further substantiated the metabolic flexibility of marathon athletes.
CONCLUSION: These results are concurrent with the severe energy-requiring nature of endurance races, indicating extensive fuel substrate catabolism and the activation of alternative mechanisms such as α-oxidation and cellular autophagy. These results could potentially aid in identifying more targeted recovery and damage prohibition supplements/therapies, subsequently improving athletic performance.

SUBJECTS WITH OBESITY HAVE DIFFERENCES IN ERYTHROCYTE FATTY ACID COMPOSITION AT BASELINE AND FOLLOWING EXERCISE AND FEEDING WHEN COMPARED TO LEAN SUBJECTS OF IDENTICAL FITNESS LEVEL

JOANISSE, D.R.1,2, GUIRGUIS, G.3, RICKETTS, A.3, BLAIR, J.3, KELLY, L.P.3, RANDELL, E.W.3, SUN, G.3, CHEEMA, S.3, BASSET, F.3
1: UNIVERSITÉ LAVAL, 2: CENTRE DE RECHERCHE DE LIUCPQ, 3: MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Individuals with obesity but with greater cardiovascular fitness (i.e., a higher VO2max), are at a relatively lower risk for metabolic or cardiovascular disease than their lesser fit counterparts. Nevertheless, their risk levels remain higher than similarly fit but lean individuals. Questions remain as to the impact of fitness on the relationship between adiposity and lipid profiles of tissues, and also on the mobilization and deposition of lipids during and after exercise and/or feeding. We report here on erythrocyte (RBC) lipid content in subjects of different obesity status submitted to an exercise at their maximal fat oxidation (MFO) intensity, followed by a meal isocaloric with the energy expenditure of the preceding workout. We hypothesized that for a given level of fitness, differences would remain in lipid composition at baseline as well as mobilization following exercise and feeding.
METHODS: Lean fit (LF, n=7) and fit with obesity (OF, n=8; BMI 23.6±1.9 vs 32.0±3.6 kg/m2, LF vs OF respectively, p<0.001) men who regularly practice structured exercise were recruited. They were matched for age (35.9±10.0 vs 30.3±9.8 yrs, NS) and fitness (treadmill VO2max 4221±509, vs 4116±545 mLO2/min, NS). Subjects exercised at their previously determined maximal fat oxidation intensity (LF 30.1±5.5% vs OF 38.7±3.9% of VO2max, p<0.002) to a fixed energy expenditure of 300 kcal, followed 30 minutes later by a 300 kcal snack. Anthropometrics (including DEXA and waist circumference [WC]) were taken at rest. Indirect calorimetry was measured at rest, before and after exercise, and after the meal. Blood was collected fasted before exercise, and before and two hours after the post-exercise snack. Blood was separated into plasma and RBCs, lipids were extracted, and FA composition analyzed by gas chromatography. Data were analyzed using full factorial (mixed model) repeated measures and Pearson correlations.
RESULTS: RBC fatty acid composition differed between groups. OF subjects had higher RBC concentrations of palmitoleic acid (PA, 16:1; model group p=0.023). PA also correlated positively with markers of obesity at baseline (e.g., with WC r=0.578, p=0.024). Linoleic acid (LA, 18:2) concentration correlated negatively with obesity (e.g., with WC r=-0.577, p=0.024). With respect to changes during the exercise

and post-exercise snack, differences were seen for docosahexaenoic acid (DHA, 22:6; group*time p=0.006), levels increasing in the LF following the snack. Stearic acid (18:0) transiently decreased in both groups following exercise (time effect p=0.047) and tended to increase more in the OF following the post-exercise snack (group*time p=0.10).
CONCLUSION: Despite being matched for fitness, differences remain between OF and LF in RBC fatty acid composition at baseline and how these lipids are handled during exercise and a subsequent snack. Metabolic differences thus remain between these groups. Additional analyses on serum lipids are ongoing.

SIX-MONTH PHYSIOTHERAPY-EXERCISE INTERVENTION IN PATIENTS WITH IDIOPATHIC INFLAMMATORY MYOPATHY IMPROVES FATTY ACID OXIDATION IN PRIMARY MUSCLE CELLS IN VITRO.

NEMEC, M., VERNEROVÁ, L., ŠPIRITOVIC, M., LAIFEROVÁ, N., VOKURKOVÁ, M., UKROPEC, J., VENCOVSKÝ, J., UKROPCOVÁ, B.

SLOVAK ACADEMY OF SCIENCES

INTRODUCTION: Inflammatory myopathies (IM) are associated with muscle atrophy and metabolic dysfunction. Regular exercise has been shown to improve muscle functional capacity along with the improvement in patients' clinical state. Our aim was to compare characteristics of fatty acid oxidative metabolism in cultures of primary muscle cells (myotubes), derived from patients with inflammatory myopathy before and after 6-month exercise intervention and in muscle cells from healthy controls.
METHODS: Patients with idiopathic inflammatory myopathy (IIM) underwent 6-month exercise intervention (supervised stretching and strengthening exercises 2x/week, combined with individual home-based exercise prescription). Body composition (BIA), fasting blood glucose and lipids, glucose tolerance (oGTT) were assessed both before and after intervention. Muscle biopsy (m. vastus lateralis) was performed by Bergstrom technique at baseline and after intervention in seven IIM patients (5F/2M) and in age/gender/BMI matched controls. Primary muscle cell cultures were established. Three-day 100μM palmitate treatment was initiated 48h after the induction of differentiation (fat overload). In radiometric fat oxidation assay using [1-14C]-labelled palmitate, accumulation of Acid Soluble Products (ASPs, incomplete oxidation products) and production of CO2 were detected and normalized to protein content.
RESULTS: Chronic exposure to saturated fatty acid (palmitic acid) increased production of both ASPs and CO2 in myotubes from IIM patients (ASP $p<0.0005$; CO2 $p<0.05$) as well as from healthy controls (ASP $p<0,01$; CO2 $p<0,01$). When acutely challenged with 100μM palmitate (3h incubation), myotubes derived from patients with IIM produced less ASPs than myotubes from healthy controls (ASP $p<0.05$), and this effect was independent on chronic (3-day) palmitate exposure (ASP $p<0.1$). When acutely challenged with palmitic acid, cells from IIM patients subjected to exercise intervention produced more ASPs ($p=0.031$) and tended to produce more CO2 ($p=0.21$) than those taken in sedentary pre-training state. Proportion of complete fatty acid oxidation (CO2 production) from the total oxidation correlated negatively with % of body fat ($R=-0.516$, $p=0.017$).
CONCLUSION: Myotubes derived from patients with idiopathic inflammatory myopathy displayed reduced capacity to oxidize fat compared to healthy controls, indicating the presence of metabolic dysfunction in patients with IIM. Importantly, fat oxidative capacity of myotubes derived from patients with idiopathic myopathy improved after 6-month exercise intervention, suggesting that positive metabolic changes are maintained in vitro by yet unexplored epigenetic mechanisms.

THE EFFECT OF Β-ALANINE SUPPLEMENTATION ON CARNOSINE AND HISTIDINE CONTENT IN THE HIPPOCAMPUS OF 14-MONTH OLD RATS

HOFFMAN, J.1, RATHMACHER, J.2, ROBINSON, J.2, GEPNER, Y.3, COHEN, H.4

(1) UNIVERSITY OF CENTRAL FLORIDA, (2) HEARTLAND ASSAYS, (3) TEL AVIV UNIVERSITY, (4) BEN GURION UNIVERSITY

INTRODUCTION: The effect of 30-days of β-alanine (BA) supplementation on changes in carnosine and histidine content in the hippocampus of 14-month-old male Sprague-Dawley rats was examined.
METHODS: Animals were assigned to either a control group (CTL; n=8) in which rats were fed regular food and water or a β-alanine group (BA; n=6), in which rats were fed regular food and provided β-alanine with glucomannan (80:20 blend) in powder form mixed in their water. Rats were provided with 100 mg of the powder per kg of body mass. Following 30-days of supplementation the animals were anesthetized and perfused transcardially with cold 0.9% physiological saline followed by 4% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4). Brains were quickly removed, treated and frozen until analysis. Brain hippocampus amino acid analysis was performed by liquid chromatography- electrospray- tandem mass spectrometry.
RESULTS: Carnosine content in the hippocampus was significantly greater for BA compared to CTL (27.9 ± 6.2 nmol·g-1 versus 14.7 ± 7.7 nmol·g-1, respectively, $p=0.005$). No differences were noted in the histidine content of the hippocampus between BA and CTL (75.1 ± 50.9 nmol·g-1 versus 92.1 ± 27.8 nmol·g-1, respectively, $p=0.438$).
CONCLUSION: Results provide initial evidence that 30-days of β-alanine supplementation can increase carnosine content in the hippocampus of middle-aged rats, without compromising histidine content.

ANALYSIS OF THE MITOCHONDRIAL PROTEOME FROM HUMAN SKELETAL MUSCLE IN RESPONSE TO ENDURANCE TRAINING REVEALS VOLUME-DEPENDENT REMODELLING

BISHOP, D.J., GRANATA, C., RELJIC, B., BOTELLA, J., JAMNICK, N., KUANG, K., JANSSEN, H.A., LASKOWSKI, A., STAIT, T.L., THORBURN, D.R., FRAZIER, A.E., STROUD, D.

VICTORIA UNIVERSITY

INTRODUCTION: Exercise represents a major challenge to whole-body homeostasis, provoking a cellular stress response that includes changes in genes encoding mitochondrial proteins. However, there has been limited investigation of how exercise training remodels the human skeletal muscle mitochondrial proteome. The aim of this study was to use mass spectrometry (MS)-based proteomics to investigate the remodelling of human skeletal muscle mitochondria to different volumes of endurance exercise training.
METHODS: Ten healthy men underwent 3 consecutive training phases: normal (six sessions in 14 days), large (training twice a day for 21 consecutive days) and reduced (seven sessions on 7 consecutive days) volume training. We took four resting muscle biopsies; one before the study, and one after each training phase. Isobarically-labelled peptides derived from mitochondria-enriched protein fractions were analysed using liquid chromatography (LC)-tandem MS (LC-MS/MS). We identified significantly altered pathways by a search of enriched

Gene ontology (GO), KEGG, Pfam and Corum terms using Perseus software. Significance was determined by a Benjamini-Hochberg false discovery rate (FDR) of < 5%.
RESULTS: We quantified the relative abundances of 1411 proteins, including >700 known mitochondrial proteins across all participants and timepoints. Training-volume-dependent increases in the levels of mitochondrial proteins were accompanied by increases in mitochondrial respiration, the enzyme activity of citrate synthase and respiratory complexes I, II, and IV, and CI+III+IV supercomplex protein content. We readily detected cytoskeletal proteins associated with the mitochondria, and their levels had a strong inverse correlation with the relative abundances of mitochondrial proteins. We were able to overcome this apparent structural remodelling in silico, allowing us to identify 172 proteins differentially regulated in response to different volumes of exercise training. Highlights include a temporary repression of oxidative phosphorylation and increase in amino acid degradation with an initial training volume, followed by increases in tricarboxylic acid cycle and mitochondrial biogenesis proteins with additional training.
CONCLUSION: Our results highlight the remarkable plasticity of mitochondria in response to exercise training and illustrate that training volume influenced this remodelling of the mitochondria proteome.

EFFECTS OF DIFFERENT EXERCISE MODES ON THE PROTEIN EXPRESSION OF BMP-4/BMP-7 AND THERMOGENESIS RELATED PROTEINS IN ADIPOSE TISSUE OF OBESE RATS

YAN, Y.

BEIJING SPORT UNIVERSITY

INTRODUCTION: BMP-4 and BMP-7 are important regulators that affect the directional differentiation of stem cells into adipocytes and promote their heat production. This study were to explore the role of BMP-4/7 and its related thermogenic regulatory proteins in exercise-induced adipose tissue thermogenesis, to explore the effective exercise mode of exercise promoting the heat metabolism of fat tissue in obese.
METHODS: 100 3-week-old male SD rats were fed with high-fat-diet for 8 weeks and 30 11-week-old obese rats were screened out to be randomly divided into 3 groups: sedentary obese group(n=10), moderate-intensity continuous exercise group(n=10) and HIIT group(n=10). Rats in the moderate-intensity continuous exercise group moved on the treadmill with an intensity of 60%-70%V̇O2max. Rats in the HIIT group moved on the treadmill with an intensity of 70%-（90%-50%）*6-70%V̇O2max. Rats were training for 8 weeks, 5 days a week, 50 minutes a day. At the end of the 8th week, 48 hours after the last exercise, brown fat, subcutaneous and peri epididymal white adipose tissue were taken from all rats. The protein expression levels of BMP-4, BMP-7, TBX1, PRDM16 and UCP-1 in adipose tissue were detected by Western blot.
RESULTS: (1) Both exercise modes could significantly reduce the intake and weight of obese rats (P<0.01).(2) The protein contents of BMP-4, BMP-7, TBX1, PRDM16 and UCP-1 in subcutaneous adipose tissue of rats in moderate intensity continuous exercise group increased significantly (P<0.01); The protein content of BMP-4, BMP-7, TBX1, PRDM16 and UCP-1 in peritesticular adipose tissue decreased (P>0.05), and the protein content of TBX1 decreased significantly (P<0.05); The protein content of BMP-4 in brown adipose tissue increased significantly (P<0.01), while the protein content of BMP-7 and UCP-1 decreased significantly (P<0.01). (3) In HIIT group, the protein content of BMP7 and TBX1 in subcutaneous adipose tissue of rats increased significantly (P<0.01), and the protein content of BMP-4 and PRDM16 increased (P>0.05), while the protein content of UCP-1 decreased (P>0.05); The protein content of BMP-7 in peritesticular adipose tissue decreased (P>0.05), while the protein contents of BMP-4, TBX1 and UCP-1 increased significantly (P<0.01). The protein contents of BMP-4, TBX1 and PDCM16 in brown adipose tissue increased significantly (P<0.05), while the protein contents of BMP-7 and UCP-1 decreased significantly (P<0.01)
CONCLUSION: For obese rats, exercise has tissue specificity in regulating the heat production of white fat while inhibiting the heat production of brown fat. In the same adipose tissue, the effects of aerobic continuous exercise and high intensity intermittent exercise on regulating adipose heat production are different. The role of BMP-4/7-regulated adipocyte differentiation and UCP-1 expression in exercise regulating adipose tissue thermogenesis needs further study.

Oral presentations

OP-MI17 Strength and power III

EFFECTS OF WHOLE-BODY VIBRATION AND BLOOD FLOW RESTRICTION ON MUSCLE MASS, STRENGTH AND JUMP PERFORMANCE: A RANDOMIZED CONTROLLED TRIAL

CENTNER, C., RITZMANN, R., GOLLHOFER, A., KÖNIG, D.

UNIVERSITY OF FREIBURG

INTRODUCTION: Whole-body vibration (WBV) training is a frequently applied training regimen in the setting of sports and rehabilitation with the aim of attaining higher neuromuscular performance and structural adaptations. In recent years, blood flow restriction (BFR) training has gained increasing attention by facilitating the adaptive responses of several low-load exercise modalities. Although first acute studies report beneficial synergistic effects of WBV and BFR (1), there is a lack of studies investigating potential long-term effects. The objective of this study was to evaluate the chronic effects of WBV combined with partial vascular occlusion on muscle mass and function, as well as jump performance.
METHODS: Forty healthy subjects (25.7 ± 4.3 years) participated in a 10-week training intervention and were randomly assigned to one of the following groups: whole-body vibration training (2-4 mm, 30 Hz) with superimposed blood flow restriction (WBV+BFR) and whole-body vibration only (WBV). Both groups performed the exact same exercise protocol (static and dynamic calf raises and squats) with BFR being the only changing variable. Before and after the intervention, muscle cross-sectional area (CSA) of the M. gastrocnemius medialis (GM), and vastus lateralis (VL) was measured. Additionally, changes in isometric muscle strength of the knee extensors and counter movement jump performance were assessed.
RESULTS: Changes in muscle CSA of the VL revealed a significant main effect of time ($p < 0.05$) but no significant difference ($p = 0.30$) between WBV (+2.6 ± 8.7%) and WBV+BFR (+5.5 ± 8.2%). Muscle mass of GM showed similar changes in both groups (WBV: +2.7 ± 5.7%, WBV+BFR: +2.9 ± 6.1%) with a significant time effect ($p < 0.05$) but no interaction effect ($p = 0.89$). Evaluation of adaptations in muscular strength ($p = 0.70$) and jump performance ($p = 0.40$) did not demonstrate significant differences between WBV and WBV+BFR.

CONCLUSION: The findings of the present study indicate that the superimposition of blood flow restriction to whole-body vibration training did not facilitate greater responses in muscle mass, strength or jump performance in young women. Although these results are not statistically significant, the combination of both training regimens induced similar muscular hypertrophy in the VL muscle to what is typically seen following high-load resistance training (2). Further research is needed in order to investigate these effects with larger sample sizes in different clinical populations.

LESS PAIN, MORE GAIN? A COMPARISON OF CONTINUOUS VS INTERMITTENT BLOOD FLOW RESTRICTION PROTOCOLS IN ELICITING MORPHOLOGICAL AND FUNCTIONAL OUTCOMES

DAVIDS, C., RAASTAD, T., GAJANAND, T., SMITH, E., CONNICK, M., KEATING, S., COOMBES, J., PEAKE, J., ROBERTS, L.
THE UNIVERSITY OF QUEENSLAND

INTRODUCTION: Low load resistance training (LLRT) combined with blood flow restriction (BFR) serves as a strategy to accelerate the onset of peripheral fatigue, and ultimately augment muscular hypertrophy and strength without the need for high external loads. Many different BFR protocols currently exist, however there is little knowledge of which protocols favour specific adaptations, or which best suit specific populations. One of such variations in BFR protocol is whether the restriction stimulus is maintained during rest periods (continuous) or released (intermittent). An intermittent application is reported to reduce perceptions of effort and discomfort which may aid in exercise adherence, especially in elderly or untrained populations (1). However, it is unknown if this comes at the cost of inferior muscular development. Therefore, the primary aim of this study was to compare morphological and functional adaptations to 7-weeks of LLRT between intermittent and continuous BFR protocols.
METHODS: Young recreationally active Males and Females (n=42, 24.4 +/- 4.4yrs) completed 21 sessions (7 weeks) of lower body LLRT (30% 1RM) with either: a) no BFR (CON), b) continuous BFR (BFR-C) or c) intermittent BFR (BFR-I). Training consisted of leg press and leg extension exercises. Before and after training, muscle cross sectional area (CSA) was assessed via peripheral quantitative CT (pQCT), and muscular strength and endurance were determined via one-repetition maximum (1RM) testing and isokinetic dynamometry. Data were analysed using repeated measures two-way ANOVA, effect sizes (d) and percent changes.
RESULTS: Muscle CSA increased pre-post training with BFR-I ($p=0.02$; 2.2%; $d=0.14$), with no change following BFR-C or CON. Maximal isometric knee extensor strength increased pre-post training with both BFR-I ($p<0.01$; 19.3%; $d=0.49$) and BFR-C ($p=0.01$; 14.3%; $d=0.21$), but not CON ($p=0.12$; 9.6%; $d=0.23$). There were no significant differences between groups in isometric strength. Leg press 1RM strength increased pre-post training in all conditions ($p<0.001$) with no differences amongst groups. Total work performed during an isokinetic endurance task increased pre-post training with BFR-I ($p=0.03$; 11.3%; $d=0.33$) and BFR-C ($p=0.02$; 9.6%; $d=0.21$), but not CON ($p>0.99$; 3.6%; $d=0.08$).
CONCLUSION: Overall, these data suggest that both continuous and intermittent BFR protocols are equally effective at enhancing muscular strength and endurance, whilst perhaps intermittent BFR is superior for eliciting muscular hypertrophy in recreationally active individuals. Given the previous findings that an intermittent BFR protocol may reduce perceptions of effort and discomfort compared to a continuous protocol (1), the current findings promote the use of intermittent BFR as an effective training method for less-trained populations who may be less tolerable to ischaemic exercise-induced pain and discomfort.

EFFECTS OF COMBINED MAXIMAL AND REACTIVE STRENGTH TRAINING ON PERFORMANCE INDICATORS IN ENDURANCE RUNNERS

FLYNN, M.F.1,2, BOLGER, R.1, SMITH, P.D.2, HANLON, M.1
1: WATERFORD INSTITUTE OF TECHNOLOGY, 2: ART HEALTH SOLUTIONS

INTRODUCTION: Resistance training has been reported to improve endurance performance indicators in a variety of endurance athletes (Rønnestad & Mujika, 2014). The most significant improvements have been in running economy (RE). An athletes ability to perform economically is in part dictated by a variety of neuromuscular factors, although the exact mechanisms by which this occurs remains unclear. The majority of studies in this area have added the resistance training programme to the subjects' weekly endurance training, while the control group maintain the pre intervention training. The aim of this study was to investigate the effect of replacing a portion of an endurance runners training with strength training.
METHODS: Nineteen competitive distance runners were divided into either the endurance & strength training group (E&S) (n = 9; 30.4 years; 78.2 kg; 59.9 ml.kg.min-1) and the endurance only training group (END) (n = 10; 31.9 years; 77.4 kg; 61.1 ml.kg.min-1). Participants completed pre and post-testing in a wide range of endurance performance indicators: physiology (v2 mmol.L-1 BLa [blood lactate], v4 mmol.L-1 BLa, RE, VO2max, vVO2max), spatio-temporal parameters (ground contact time, flight time, stride length, stride frequency, strength (1 repetition maximum back squat; countermovement jump and 30-cm drop jump). Both groups were required to increase their pre-intervention weekly training by one hour. The strength intervention consisted of a combination of reactive and maximal strength exercises. Participants in the E&S group reduced their endurance training by one hour each week and added two hours of strength training. The END group increased their weekly endurance training by one hour. The within subject changes were assessed using a paired samples t-test. The repeated measures ANOVA test was used to assess the group by time differences following the intervention.
RESULTS: Significant improvements were observed in the E&S group in RE (2.3%), vVO2max (2.5%), maximal (71%) and reactive strength qualities (10.8%) ($p<0.05$), while no significant changes were observed in the END group. No significant changes were observed in any of the spatio-temporal parameters in either group following the intervention period.
CONCLUSION: This study demonstrates that reducing a competitive long distance runners endurance training by one hour and adding two hours of strength training per week results in greater improvements in RE, vVO2max, maximal and reactive strength, when compared to adding an additional hour of endurance training.

CHANGES IN THE LOCATION ON FORCE-VELOCITY RELATIONSHIP OF FORCE AND VELOCITY PERFORMED WITH THE 1RM LOAD AFTER TWO RESISTANCE TRAINING PROGRAMS DIFFERING IN SET CONFIGURATION.

RIAL-VÁZQUEZ, J., IGLESIAS-SOLER, E., FARIÑAS-RODRÍGUEZ, J., RÚA-ALONSO, M.

UNIVERSITY OF A CORUNA

INTRODUCTION: Cluster training is defined as a set configuration in which rest periods are more frequent than traditional protocols (1). It has been suggested as a method for allowing each repetition of the set to be performed with the highest quality (2). By the manipulation of set configuration is possible to improve the velocity of training while keeping constant the load, volume, work-to rest ratio and the intended velocity. The aim of this study was to examine the effect of two training programs differing in set configuration on the position on the Force-Velocity relationship (FV) of force (F1RM) and velocity (V1RM) performed with 1RM load.
METHODS: 39 active subjects were recruited. After obtaining the individual FV and the 1RM load for bench press (BP) and parallel squat (SQ) subjects were divided in 3 groups: Traditional Training (TT), Cluster Training (CL) and Control (CON) group. 10 training session consisting in four exercises (BP, SQ, lat pull and leg curl) were carried out by the experimental groups in 5 weeks (2 session a week). TT performed 4 sets of 8 reps with the 10RM load and 5 min. of rest between sets and exercises, whereas CL carried out 16 sets of 2 reps with 1 min. of rest between sets and 5 min. between exercises. At the end of the intervention, baseline evaluations were repeated. In order to contrast the position of F1RM and V1RM, two ratios were obtained: F1RM with respect to the theoretical maximum force (F0) and V1RM with respect to the theoretical maximum velocity (V0) estimated from FV (F1RM /F0 and V1RM/V0 respectively).
RESULTS: The analysis of V1RM showed higher values after training in SQ ($p=0.045$) but not for BP. V0 analysis showed higher results at postest only in CL for SQ ($p=0.009$) and both in TT ($p=0.009$) and CL ($p<0.001$) for BP.
F1RM /F0 was higher after training in SQ ($p=0.016$) and BP ($p=0.040$). F1RM was over 89% for all groups after training. Regarding V1RM /V0, lower values after training were observed in BP ($p=0.003$). No significant results were observed for SQ.
CONCLUSION: Values of F1RM /F0 were similar to those previously reported (3), although our results showed that this ratio is affected by the resistance training.
Concomitant changes of V1RM and V0 of SQ resulted in similar V1RM/V0 ratios before and after cluster training. Focus on BP, both experimental groups incremented V0 after training whereas V1RM was unchanged what is consistent with previous studies (4). However, V1RM/V0 was only reduced after CL suggesting a higher effect of this type of training on V0.

IMPACT OF BLOOD FLOW RESTRICTION EXERCISE ON MUSCLE FATIGUE DEVELOPMENT AND RECOVERY

BEHRENS, M., ZSCHORLICH, V., MITTLMEIER, T., BRUHN, S., HUSMANN, F.

UNIVERSITY OF ROSTOCK

INTRODUCTION: Low-intensity resistance exercise (20-30% one repetition maximum (1RM)) combined with blood flow restriction (BFR) is considered as a promising approach to induce hypertrophic adaptations similar to high-intensity resistance exercise (70-80% 1RM). However, it is still unclear how the central and the peripheral sites of the neuromuscular system respond in the course of BFR exercise and how these sites acutely recover. Therefore, we investigated the time-course and etiology of muscle fatigue development and recovery during and after low-intensity BFR exercise.
METHODS: Seventeen resistance-trained males completed four sets of low-intensity isotonic resistance exercise under two experimental conditions: knee extension exercise combined with (i) BFR and (ii) without BFR (CON). Neuromuscular tests were performed before, during (immediately after each set of knee extension exercise) and 1, 2, 4, and 8 min after each experimental condition. Maximal voluntary torque (MVT), quadriceps twitch torque in response to paired electrical stimuli at 10 Hz (PS10) and 100 Hz (PS100), PS10·PS100-1 ratio as an index of low-frequency fatigue, and voluntary activation were measured under isometric conditions. Perception of effort, leg muscle pain and EMG data were recorded during each exercise condition.
RESULTS: After the first set of exercise, BFR induced significantly greater reductions in MVT, PS100 and PS10·PS100-1 ratio compared to CON. These parameters progressively declined throughout the BFR protocol but recovered substantially within 2 min post-exercise when blood flow was restored. Neither a progressive decline in the course of the exercise protocol nor a substantial recovery of these parameters occurred during and after CON. Only at exercise termination, voluntary activation differed significantly between BFR and CON with greater reductions during BFR. Except for the first exercise set, perception of effort and leg muscle pain were significantly higher during BFR compared to CON.
CONCLUSION: At the early stage of exercise, BFR exacerbated the development of muscle fatigue mainly due to a pronounced impairment in contractile function. At exercise termination, central factors also contributed to the BFR-induced MVT reduction. Despite the high level of muscle fatigue during BFR exercise, the impact of BFR on muscle fatigue was diminished after 2 min of reperfusion, suggesting that BFR has a strong but short-lasting impact on neuromuscular function. The fast restoration of neuromuscular function following BFR could allow athletes to implement high-frequency training regimes without adversely affecting the recovery process. However, the increased perception of effort and leg muscle pain during BFR might be adverse for the use of BFR training in patients and deconditioned people.

GREATER RATING OF PERCEIVED EXERTION DURING TRADITIONAL SETS THAN REST-REDISTRIBUTION SETS AT FAST AND SLOW VELOCITIES

PISZ, A., OMCIRK, D., MALECEK, J., HALAJ, M., TUFANO, J.J.

CHARLES UNIVERSITY, PRAGUE,COMENIUS UNIVERSITY, BRATISLAVA

INTRODUCTION: Previous research has shown that performing shorter but more frequent sets is perceived to be easier than performing longer but less frequent sets during resistance training. However, these studies either included a single multi-joint exercise where coordination and experience play a role, did not have an identical range of motion, or resulted in different movement velocities between protocols, all of which result in confounding variables which may affect subsequent results. As such, the effect of rest-redistribution on the

rating of perceived exertion (RPE) in a controlled resistance training setting remains uninvestigated. Therefore, the purpose of this study was to determine the effects of rest-redistribution on RPE during high- and low-velocity concentric isokinetic knee extensions.
METHODS: Sixteen resistance-trained men (23.7 ± 2.8 years; 81.1 ± 8.8 kg; 181.3 ± 7.3 cm) performed a familiarization visit and then four counterbalanced, randomized visits on an isokinetic dynamometer. Slow (STS; 60°s-1) and fast traditional sets (FTS; 360°s-1) included 4 sets of 10 concentric knee extensions with 95 s of inter-set rest, whereas the slow (SRR; 60°s-1) and fast rest-redistribution (FRR; 360°s-1) sets included 20 sets of 2 with 15 s inter-set rest. In all protocols, RPE was recorded after every 10 repetitions. Each session occurred around the same time of day and was separated by 48-96 hours. For each velocity, a two-way repeated measures ANOVA was conducted to determine differences in RPE between TS and RR, while effect sizes (Hedge's g) were calculated to assess the magnitude of the difference between the set structures.
RESULTS: There was not a protocol*set interaction for either velocity. There was no main effect for protocol at 360°s-1 (FTS = 2.84 ± 1.15, FRR = 2.32 ± 1.44; g = 0.39), but there was at 60°s-1 (p = 0.003; g = 0.64), with STS (6.88 ± 1.41) being greater than SRR (5.90 ± 1.55). Comparing individual sets between STS and SRR, effect sizes were moderate to large, with greater RPE during STS (Set1, g = 0.58; Set2, g = 0.87; Set3, g = 0.57; and Set4, g = 0.70). A similar pattern existed for FTS and FRR, but with small to moderate effects (Set1, g = 0.30; Set2, g = 0.38; Set3, g = 0.36; and Set4, g = 0.52).
CONCLUSION: At both velocities, RPE during RR was less than during TS. Therefore, when aiming to reduce the perceived effort of resistance training, redistributing long inter-set rest intervals into shorter but more frequent rest intervals could be useful, especially with high-load, low-velocity movements.

OP-PM64 Physical activity for older people

A NOVEL, INTERACTIVE, BODY-WEIGHT EXERCISE PROGRAM FOR OLDER ADULTS - IS IT EFFECTIVE?

CROGNALE, D., KRAUSE, M., EGAN, B., NEWSHOLME, P., DE VITO, G.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: There is strong scientific evidence that regular physical activity, even of moderate intensity, produces major and extensive health benefits in both adults and in older individuals. However, in many cases research has focused on a single modality of training or machine-based training programs. Although these training modalities are effective, they can be difficult to implement due to lack of equipment, higher cost, boredom and repetitiveness. In addition, the feasibility of these training programs in the long term is not well-described. In light of this, we developed an interactive, full-body training program consisting of body-weight and elastic band exercises, athletics drills, yoga/martial arts stretching and positions to maximise group interaction and increase exercise variety.
METHODS: Thirty-nine medically-stable, older adults (age: 63.5±4 years) were randomly allocated to either 12-week (3 times per week) exercise program (EXE, n=21), or non-training control (CON, n=18) consisting of 1 to 3 multi-joint/core exercises, 1-2 assistance exercises for upper and lower body for 2-4 sets per exercise, 8-12 reps per set. Additionally, we included interactive athletics drills (15 min) during warm up and martial arts/yoga stretching exercises (10 min) during cool-down phases. All sessions were supervised by an experienced instructor to ensure proper intensity and appropriate exercise technique. Total duration of each session was 45-55 min. Outcome measures included functional performance (repeated chair rise tests), lean mass and body fat. Body composition was measured by dual-energy x-ray absorptiometry. Blood samples were assessed for Total Cholesterol, Triglycerides, Calcium, Vitamin D, Glucose and Insulin.
RESULTS: Body Fat Percentage (-1.5%; P<0.05), whole-body lean mass (2%; P<0.001) and legs lean mass (1.7%; P<0.001), increased significantly after training in EXE group but not in CON. Significant improvement (P<0.05) also occurred in the chair raise tests (reps in 30s, 21%; and time for 5 reps, -20%) in EXE group. There were no significant changes in Total Cholesterol, Tryglicerides, Calcium, Vitamin D, Glucose and Insulin in both EXE and CON groups.
CONCLUSION: This interactive, progressive exercise program has beneficial effects on lean body mass and functional performance in older adults and should be considered to improve body composition. After this intervention, the EXE group continued to meet twice weekly, with many of the original participants in regular attendance. This suggests a need for more interactive, age appropriate opportunities to engage older people, sustain motivation and generate long lasting results.

EFFECTS OF A LOW-THRESHOLD ICT-MEDIATED PROGRAM ON FUNCTIONAL FITNESS IN FEMALE HOME-CARE RECIPIENTS

JUNGREITMAYR, S.1, RING-DIMITRIOU, S.1, TRUKESCHITZ, B.2, EISENBERG, S.2, RIESER, H.3, SCHNEIDER, C.3

1: PARIS LODRON UNIVERSITY OF SALZBURG / 2: VIENNA UNIVERSITY OF ECONOMICS AND AGING / 3: SALZBURG RESEARCH FORSCHUNGSGESELLSCHAFT M.B.H.

INTRODUCTION: The majority of interventions that promote exercise and fitness in older adults are conducted with face-to-face supervision and instruction or by giving written information [1]. Information and communication technologies (ICT) offer new possibilities, thus an ICT-mediated exercise program consisting of short, low-threshold training bouts was developed and delivered to female home care recipients. The effect of the ICT-mediated fitness program on balance, upper- and lower-body strength was investigated.
METHODS: A total of 109 female home care users were tested for body mass index (BMI), grip strength (GRIP), balance (UPS) and lower body strength (30CR) before (= t0), at 6 months in (= t1) and after the intervention of 8 months (= t2). 55 participants were assigned to the test group and received the ICT-mediated functional fitness program (10 min-bouts) without obligation to use, whereas 54 participants were allocated to a control group. For statistical analysis, the test group was further divided into a treated test group (tTG: n = 32; usage at least two times per week) and those who infrequently or did not use the system (iTG: n = 23). A randomized sample out of the CG was then created to get an equally strong group size in CG (n: 32). Statistical analyses were performed to determine differences between groups over time by utilizing a p-value of < .05.
RESULTS: At baseline (t0) no significant differences in age, grip and UPS were found with a mean age of 74.7 ±6,7y (tTG) vs. 76.3 ± 7,3y (iTG) vs 76.8 ± 8.2y (CG), mean GRIP of 20.3 ± 6.5kg (tTG) vs. 17.4 ± 5.9kg (iTG) vs. 17.7 ± 5.7kg (CG) and a mean UPS of 14.1 ± 16.9sec (tTG) vs. 10.1 ± 10.6sec (iTG) vs. 9.9 ± 15.8sec (CG). The descriptive data imply a highly aged and overweight respectively obese population with

poor levels of strength and balance. Non-parametric statistical analysis showed that tTG increased balance at t1 and maintained lower body strength at t2, whereas iTG and CG showed a decrease over time in both variables
CONCLUSION: The fitness level in balance, grip and lower body strength of the investigated females was below average compared to proposed normative values at t0 [2-4]. The program showed to affect UPS and 30CR over the time course. The study shows that a low-threshold fitness program consisting of short training bouts mediated via ICT has a positive impact on physical function in female home-care recipients.

LAND- VERSUS WATER-WALKING INTERVENTIONS IN OLDER ADULTS: EFFECTS ON AEROBIC FITNESS AND BODY COMPOSITION

NAYLOR, L.H., HAYNES, A., MASLEN, B.A., SPENCE, A.L., ROBEY, E., CARTER, H.H., LAUTENSCHLAGER, N.T., COX, K.L., AINSLIE, P.N., PESTELL, C., RIDGERS, N.D., GREEN, D.J.

UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Interventions aimed at fostering health and wellbeing in older age are paramount. Low cardiorespiratory fitness and unhealthy body composition traits are strong predictors of all-cause and cardiovascular mortality and morbidity. Water-based exercise programs offer many potential benefits, namely, decreased musculoskeletal impact and risk from falls in older sedentary individuals. However, it remains unclear whether water-walking confers similar improvements in fitness and body composition compared to weight-dependent, land-walking when both are undertaken at matched intensity.
METHODS: 72 participants (62.5 ± 6.8 years) were recruited and randomised into one of three groups: no-exercise control (CG), land-walking (LW) and water-walking (WW). Measures were collected at baseline, following the 24 week supervised and centre-based intervention, and again after return to normal activities (wk 48). Height, weight, body mass index (BMI), waist and hip girths were collected and dual X-ray absorptiometry (DXA) was used to determine fat and lean tissue mass. r˙O2max was assessed via a maximal graded exercise test performed on a treadmill.
RESULTS: R˙O2max increased with training in both exercise groups (LW +0.54 ± 0.62ml.kg-1.min-1, +0.02 ± 0.04L/min-1; WW +0.83 ± 0.75ml.kg-1.min-1, +0.06 ± 0.06L/min-1) compared to CG (-1.81 ± 0.78ml.kg-1.min-1, -0.15 ± 0.06L/min-1) (group-x-time, P<0.05). Time to exhaustion increased following LW (+2.17 ± 0.43mins), which was significantly greater (P=0.001) than the CG (+0.4 ± 0.31mins). Benefits were independent of any beneficial effects on body composition. By week 48, the training-induced adaptations in the exercise groups returned to near baseline levels. No significant between group differences were observed for changes in body mass or BMI. However there were significant within-group reductions in central adiposity in both exercise groups. DXA data revealed a decrease in android fat mass in the WA group (LW -70 ± 42g; WW -165 ± 52g, group-x-time, P<0.05). Waist girth was reduced in the LW group (LW -1.4 ± 0.8cm; WW -0.4 ± 0.7cm, group-x-time, P<0.05), Further, there was an increase in lower limb lean mass in the WW, but not LW group (LW +323 ± 140g; WW +599 ± 180g).
CONCLUSION: A 24 week walking intervention increased aerobic capacity, and body composition, compared to remaining inactive. The adaptations were similar regardless of whether walking was conducted in water or on land. Water walking can be recommended as an exercise strategy for this age group due to its beneficial effects on fitness and body composition which are similar to, or exceed, those associated with land-walking. For benefits to persist, it appears that exercise needs to be maintained.

PHYSICAL PERFORMANCE MAINTENANCE 1 YEAR FOLLOWING THE END OF AN INTERVENTION: IMPACT OF THE TYPE OF EXERCISE?

AUBERTIN-LEHEUDRE, M.

UNIVERSITÉ DU QUÉBEC À MONTRÉAL

INTRODUCTION: Exercise training improves or maintains muscle function and physical parameters in older adults. However, older adults tend to stop their workout habits after the cessation of an exercise intervention. This lack of continuity could lead to a potential detraining health effect. Thus, we aimed to evaluate physical performance 1 year after the end of an exercise intervention and to determine if the results are dependent of the type of exercise.
METHODS: A 12-wks aerobic intervention (HIIT vs CONT) was completed by 25 older adults (HIIT:8men/15; 66.9yrs, CONT:6men/10; 67.1yrs). They were evaluated at baseline (T0), the end of the intervention (T1) and one year later (T2). Anthropometric parameters [Height (Ht), Weight (BW), BMI (BW/Ht2), waist circumference (WC)], handgrip strength (HS/BW), aerobic capacity [6-minute walk test (6MWT)] and functional capacities (normal or fast TUG, chair/step tests, unipodal balance) were assessed.
RESULTS: Both groups presented similar physical parameters (BMI, WC, relative handgrip strength) and aerobic or functional capacities at T0 and T1. However, at T2, almost all functional and aerobic capacities had declined significantly (p<0.05) in the HIIT group [fast TUG (T1:6.1s vs T2:7.0s), unipodal balance (T1:46.6 vs T2:34.3/60s), chair test (T1:15.5 vs T2:20.7s/10rep), step test (T1:35 vs T2:28 steps) & 6MWT: T1:645 vs T2:580m)]. Physical parameters [WC (T1:103 vs T2:101cm; p=0.18), BMI (T1:29.6 vs T2:28.2kg/m2; p=0.46), HS/BW (T1:0.44 vs T2:0.45kg/kg; p=0.43)] & normal TUG (T1:8.59 vs T2:9.49s; p=0.58) were unaltered. By contrast, CONT group declined significantly on some functional [chair test (T1:18.3 vs T2:27.1s/10rep); step test (T1:28 vs T2:32 n) & aerobic (6MWT: T1:608 vs T2:569 m) capacities but maintained physical [BMI (T1:29.6 vs T2:32.1kg/m2; p=0.58), WC (T1:101 vs T2:109cm; p=0.17) or HS/BW (T1:0.42 vs T2:0.42 kg/kg; p=0.88)] and functional [normal TUG (T1:9.8 vs T2:10.1s; p=0.31), fast TUG (T0:7.3 vs T2:7.0s; p=0.31), unipodal balance (T1:37.0 vs T2:33.5 s/60s; p=0.89)] parameters. However, relative (Δ) changes indicated no significant differences between groups except for fast TUG (CONT: -2% vs HIIT: +14%; p=0.002) and WC (CONT: +9% vs HIIT: -2%; p=0.05). Finally, when compared to T0 values, CONT group maintained all parameters except the chair test time (T0:19.1 vs T2: 27.1s/10rep; p<0.001) whereas HIIT group improved significantly WC (T0:105 vs T2:101cm; p=0.019) and maintained all others.
CONCLUSION: Our preliminary data indicates that 1 year after a 12-weeks aerobic intervention, aerobic and some functional capacities declined in healthy older adults but not lower than prior to participating. Our results suggested that, independent of the type of aerobic exercise, healthy older adults seem to have a "detraining" effect but be preserve to aging effect. A larger sample and more studies are needed to confirm our preliminary conclusion.

THE INFLUENCES OF THE ABILITY OF AGILITY IN DIFFERENT SITE BASED EXERCISE PROGRAM IN COMMUNITY-DWELLING OLDER ADULTS

CHOU, J., LIN, L., CHEN, H., CHANG, C., HUNG, C.

INSTITUTE OF PHYSICAL EDUCATION, HEALTH & LEISURE STUDIES, NATIONAL CHENG KUNG UNIVERSITY, TAINAN, TAIWAN

INTRODUCTION: Agility, referring to the ability to move freely and swiftly for maintaining the activities of daily living (ADLs) and complete tasks of older adults. The agility is an integration ability of vision, attention, reaction time, lower extremity muscle strength, and balance, closely linked to reduction of falls. This study aimed to compare the effectiveness of different site based (Gym and Community) for multi-component exercise program intervention at improving reaction time, dynamic balance in community older adults.
METHODS: 80 subjects (age: 72.3±8.05 years) in the community-dwelling older adults were assigned into three groups: the community-based group (COM, n= 27), the gym-based group (GYM, n=26) and control group (CON, n = 27). Exercise groups performed 90 minutes of low-and medium-intensity multi-component exercise groups program of 2 days per week for 12 weeks by combination of stretching, strength, balance, agility and aerobic exercise. The hand-eye coordination activities (no exercise), and community-based health literacy interventions were conducted for control group. The primary outcome measure were simple reaction time (attention), simple action time, overall reaction time, dynamic balance (the 8-foot up and go test) before and after interventions. One-way ANCOVA was used to analyze the changes in the ability of agility indicators.
RESULTS: After the intervention period, of the80 participants, 55 completed 12-week courses. In the attention, the attention time of the GYM (-7.76%) and the CON (-4.72%) were significantly improved than the COM group (-1.09%) ($p < .05$).The simplest movement time of the GYM (-17.81%) was significantly improved than the COM (+5.45%) and the CON (-4.89%) ($p < .05$). The ability of total reaction time of the GYM (-13.85%) was significantly better than the CON (-5.54%) ($p < .05$) and COM (+1.38%) ($p < .05$). In whole body agility and dynamic balance, GYM (-12.11%) and COM (-7.89%) were significantly faster than the CON group (-1.03%) ($p < .05$).
CONCLUSION: These findings indicate that participating in the gym-based, which focused specifically on learning more equipment that can improve the attention, action and reaction time. The hand-eye coordination of cognitive activities only can improve the attention time. Both gym-based and the community-based multi-component exercise can improve the ability of dynamic balance in community-dwelling older adults. Therefore, the findings suggest improving the ability of agility in community-dwelling older adults; gym-based multi-component exercise program is a priority. In addition to, community-based multi-component exercise program combining cognitive activities may have the same effectiveness as the gym-based.

A RANDOMISED CONTROLLED STUDY OF 12-WEEKS OF PILATES ON FALL RISK FACTORS IN HEALTHY OLDER ADULTS

DONATONI DA SILVA, L., MCINTOSH, C., SHIEL, A.

NATIONAL UNIVERSITY OF IRELAND, GALWAY

INTRODUCTION: Exercise programs are effective in reducing the risk of falls (1). Previous studies of Pilates have shown efficacy in both the short-term and long-term to predict falls. However, there is still a shortage of studies that evaluate the spatiotemporal parameters of gait after a Pilates intervention. Studies suggest that if there is early identification of changes in gait intervention should begin as soon as possible to reduce the risk of falls (2). The aim of this study was to evaluate a period of 12 weeks of Pilates with a supplementary at home program improved spatiotemporal parameters of gait, mobility, postural stability, functional mobility, fear of falling and physical activity in the older adults over 65.
METHODS: Subjects included were healthy people over 65 years of age who had not fallen in the previous 6 months. A screening test of global cognitive function, the Montreal Cognitive Assessment (MOCA) confirmed eligibility for participation in the study. Participants were assessed using the following fall-predictor measures: the 16-item Falls Efficacy Scale International (FES-16), the International Physical Activity Questionnaire (IPAQ), the Functional Reach Test (FRT), the Timed Up and Go (TUG), the GAITRite system, and Platform for the anteroposterior and mediolateral sway (AP-ML). In total, 60 healthy older adults were eligible to participate and randomized to the Pilates (PG) (n=29) and the control (CG) (n=32) groups. Statistical analysis was performed using Generalized Estimating Equations (GEE) to compare Pilates and control groups and time effects for the pre and post-test for the factor of Pilates were applied. Bonferroni post-hoc tests were used to identify differences between effects and interactions. Significance was set at .05.
RESULTS: Data on PG=17 and CG=31 participants analyzed. Mean (M) and Standard deviation (SD) for demographic data were: age 70.08 (5.51), Height 163.26 (8.06), BMI 25.49 (3.21), and cognitive 27.39 (1.26). The results found a decrease in TUG, directions in both AP-ML with eyes opened. The following parameters of gait: Step Time, Stance Time and the Double Support Time. There was an increase in Cadence. The significance in time effects for all response was ($P<0.05$).
There was a significance between groups effects in Cadence, Velocity, Step Time, Stance Time and the Double Support Time ($P<0.05$). Further interactions between groups and Pilates were found for the Velocity, Stride Length, and Step Length ($P<0.05$). Only one variable (FRT) was significant for the interaction between time and group ($P<0.05$).
CONCLUSION: The Pilates intervention for the biomechanical variables in the spatiotemporal gait parameters was identified. Positive effects on time, groups and interactions were found. Our results suggest that functional mobility, stabilometry, and gait patterns have improved in healthy older people after 12 weeks of Pilates exercise with supplementary at home.

Invited symposia

IS-BN07 Towards a better understanding of running injuries [Clinical track]

FOOTSTRIKE PATTERNS AND INJURY RISK

HAMILL, J.

UNIVERSITY OF MASSACHUSETTS

There are three footfall or footstrike patterns that human can utilize: 1) rearfoot (RF); 2) midfoot (MF); and 3) forefoot (FF). The vast majority of runners use an RF pattern (80-90% of all runners) while very few use a MF or FF pattern. Miller & Hamill (2015) suggested that the reason for utilizing one footstrike pattern over another is task specific. Gruber and colleagues (2014) reported that RF runners had an advantage over MF or FF runners in distance running. There does not seem to be conclusive evidence that MF or FF running can reduce the incidence of running related injuries. However, the lay and some scientific literature have recently advocated for runners to change from an RF to an

MF or FF pattern in order to prevent injury or as a rehabilitation protocol for injury. The reasons given to change range from reduction of the foot/ground impact to a reduction in the energy cost of running. However, there are also a number of researchers who suggest that this may not be beneficial to runners. This lecture will present an argument that changing one's footstrike pattern will not reduce the risk of a running related injury.

THE IMPORTANCE OF SATELLITE CELL AND CAPILLARY INTERPLAY FOR MUSCLE HYPERTROPHY

PARISE, G.

MCMASTER UNIVERSITY

Regulation of human muscle stem cells (satellite cells) is complex and not well understood. Although a plethora of cytokines and growth factors have been identified as candidates of muscle stem cell regulation in humans, the process from stimulus to stem cell activation, proliferation and differentiation remains nebulous. We have recently shown that the extent of muscle fiber perfusion may be a critical factor in the regulation of muscle stem cells. We hypothesize that muscle fiber perfusion may be an important delivery tool of signaling molecules for stem cell regulation and the extent of perfusion may dictate the extent and capacity for adaptation. Furthermore, age-related deficiencies in muscle fiber perfusion may, at least in part, be responsible for the observed ag-related deficiency in the muscle stem cell response to exercise. These hypotheses are generated from a number of observations recently made by my lab. They include the following: 1. There is a close anatomical relationship between muscle fiber capillaries and satellite cells. 2. Satellite cell located closer to capillaries tend be in the active state while those further from capillaries tend to be quiescent. 3. Individuals with a higher capillary content per fibre experience the greatest muscle satellite cell response in the days following injury, while those with the smallest capillary content per fibre experience the smallest expansion of the satellite cell pool. 4. Older adults with the a higher capillary content at baseline tend to increase muscle fibre cross sectional area with resistance training, while those with a lower capillary content tended not to increase muscle fibre cross section area and 5. Preliminary evidence suggests that those aerobically preconditioned to increase muscle perfusion tend to realize the greatest gains in muscle mass with resistance training.

DYNAMIC BONE MOVEMENTS DURING LOCOMOTION

Dynamic Bone Movements During Locomotion
Kepple, T., Bradley, K., Loan, J.P., Maxim*, A., Anderst*, W.
C-Motion, Inc
*University of Pittsburgh
INTRODUCTION: The principal assumption of 3D optical marker-based motion data for studying running is that the markers move rigidly with the body segments to which they are attached. It is known, however, that especially during running, segmental measurements have errors related to marker placement, marker measurement noise, and soft-tissue artifact (STA). It has been argued that uncertainties related to these error sources cannot be mitigated using discriminative pose estimation methods such as inverse kinematics (IK), and that pose estimation from traditional optical motion capture (MoCap) data is best estimated by assuming uncertainty in the data. Well-established probabilistic algorithms, based on Bayesian inference, can provide a principled way for making optimal inferences from uncertain data in combination with previous experience (1).
METHODS: To develop our Probabilistic Pose estimation, we collected dynamic stereo x-ray (DSX) data (2), synchronized with MoCap data, on 16 healthy subjects running on a treadmill. For all subjects the DSX volume focused on the femur and tibia (knee motion). The final Bayesian Prior was a combination of: 1) relocating the joint center by finding the location that minimized the movement between the tibia and femur over multiple gait cycles, and 2) a STA model that was a function of hip flexion. The end result was a cost function that mitigated the knee translational errors through the use of an experimentally developed Bayesian inference model.
RESULTS: We tested the Probabilistic Pose estimation against a data set from 4 normal control subjects. The testing occurred during the stance phase of running and was divided into early and late stance, as the data from those portions of the gait cycle needed to be collected in two separate DSX trials. For the tibia the average RMS error in locating the tibia position over the entire stance was 48.4 mm when traditional IK tracking was used. By using our Probabilistic Inference (Bayesian) pose estimation this average RMS error was reduced to 23.1 mm. At the femur the average RMS error in locating the femur position over the entire stance was 38.8 mm when traditional IK tracking was used. Again, by using our Probabilistic Inference (Bayesian) this average RMS error was reduced to 18.2 mm.
CONCLUSION: The results from these data suggest that error in pose estimation during running can possibly be reduced via the application of algorithms based on Probabilistic Inference to MoCap data.

OP-BN31 Biomechanics and neuromuscular: Mixed I

THE ANTICIPATION OF VARYING GRAVITY LEVELS IN HUMAN BALLISTIC MOVEMENT

WALDVOGEL, J.1, FREYLER, K.1, MONTI, E.4, ALBRACHT, K.2,3, STÄUDLE, B.3, GOLLHOFER, A.1, NARICI, M.4, RITZMANN, R.1,5

1: UNIVERSITY OF FREIBURG, 2: GERMAN SPORT UNIVERSITY COLOGNE, 3: UNIVERSITY OF APPLIED SCIENCES AACHEN, GERMANY, 4: UNIVERSITY OF PADUA, ITALY, 5: PRAXISKLINIK RENNBAHN, BASEL, SWISS

INTRODUCTION: The stretch-shortening-cycle (SSC) describes the neuromechanical pattern underlying locomotor movements. The SSC is defined by a stretching of a pre-activated muscle-tendon complex immediately followed by a muscle shortening in the concentric (CON) push-off phase (3). Regarding the efficiency of the SSC, both the muscle's pre-activation (PRE) and the reflex activity after touchdown are important to regulate the muscle's stiffness which is crucial for the energy management (1). These factors are supposed to be modulated

in response to load variation (2). This study aimed to identify load-dependent changes in biomechanical and neuromuscular characteristics of the SSC in drop jumps (DJs) under conditions of varying gravity (g) levels during a parabolic flight.
METHODS: DJs were executed in under (0.1-1g, UG), normal (1g, NG) and overload (1-1.9g, OG) gravitation. In 11 subjects peak force (Fmax), rate of force development (RFD) and 2D kinematics (sagittal plane) were recorded, and leg stiffness, ankle joint power and maximal ankle joint moment were calculated. Electromyographic activities (EMG) in M. soleus (SOL) and gastrocnemius medialis (GM) were assessed before (PRE) and during ground contact (eccentric phase (ECC), CON). Changes in GM fascicle length (FASC) were determined through ultrasound. Friedman test was used for statistical analysis.
RESULTS: Jumping under gradually increasing gravitation increased Fmax, RFD, ankle joint flexion, leg stiffness and ankle joint power ($p<0.05$). Ankle joint moment was highest in NG and reduced in UG and OG ($p<0.05$). EMG for SOL and GM progressively increased in PRE and partially in CON with increasing g load. In contrast to this EMG in ECC was highest in NG and diminished below and above NG ($p<0.05$). Accordingly, GM FASC lengthened in OG compared to the UG conditions ($p<0.05$).
CONCLUSION: These findings emphasize that biomechanically relevant kinematic adaptations in response to varying gravity levels are accompanied by phase-specific modulations in neural control (3). Gravitational variation is anticipated and compensated by a load-adjusted muscle activity to execute the SSC (2). Importantly, PRE, CON and ECC were differently affected: While PRE and CON demonstrate a load-dependent increase in EMG, ECC shows a downregulated neuronal activity associated with FASC lengthening. This reduction may help to protect the musculoskeletal system from exceeding muscle and tendon safety factors (4) possibly caused by central inhibition (2).

THE EFFECTS OF STRETCHING RATE ON PLANTAR FLEXOR NEUROMECHANICAL PROPERTIES AND MAXIMUM ANKLE RANGE OF MOTION

PINTO, M.D., WILSON, C.J., KAY, A.D., BLAZEVICH, A.J.
EDITH COWAN UNIVERSITY

INTRODUCTION: Maximal joint range of motion (max-ROM) and resistance to tissue elongation (flexibility) are important physical attributes influencing performances in athletic tasks and activities of daily living. Max-ROM tests are typically performed by rotating a joint on the dynamometer at slow angular velocities, which might be of little functional relevance for most daily and sports activities that are performed at faster angular velocities. However, the effects of stretching velocity on max-ROM and the potential neuromechanical factors influencing it have been overlooked. The aim of this study was to test the effects of stretching velocity on plantar flexor (PF) neuromechanical properties and max-ROM, and to assess relationships between them.
METHODS: Fifteen participants attended two familiarisation sessions followed by one experimental session. Testing included the performance of PF max-ROM tests on an isokinetic dynamometer at 5, 30 and 60 deg/s, interspersed by 90 s, whilst joint position, joint moment, and surface electromyograms (sEMG) were recorded synchronously. Max-ROM was determined at the end of the isovelocity phase to account for potential errors in max-ROM estimates between stretching velocities.
RESULTS: Stretches performed at 30 and 60 deg/s resulted in significantly greater max-ROM (23.5% and 19%), peak passive moment (i.e. stretch tolerance, 68% and 71.1%), elastic energy storage (area under the moment-angle curve, 25.6% and 15.7%), slope of the joint moment-angle relation (musculo-articular (MAC) stiffness) calculated in the ranges 0-10 and 0-20 deg, and earlier EMG onset compared to stretches performed at 5 deg/s. Only MAC in the ranges 0-10 and 0-20 deg differed between 30 and 60 deg/s. Overall, no significant correlations between max-ROM and MAC stiffness and sEMG onset angle were found for any stretching velocity tested.
CONCLUSION: Greater max-ROM can be achieved at faster compared to slower stretching velocities, although no statistical difference was observed in max-ROM between stretches at 30 vs. 60 deg/s. In addition, greater strength tolerance, energy storage and stiffness were attained at faster velocities, which is likely explained by musculo-articular tissues being viscoelastic (i.e. rate-dependent) and reflexive activation (sEMG gain) increasing with stretch speed. Earlier PF sEMG onsets were correlated with stiffer MAC at all stretching velocities. However, sEMG onset and MAC stiffness were not correlated with max-ROM, suggesting that the neuromechanical variables tested in this study were not determinant factors affecting max-ROM. The greater stretch tolerance in faster stretches, where greater max-ROM was attained, may also indicate that stretch tolerance is not a factor limiting max-ROM. Because these are commonly believed to affect max-ROM and could not explain these results, further research will need to be undertaken. The results of the present study have important practical and clinical implications that will improve future assessment of max-ROM.

ACUTE STATIC STRETCHING DOES NOT ALTER BALANCE CONTROL ABILITY: THE ROLE OF NEUROMUSCULAR ACTIVATION

SHOKOHYAR, S., BRAMBILLA, B., CÈ, E., LONGO, S., CORATELLA, G., RAMPICHINI, S., BORRELLI, M., DORIA, C., LIMONTA, E., ESPOSITO, F.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Balance control is the resultant of an integrative network involving sight, vestibular function, and proprioceptive feedback. Perturbations of one of these contributors could turn into a reduction in balance regulation. Muscle stretching is generally applied in sport and rehabilitative programs with the aim of improving joint range of motion (ROM). For this reason, it is also proposed as a complementary method to ameliorate balance control (1). Contextually, a possible transitional alteration of the proprioceptive feedback has been reported after stretching administration, in particular in its passive form (2). This occurrence could, in turn, decrease balance control ability. The role of muscle stretching in enhancing balance control ability is yet to be verified. This study sought to evaluate the acute effects of passive (PS) and active stretching exercises (AS) of the lower limbs on static and dynamic balance control.
METHODS: Thirty-eight participants (male/females: 19/19; age: 26±3 yrs; stature: 1.72±0.10 m; body mass: 69±17 kg) underwent a PS, AS and control session randomly on different days. Stretching routines had similar durations (4 exercises of 4 min each) and involved knee and ankle flexor and extensor muscles bilaterally. Before and immediately after stretching administration, hip, knee and ankle ROM, maximum voluntary contraction (MVC), and maximum muscles activation (surface electromyography (sEMG root mean square [RMS] from

vastus lateralis, biceps femoris, medial gastrocnemius, and tibialis anterior) were measured. Static and dynamic balance control were determined by computerized stabilometry in bipedal and monopedal conditions, with open and closed eyes. sEMG was recorded during balance evaluation, thereafter, RMS was calculated and normalized to the sEMG RMS measured during MVC.
RESULTS: After stretching administration, ROM increased at each joint level ($p<0.001$), MVC decreased (PS: $p<0.001$; AS: $p=0.03$), together with RMS (PS: $p<0.01$; AS: $p<0.05$) in all the investigated muscles. Regardless of the test modalities and stretching protocol, static and dynamic balance control resulted unaffected. However, an overall significant increment in sEMG RMS was found in all the tested muscles during balance tests (p from 0.02 to <0.001).
CONCLUSION: Independently of the modalities, the overall balance control capacity was neither improved nor altered by acute stretching administration. Interestingly, to maintain a similar performance, the muscles directly involved in balance control are more activated, likely as a possible compensation to an altered proprioceptive feedback from the stretched muscles and joints.

WHAT MAKES LONG-TERM RESISTANCE-TRAINED INDIVIDUALS SO STRONG? A COMPARISON OF SKELETAL MUSCLE MORPHOLOGY, ARCHITECTURE, AND JOINT MECHANICS.

MADEN-WILKINSON, T., BALSHAW, T.G., MASSEY, G.M., FOLLAND, J.P.
SHEFFIELD HALLAM UNIVERSITY; LOUGHBOROUGH UNIVERSITY

INTRODUCTION: The greater muscular strength of long-term resistance-trained (LTT) individuals is often attributed to hypertrophy but the role of other factors, notably maximum voluntary specific tension (ST), muscle architecture and any differences in joint mechanics (moment arm) have not been documented. The aim of the present study was to examine the musculoskeletal factors that might explain the greater Quadriceps strength and size of LTT vs untrained (UT) individuals and examine the evidence for regional hypertrophy in LTT individuals.
METHODS: LTT (n=16, age 22 ± 2 years) had 4 ± 1 years of systematic knee extensor heavy-resistance training experience, whereas UT (n=52; age 25 ± 2 years) had no lower-body resistance training experience for >18 months. Knee extension dynamometry, T1-weighted magnetic resonance images of the thigh and knee and B-Mode ultrasonography of the Quadriceps muscle group at 10 locations (VM 20% of thigh length (VMDIS) and 40% (VMPRX), VL and VI at 30% (VLDIS, VIDIS), 50% (VLMID, VIMID) and 70% (VLPRX, VIPRX), RF 55% (RFMID) and 75% (RFPRX)) were used to determine Quadriceps: isometric maximal voluntary torque (MVT), muscle volume (QVOL), patella tendon moment arm (PTMA), pennation angle (QΘP) and fascicle length (QFL), physiological cross-sectional area (QPCSA) and ST.
RESULTS: LTT had substantially greater MVT (+60% vs UT, $P<0.001$) and QVOL (+56%, $P<0.001$) and QPCSA (+41%, $P<0.001$) but smaller differences in ST (+9%, $P<0.05$) and moment arm (+4%, $P<0.05$). There was no evidence for regional hypertrophy either between or along the Quadriceps muscles with LTT (all $P>0.26$). 6 out of 10 sites showed greater FL of LTT vs UT (VMPRX, VIPRX, VIMID, RFMID, VLDIS and VLPRX sites; all $P<0.001$), with a tendency to be longer for RFPRX ($P=0.06$) with no differences at the remaining 3 measurement sites (all $P>0.15$). LTT had greater ΘP than UT at 3 out of 10 sites (VMPRX, VIPRX, VLDIS; $P<0.05$), with a tendency to be greater observed at four further sites (VLPRX, VLMID and both RF sites; adjusted $0.05\leq P\leq 0.07$).
CONCLUSION: Muscle size was the primary explanation for the greater strength of LTT. The greater muscle size (volume) of LTT was primarily attributable to the greater QPCSA (+41%; i.e. sarcomeres in parallel) rather than the more modest difference in QFL (+11% i.e. sarcomeres in series). There was no evidence in the present study for regional hypertrophy after LTT hypertrophy either between or along the Quadriceps muscles with LTT.

SPECTRAL ALTERATIONS OF LOWER LIMB EMG SIGNAL DURING A 4-KM TRACK CYCLING TIME TRIAL IN HIGH-LEVEL FEMALE CYCLISTS

BIDEAU, N., CORDILLET, S., MADOUAS, V., MENARD, M., BIDEAU, B., NICOLAS, G.
M2S LABORATORY - UNIVRENNES

INTRODUCTION: 4-km time trial (TT) cycling requires high power output as well as neuromuscular capabilities all along the event. While some authors demonstrated a significant degree of fatigue following a 4 km TT [1], few studies monitored neuromuscular fatigue during such a self-paced exercise. In the context of high intensity cycling exercise, analysis of the frequency content of the EMG signal is commonly used to assess the local muscle fatigue. More specifically, studies analyzed EMG in frequency domain to track non-monotonic variation of EMG signal [2]. The purpose of this study was to investigate changes in lower limb muscle activity during a 4-km cycling time trial in high-level female cyclists.
METHODS: 7 high-level female cyclists performed a self-paced 4-km TT on an outdoor velodrome. Muscle activity of 6 selected muscles of the right side were monitored all along the test using wireless EMG units (Cometa MiniWave Infinity) at a sampling rate of 2000 Hz. Electrodes were protected with adhesive tapes. Following SENIAM recommendations, bi-polar electrodes were placed over Rectus Femoris (RF), Vastus Medialis (VM), Gluteus Maximus (GM), Tibialis Anterior (TA), Biceps Femoris (BF) and Gastrocnemius Medialis (GaM). A spectral analysis was used to investigate the evolution of median power frequency during the TT. Median frequency (MDF) was calculated for each cycle and averaged with moving windows length of 3 cycles. Pedaling cycle was splitted into downstroke and upstroke phases. A slope of the regression line k that fits the MDF in a least-square sense was used as a fatigue index.
RESULTS: The analysis of slope of the regression lines revealed significant decrease of MDF for the full cycle concerning RF (k=-0.021(0.038) Hz.s-1) and VM (k=-0.013(0.042) Hz.s-1). A significant decrease of MDF concerning RF was also observed for the downstroke (k=-0.015(0.032) Hz.s-1) and for the upstroke (k=-0.023(0.039) Hz.s-1). A significant decrease of MDF for VM was quantified for downstroke (k=-0.014(0.042) Hz.s-1), as well as for GM for upstroke (k=-0.015(0.033) Hz.s-1). GaM reveled a different trend with a significant increase during downstroke (k=0.010(0.027) Hz.s-1).
CONCLUSION: Only RF and VM presented a systematic decrease of MDF during this 4-km track TT which is commonly associated to fatigue appearance and related to the action potential conduction velocity of the muscle fiber. Future works may address the link between neuromuscular coordination and potential concomitant joint kinematics alteration during self-paced 4-km TT.

A COMPARISON OF VASTUS MEDIALIS, VASTUS LATERALIS, BICEPS FEMORIS, AND LATERAL GASTROCNEMIUS ELECTROMYOGRAPHIC ACTIVITY BETWEEN SEXES DURING A JUMP LANDING.

PANTANO, K.

CLEVELAND STATE UNIVERSITY

INTRODUCTION: The timing and magnitude of muscle activation of the quadriceps and hamstring muscles are important for maximizing dynamic knee stability and neuromuscular control. Co-contraction of opposing muscle groups provide compression and stabilization, dampening knee joint forces, and protecting passive knee joint restraints from exceeding their tensile strength. These factors are essential in preventing knee joint injury, such as anterior cruciate ligament rupture. Differences in muscle activation patterns between sexes may contribute to a disparity in knee injury rates. The purpose of this study was to compare the timing and magnitude of muscle activation of the vastus medialis (VM), vastus lateralis (VL), biceps femoris (BF), and lateral gastrocnemius (LGS) between groups of active young men and women during a jump landing to determine if sex differences exist.
METHODS: Thirty male and 30 female recreational athletes 18-30 years with no prior knee injury, pathology or surgery participated in the study. Muscle activity during a jump-landing task was monitored with surface electromyography (EMG) from VM, VL, BF and LGS of the right lower extremity. EMG data was collected during the pre-contact phase (200 ms prior to initial foot contact or IFC), and post-contact phase (200 ms after IFC) and was converted to a Linear Envelope (LEEMG) using a 4th order, zero-lag, low-pass Butterworth filter with a 10 Hz cut-off. Muscle onset times were designated as the time when muscle activity exceeded the mean resting value plus 2 standard deviations for 14 ms or more. Independent paired sample t-tests ($P \leq .05$) compared temporal and spatial aspects of EMG between groups for the muscles studied including: muscle onset times during pre-contact phase, time to reach peak amplitude during post-contact phase, and integrated EMG during pre-contact and post-contact phases of the jump.
RESULTS: During the pre-contact phase of the jump muscle onset for VL ($P = 0.013$) and LGS ($P = 0.01$) occurred significantly sooner in women than men ($P \leq 0.05$). There were no significant group differences in time to peak amplitude for all 4 muscles during the post-contact phase of the jump ($P \leq 0.05$). The magnitude of muscle activation during the pre-contact phase for VM ($P = 0.01$), VL ($P = 0.005$), and BF ($P = 0.01$) were significantly greater in women than in men ($P \leq 0.05$). During the post-contact phase, muscle activation for VM ($P = 0.048$), BF ($P = 0.008$) and LGS ($P = 0.008$) were significant greater in women compared to men ($P \leq 0.05$).
CONCLUSION: The findings indicate that sex-related differences in muscle timing and magnitude of muscle activation of the selected muscles prior to and after landing from a jump exist. Women had an earlier onset and greater magnitude of quadriceps and hamstring activation than men, which may have been a protective strategy to improve knee joint stability. Greater muscle co-contraction under fatigued conditions could compromise the neuromuscular system and contribute to knee joint injury.

DIFFERENCE IN ENERGY GAIN AND TAKE-OFF PARAMETERS ACCORDING TO SEX AND LEVEL OF EXPERTISE IN THE POLE VAULT

FRÈRE, J.1, THIRIOT, H.1, POTVIN-GILBERT, M.1, SANCHEZ, H.2,3, CASSIRAME, J.4

1: UNIVERSITÉ DE LORRAINE, 2: FÉDÉRATION FRANÇAISE D'ATHLÉTISME, 3: UNIVERSITÉ GRENOBLE ALPES, GRENOBLE, 4: UNIVERSITÉ BOURGOGNE-FRANCHE COMTÉ

INTRODUCTION: In pole vaulting, athletes benefit from the elastic properties of the pole and gains in mechanical energy through muscular work (1). However, the underlying determinants of this energy gain remain largely unknown. As the maximal pole bending (MPB) is related to several take-off (TO) parameters (2), we supposed that they may influence the pole-athlete interaction and thus the amount of energy gain. Here, we determined which parameters could differentiate athletes according to their sex and level of expertise.
METHODS: Trials (n=202) performed by women and men during competitions were captured by 2D-video at 100 frames/s. The performances ranged between 3.00-5.93 m and were split into 6 groups according to sex and level of expertise: interregional, national and international for both women and men. Body markers were digitized just before the last foot support up to bar clearance to compute the kinematics and the time-profile of the athlete energy. Energy gain was calculated as the difference between the amount of energy at bar clearance and at last touch-down of the TO-foot (E_initial). The following TO-parameters were retained: E_initial, the energy loss during the last foot support, the pole plant timing, the pole-ground angle at pole plant and the TO-angle. The MPB was also calculated.
RESULTS: For each group, E_initial and the energy gain were inversely correlated (r ranging from -0.87 to -0.71), with increasing values of both parameters within each factor (main effects of sex and level of expertise, $p<0.01$). Two discriminant functions, which accounted for 97% of the explained variance, differentiated the 6 groups. The energy loss and MPB did not contributed significantly ($p>0.05$) while pole-angle contributed the most, pole plant timing and TO-angle second most to the overall discrimination (Partial Wilks Lambda=0.50, 0.89 and 0.90, respectively). The pole-angle mostly negatively weighted the first function, the TO-angle mainly negatively marked the second function, while pole plant timing contributed positively and negatively to functions 1 and 2. The scores of the first function increased within each factor (main effects of sex and level of expertise, $p<0.001$), while solely an interaction effect has been found on the scores of the second function ($p=0.018$).
CONCLUSION: For each group, the amount of energy gain is inherently related to the amount of energy at the run-up end: the faster the athlete, the lower the energy gain. However, athletes might go beyond this paradox and increase their overall level of performance by increasing the grip length (= a low value of pole-angle) and in a lesser extent decreasing the TO-angle while increasing the pole plant timing. Indeed, athletes from higher levels of expertise, whatever the sex, were able to increase their amount of E_initial while maintaining (or even increasing) the efficiency of their interaction with the pole (= energy gain).

INTER-SESSION RELIABILITY OF SAGITTAL PLANE HIP PROPRIOCEPTION MEASUREMENT IN HEALTHY YOUNG ADULTS

STEINGREBE, H., SELL, S., STEIN, T.

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: Aging and several illnesses have been associated with impaired proprioception leading to a decrease in motor control and subsequent increase in the risk of falling and injury (1).
Hence, there is a need for valid and reliable methods to assess joint proprioception to quantify impairments and effectiveness of treatment strategies.
Joint position reproduction (JPR) tests are a common and feasible method to assess joint proprioception.
Studies analysing reliability of hip joint JPR tests are sparse and results are moderate at the best (2,3).
Therefore, the aim of this study was to assess the reliability of a refined hip flexion JPR test.
METHODS: Inter-session reliability was assessed in 2 sessions (interim period 1 week) in a population of 16 healthy young adults (age: 24.9 ±2.2).
Active-active hip flexion JPR was conducted in two angle ranges: 10-20° (LA) and 40-50° (HA).
The blindfolded subjects stood upright on one limb and performed hip flexion with a flexed knee joint (5 repetitions per angle range).
Target angles were set visually without obstruction object. Positioning and repositioning events were defined autonomously by the subject by pressing a switch attached to a handlebar.
Hip flexion angles were analysed using a five-piece marker set (lateral knee, left & right ASIS & PSIS) captured by a motion capture system (200 Hz).
Mean absolute errors (AE) between positioning and repositioning angle were calculated across 5 trials.
Paired t-test, ICC (2,k), standard error of measurement (SEM) and coefficient of variation (CV) were calculated to check for systematic bias as well as relative and absolute reliability.
RESULTS: Absolute error for test and retest was 3.44 (±1.47) and 3.15 (±1.31) for LA and 2.85 (±1.67) and 2.68 (±1.36) for HA.
No significant systematic error was observed between sessions (LA: p=0.46; HA: p=0.64).
Inter-session ICC was 0.58 (95% CI: -0.21-0.85) for LA and 0.75 (95% CI: 0.28-0.91) for HA.
SEM was 0.90° for LA and 0.76° for HA. CV was 27.3% for both angle ranges.
CONCLUSION: The results obtained in this study are in accordance with those reported by Benjaminse et al. (ICC: 0.74; SEM: 0.72).
They, however, used a constant target angle of 45° which could have decreased variability.
The resultant ICCs are larger than those presented by Arvin et al. (ICC: 0.11-0.56; SEM: 0.6-0.7).
Surprisingly, the described AE and inter-subject variability (1.2-1.6 ±0.4-1.0) were smaller than in the present study despite analysing an older population (age: 73.5 ±7.8) with potentially decreased proprioceptive capacity.
In general, the JPR test in this study showed moderate to fair reliability with better results for larger flexion angles.
Due to a small AE coupled with large intra- and inter-subject variability the CV is relatively high, raising the need for large group or treatment effects to detect significant changes in joint proprioception.

THE EFFECT OF LATERAL WIND ON THE FLIGHT STABILITY IN SKI JUMPING

HU, Q., ZHANG, W.Y., WANG, X.D., CHEN, Q.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Wind is not only closely associated with the discussion of fairness in ski jumping [1], but also very important to the flight safety. Stability in flight is essential for performance and safety in ski jumping [2]. However, the effect of lateral wind on the flight stability in ski jumping remains unknown. In this study, a special computational fluid dynamics (CFD) method was used to simulate and predict the aerodynamics characteristics during flight in ski jumping under lateral wind, and the effect of lateral wind on the flight stability was analyzed.
METHODS: The jumper and skis were regarded as a multi-body system, and refined three-dimensional geometric model and mesh model of the system were established based on a general attitude during flight. The partially averaged Navier-Stokes (PANS) turbulence model was used to simulate the aerodynamic characteristics of the system. The forces and moments of the system were obtained, and the information of the flow field around the system were displayed intuitively, including pressure distribution, airflow velocity streamlines, vortex forms and so on. The lateral wind speeds involved include six conditions, including 0 m/s, 0.5 m/s, 1.5 m/s, 2.5 m/s, 3.5 m/s, 4.5 m/s, and so on.
RESULTS: The obtained force and torque are relative to the mass center of the multi-body system. The lateral wind affected flow field characteristics around the system, thus the corresponding force and torque were produced. The lateral wind velocity is approximately linearly related to the yaw force, yaw torque and roll torque generated by the wind. When the wind velocity increases 1 m/s, the yaw force, the yaw torque and the roll torque increase by 10.5 N, 3.5 N•m and 2.8 N•m, respectively. Meanwhile, this relationship may vary with the posture of the system during flight.
CONCLUSION: The influence of lateral wind on the flight stability of ski jumping can't be ignored, which can cause the athletes to deviate from the flight trajectory and possibly shift or rotate, thus cause the posture asymmetry, especially when the wind velocity is relatively large, there may be serious consequences of unstable yaw or pitch control during flight. The results lay the foundation for the further study of integrated flight stability based on wind tunnel tests, and also have some application value to improve the safety of ski jumping, and also provide useful scientific guidance for the flight stability control training of athletes.

MULTIVARIATE REGRESSION MODELLING OF CHINESE ARTISTIC GYMNASTIC HANDSPRING VAULTING KINEMATIC PERFORMANCE AND JUDGES SCORES

HE, W.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Vault kinematic such as approach velocity, maximum speed on springboard, 1st and 2nd flight time, duration on support table of the artistic gymnastic handspring vault were strongly correlated with vault difficulty value (DV) and judges score. However, FIG Code of Points (COP) was updated every four years after Olympic Games. Thus, previous regression studies might have its limited use. The purposes of the study were 1) to develop vaulting performance judges score prediction model and 2) to predict vaulting performance score.
METHODS: The study sample recruited (n=70) handspring vaults from Mens Artistic Gymnastic qualifying round of the 2017 China National Artistic Gymnastics Championship which adopted COP 2017-2020. A 50Hz JVC PX100 video camera was placed about 50m perpendicular to the vault table. Kinematic data were coded by an experience coder (r=0.91-0.96) by using Dartfish 2D video analysis software, whereas judges score was official competition final score. The sample divided into two parts - 65 (4 outliers were excluded) vaults were used to develop mathematic model and 5 vaults were used as new sample to compare against predicted score. Partial Least Squares Regression (PLSR) was used to calibrate and cross validate of the model. By referring to the known kinematic variables and DV, the developed model was used to predict judges score.
RESULTS: The goodness-of-fit of 3-factors model was chosen which explained calibration variance R2cal= 90.13% and explained validation variance R2val= 87.30% of the model. A significantly strong relationship between predicted Y (FS) and reference Y (FS) in both calibration and validation of model (rcal=0.949, rval=0.932). The Y-calibration error was expressed by Root Mean Square Error of Calibration (RMSEC) and the Y-prediction error by Root Mean Square Error of Prediction (RMSEP) which were 0.1727 and 0.1990 respectively. This means that although the calibration data were well fitted, the model may moderately described calibrated dataset well. The maximum height, 2nd flight time and DV were the important dependent variables against judges score. By using the judges score prediction model, 60% of new samples were within the acceptable range.
CONCLUSION: The 2D video analysis kinematic variables and known DV were sufficient to form judges score prediction model without technical input. This may assist in vault training monitoring and offer a better scientific approach of training guide.

HABITUAL LOADING LEADS TO TENDON HYPERTROPHY IN THE ELDERLY AND YOUNG HUMAN PATELLAR TENDON

COUPPÉ, C., SVENSSON, R.B., SKOVLUND, S.V., NYBING, J.D., JENSEN, J.K., KJAER, M., MAGNUSSON, S.P.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Habitual loading leads to tendon hypertrophy and greater mechanical properties of the young human patellar tendon (PT) [1]. However, it remains unknown if life-long habitual side-specific loading results in augmented structural and mechanical properties of the older tendon. The purpose was to investigate if life-long side-specific loading leads to greater cross-sectional area (CSA) and mechanical properties of the patellar tendon (PT).
METHODS: Nine elderly (OM) (age: 66±7yrs, BMI: 24.7±2.7, 51±8 playing-yrs) and 6 young (YM) (age 23±5, BMI: 22.0±1.7, 15.8 playing-yrs) knee-injury free elite badminton players and fencers were included.
CSA of the PT, obtained by 3-Tesla MRI, and ultrasonography-based measurement of tibial and patellar movement together with PT force during isometric contractions were used to estimate mechanical properties of the PT bilaterally. MRI images and mechanical properties of the PT were evaluated in a blinded fashion. Differences between legs (lead vs. non-lead) were analyzed using paired two-tailed t-tests, while differences between the two groups (YM vs. OM) were analyzed using unpaired two-tailed t-tests with the level of significance set at $p < 0.05$. Data are reported as Mean±SD or Mean±SE.
RESULTS: We found that the CSA of the lead leg was greater than the non-lead at the proximal and distal, but not the mid PT, in both OM (Proximal: 154±12 mm2 vs. 126±8 mm2, mid: 130±10 mm2 vs. 113±4 mm2 and distal: 128±9 mm2 vs. 112±5 mm2; $p<0.05$) and YM (Proximal: 114±6 mm2 vs. 97±6 mm2, mid: 99±4 mm2 vs. 93±6 mm2 and distal: 108±11 mm2 vs. 102±12 mm2; $p<0.05$).
For a given common force, OM had a stress (based on average CSA) that was lower on the lead leg compared with the non-lead (28±4 MPa vs. 32±4 MPa; $p<0.05$). Again, in the YM, the lead leg demonstrated lower PT stress than the non-lead (55±4 MPa vs. 64±7 MPa; $p<0.05$) and also lower tendon strain on the lead compared to their non-lead leg (3.5±0.3%, vs. 4.6±0.4%; $p<0.05$). The OM PT stiffness did not differ between the lead and non-lead legs (4997±887 N/mm vs. 4800±1016 N/mm). However YM had 29% greater PT stiffness on the lead than on the non-lead leg (7571±749 N/mm vs. 5861±397 N/mm, $p<0.05$). Moreover, there was no side-to-side difference for PT elastic modulus either in OM (lead 1.6±0.3 GPa vs. non-lead 1.8±0.3 GPa) or in YM (lead 3.0±0.2 GPa vs. non-lead 2.6±0.3 GPa) at a given common force.
CONCLUSION: These data confirm previous data that habitual loading leads to tendon hypertrophy and greater mechanical properties of the young human patellar tendon. The data also demonstrate that life-long unilateral habitual loading in elderly elite athletes yields region-specific tendon hypertrophy that may serve to lower the mechanical stress and thereby reduce the risk of injury.

OVERUSE INJURIES IN SWEDISH ELITE ATHLETICS – A PROSPECTIVE COHORT STUDY

LUNDBERG ZACHRISSON, A., DESAI, P., KARLSSON, J., GRAU, S.

UNIVERSITY OF GOTHENBURG

INTRODUCTION: Elite athletics seems to be associated with the onset of high numbers of overuse injuries (OI), regardless of discipline. Injury proportions differ substantially between different studies and seem to be higher with regard to studies in other sports. One reason for these high numbers of OI and the inconsistencies in reported incident proportions of OI might be that previous studies have relied upon self-reporting of injuries by the athletes rather than getting a diagnosis provided by a medical professional. Further, varying definitions of OI have been used in the past. The purpose of this study is to research OI incidence proportion, injury severity, injury location and

injury occurrence in Swedish elite athletics during a complete athletics season. The basis for the study is an athletics consensus statement of OI classification as well as the diagnosing of OI by a medical professional.
METHODS: A total of 108 elite athletes from western Sweden were included in the study. Elite status was defined as a top 6 placement at the National Swedish championships or a top 3 placement at the Swedish Junior National championships during the previous or current season. Injury status was screened at the beginning of the new season (October) after an active recovery period of about 4 weeks. Overall, 74 athletes have been uninjured after the screening and were willing to take part in the study. Athletes were asked to document their training and pain status for the next 12 months on a daily basis with help of a newly developed App. Injuries were recorded in accordance to the consensus statement either by notice of the athlete or by information gathered from the app. All injuries were diagnosed by a medical professional after the reporting. The season was split into four parts; conditioning part one (autumn), indoor competition, conditioning part two (spring) and outdoor competition. Descriptive statistics were used to evaluate the data.
RESULTS: Fifty-eight Swedish elite athletes completed a full athletics season. The OI incidence proportion during a complete season for the 58 athletes was 77,6% (all disciplines). Overall the 45 injured athletes suffered from 74 injuries. 54% of all injuries were classified as severe and resulted in training loss of at least 28 days. The most common injury location was the foot/shank (41%) followed by the thigh/hip (39%). Most injuries occurred during conditioning part one (autumn, 35%), followed by conditioning part two (spring, 30%).
CONCLUSION: The main findings from the study show that the overall injury proportion is surprisingly high compared with previous studies even though a more conservative definition of OI has been used. A reason for this could be the definition of elite status of the athletes in our study compared to other studies as well as the use of a medical professional to diagnose injuries. Injury severity differs compared with previous studies, possibly due to the large number of runners in our cohort and the different elite status.

BASIC RESEARCH ON OCCURRENCE FACTORS OF HEAD BRUISES IN THROWING TECHNIQUE OF JUDO - INFLUENCE OF UNEXPECTED CONDITION ON BACKWARD BREAKFALL -

HAYASHI, H.1, ANATA, K.2, UCHIMURA, N.3, ISHIKAWA, Y.4

1: FACULTY OF SPORTS STUDY, BIWAKO SEIKEI SPORT COLLEGE, 2: NATIONAL INSTITUTE OF TECHNOLOGY, ISHIKAWA COLLEGE, 3: OSA-KASANGYO UNIVERSITY, 4: FACULTY OF EDUCATION, OSAKA KYOIKU UNIVERSITY

INTRODUCTION: By 1983 - 2011, there were 118 deaths of judo under school management in Japan, most of which occurred during after-school activities. Regarding the accident, the All Japan Judo Federation reports that it often bruises the head in Randori (free practice). The Randori a practice that throws each other without announcing techniques in advance. Therefore those throwers may not be able to respond to throwing techniques. From this, we thought that being thrown in an unexpected condition is the cause of head bruising. Therefore, the purpose of this study was to clarify that being thrown in an unexpected condition is a cause of head bruising. Since it is dangerous to throw in an unexpected condition, we carried out the experiment with backward breakfall rather than throwing technique.
METHODS: Subjects were six expert men judo club members of university (mean age, 19.5 ± 0.55 years; mean height 169.8 ± 7.86 cm; mean weight 81.4 ± 16.44kg; mean rank: 2.0 ± 0th dan; mean year of judo experience 13.5 ± 2.17 years). Subjects were selected from 6 weight categories (1 person at under 60kg, 1 person at under 66kg, 1 person at under 73kg, 1 person at under 81kg, 1 person at under 90 kg, 1 person at under 100kg). The subject became in a middle posture and was pushed with a certain force by the pushing apparatus to perform backward breakfall (three times per person). The timing of pushing was set in advance as 1) closed eye condition not announcing of pushing and 2) eye opening condition announcing pushing. At that time, we measured angular acceleration and resultant translational acceleration of the head were with an accelerometer. In order to compare the angular acceleration and the resultant translational acceleration of the head in the backward breakfall of the two conditions, Wilcoxon rank sum test was performed. The level of significance was less than 5%.
RESULTS: There was a significant difference in the head angular acceleration (anteroposterior direction) in the closed eye condition (217.0 rad/s2) not announcing in advance pushing and the open eye condition (198.4 rad/s2) announcing to push in advance ($P < 0.05$). There was a significant difference in the head translational combined acceleration in the closed eye condition (65.9 m/s2) not announcing in advance pushing and the open eye condition (53.6 m/s2) announcing the user to push in advance ($P < 0.05$).
CONCLUSION: In this study, it became clear that those who performed backward breakfall in an unexpected condition have a high risk of bruising the head. From this, it was suggested that being thrown in an unexpected condition is a cause of head bruising in judo throwing technique.
This work was supported by JKA and its promotion funds from KEIRIN RACE.

VISUAL ANALOGUE SCALE AND BODY MASS INDEX MAY PLAY IMPORTANT ROLES FOR DETERIORATE WOMAC SCORES OF PREVENTIVE AGAINST KNEE OSTEOARTHRITIS IN COMMUNITY-DWELLING OLDER ADULTS

CHEN, C.H.1,2, LIN, L.L.1, CHOU, J.W.1, CHUANG, C.Y.1

1.KAOHSIUNG VETERANS GENERAL HOSPITAL, TAINAN BRANCH 2.NATIONAL CHENG KUNG UNIVERSITY, TAIWAN

INTRODUCTION: Degenerative joint disease especially for the knee osteoarthritis (OA) is common of all the problems at outpatient Orthopedic department and the main cause of disability in older adults . Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) is the most common clinical knee score using for evaluating the scoring of systemic knee function (pain, stiffness, and physical function). The purpose of this study is to determine which factor may affect WOMAC score.
METHODS: 79 community-dwelling older adults (mean age: 69.24+/- 8.08 years) were divided into normal group (NOR, N=34), mild disabled group (MIL, N=35), and severe group (SEV, N=10) group using the Saint Louis University Mental Status (WOMAC) examination. We set O as normal people. 1~10 as mild disabled knee, more than 10 we set as severe. The OA factors we collected including body mass index(BMI), American College of Rheumatology (ACR), visual analogue scale (VAS), individualized lower limb muscle power, individualized knee range of motion (ROM), standing on one leg(balance), 30 seconds to sit up(lower extremity muscle strength), stand up and go(agility/dynamic balance), and 2-minutes step (aerobic endurance). One-way ANCOVA and Pearson's product moment correlation were used to determine plasticity of WOMAC score grading and factor.

RESULTS: BMI, ACR, VAS, balance, lower extremity muscle strength and agility/dynamic balance had the significant correlations with OA Index (WOMAC).The results showed the major impact factors came from BMI(p=.015), ACR(p=.004), and VAS(p=.007) after one-way ANCOVA test. There's no obvious effect over knee range of motion (ROM), standing on one leg, 30 seconds to sit up, stand up and go, and 2 minutes up and go test.
CONCLUSION: Based on our clinical data, we could find pain plays an important role for American College of Rheumatology (ACR) and visual analogue score(VAS), especially for the people with overweight. Conclusion:These parameters are essential to interpret WOMAC interfering factors. When the health suffering from knee pain, especially for the people with overweight, earlier diagnosis with early treatment is suggested.

CHALLENGING BELIEFS: CHANGES IN GMFCS TWO DECADES AFTER IVE DORSAL RHIZOTOMY OR ORTHOPAEDIC SURGERY

LANGERAK, N.G.1, FIEGGEN, A.G.1, LAMBERTS, R.P.2

1:NEUROSCIENCE INSTITUTE & DIV. OF NEUROSURGERY, UNIVERSITY OF CAPE TOWN, SOUTH AFRICA; 2:INSTITUTE OF SPORT AND EXERCSIE MEDICINE & DIV. OF ORTHOPAEDICS SURGERY, STELLENBOSCH UNIVERSITY, SOUTH AFRICA

INTRODUCTION: The Gross Motor Function Classification System (GMFCS) is a well-accepted tool to objectively classify the level of gross motor function in people with Cerebral Palsy (CP) [1]. While the GMFCS has been shown to be stable [2,3], it is not known whether major interventions lead to long term changes in GMFCS level. The aim of this study was to determine in adults with bilateral spastic CP whether there was i) a change in GMFCS level two decades following a major intervention, either Selective Dorsal Rhizotomy (SDR) or Orthopaedic surgery (ORTH); and ii) a relation between change in GMFCS levels and contextual factors such as age, sex, education, employment, marital and socioeconomic status.
METHODS: Participants were recruited from databases of a children's hospital and a special needs school in Cape Town, South Africa. Pre-operative GMFCS levels were retrospectively determined from clinical records while current GMFCS levels and information on contextual factors was captured at the time of follow-up assessment. The study cohort consisted of 61 participants, including 31 in SDR group (mean (SD) age: 28y8m (5y6mo), 13 females) and 30 in ORTH group (age: 33y1mo (7y8mo), 18 females). Statistical analyses included Wilcoxon matched-pairs signed rank tests (aim i) and Spearman correlations (aim ii).
RESULTS: Preoperatively, 9 children could be classified as GMFCS level I (0-SDR, 9-ORTH), 36 as level II (22-SDR, 14-ORTH) and 16 as level III (9-SDR, 7-ORTH), while after a mean (SD) follow-up time of 24y3mo (6y2mo) 30 participants were classified as level I (15 SDR, 15 ORTH), 22 as level II (11-SDR, 11-ORTH), and 9 as level III (5-SDR, 4-ORTH). Of the 33 participants for whom the GMFCS level changed, 30 improved at least one level (18-SDR, 12-ORTH) and 3 deteriorated one level (0-SDR, 3-ORTH), while 28 (13-SDR, 15-ORTH) were unchanged. The changes in GMFCS level were significant (All: $p<0.0001$; SDR: $p<0.0001$; ORTH: $p=0.04$) and only associated with pre-operative GMFCS levels (All: $p=0.04$, $r=0.26$; ORTH: $p<0.01$, $r=0.48$).
CONCLUSION: Two decades after SDR or orthopaedic surgery, more than half of this study cohort was classified at a different GMFCS level compared with pre-operative levels, with the majority experiencing an improvement. These findings suggests that in some circumstances (e.g. in developing countries) GMFCS can change after major interventions.

EXERCISE ADHERENCE AND PSYCHOLOGICAL NEEDS SATISFACTION IN THE PHYSICAL ACTIVITY AND ASTHMA IN YOUTH (PLAY) INTERVENTION

WESTERGREN, T.1, STANG, J.2, STENSRUD, T.2, ANDERSEN, O.K.2, SIGDESTAD, J.B.1, BRYNJULFSEN, T.1, NIELSEN, A.3, FOYN, T.H.1, DEMMELMAIER, I.1,2, BERNTSEN, S.1

1. UNIVERSITY OF AGDER, 2. NORWEGIAN SCHOOL OF SPORT SCIENCES , 3. UNIVERSITY OF OSLO, 4. UPPSALA UNIVERSITY

INTRODUCTION: The objective of this study was to examine exercise adherence and perceived psychological needs in the PhysicaL activity and Asthma in Youth (PLAY) intervention for adolescents with asthma aged 13-18 years.
METHODS: A 10-week interval- and play-based indoor exercise intervention including two one-hour sessions weekly was conducted at two locations during winter and late autumn 2018. Sessions were led by sports students and a physiotherapist and included different themes with a progression from play to sports; games to learn to know each other, high-intensity team-based games and relays, team-building and competition, combat sports, high-intensity fitness center sessions, and ball-sports. Attendance, rated perceived exertion (Borgs RPE 6-20) (Borg, 1970) after each session, and heart rate (HR) (Polar M400, Polar Electro OY, Kempele, Finland) during sessions were recorded. Peak HR (HRpeak) was recorded pre-intervention with a maximal incremental cardiopulmonary exercise test on a treadmill. The Basic Psychological Needs in Exercise Scale (BPNES) (Vlachopoulos & Michailidou, 2006) including sub-domains about perceived autonomy, competence and relatedness (4 items each with response from 1;"not true at all" to 7;"very true") were distributed after week 2 and 10 of the intervention. Change in BPNES score was assessed by paired samples t-test.
RESULTS: Twenty-two adolescents (15.7±1.2 years) with an asthma diagnosis confirmed by an allergologist, pneumonologist, or pediatrician were pre-tested. Twenty adolescents entered the intervention whereas 16 (80%) completed the entire intervention period with a mean attendance of 15.7±2.8 out of 20 sessions. Mean HR during all sessions were 150±10 beats per min, mean minutes per session ≥80% of HRpeak were 21±8 and ≥90% of HRpeak were 7±5 minutes. Mean RPE score was 14±3. In week 10, participants reported a BPNES total score of 6.25±0.52. Subdomain score of autonomy was 6.07±0.62, competence 6.13±0.77, and relatedness 6.55±0.61. Compared to week 2, total score increased by 0.59±0.68 ($p=0.01$), autonomy by 0.91±0.82 ($p<0.01$), and relatedness by 0.50±0.78 ($p=0.03$), whereas perceived competence did not improve significantly.
CONCLUSION: The PLAY intervention had satisfactory exercise adherence by attendance, completion rate, and exercise intensity which on average was perceived and monitored as vigorous. Participants reported increased psychological needs satisfaction from week two to post intervention.

AEROBIC EXERCISE AND VENTILATORY FUNCTION IN CYSTIC FIBROSIS: WHAT ARE THE IMPLICATIONS OF DYSGLYCAEMIA?

CAUSER, A.J., SHUTE, J.K., CUMMINGS, M.H., SHEPHERD, A.I., WALLBANKS, S.R., ALLENBY, M.I., ARREGUI-FRESNEDA, I., BRIGHT, V., CARROLL, M.P., CONNETT, G., DANIELS, T., MEREDITH, T., SAYNOR, Z.L.

UNIVERSITY OF PORTSMOUTH

INTRODUCTION: Cystic fibrosis (CF) is the most common life-shortening, autosomal recessive disease affecting Caucasians. Whilst respiratory complications are the main cause of morbidity, non-pulmonary complications such as CF-related diabetes (CFRD) are an increasingly common problem throughout the CF life-course. Notably, aerobic fitness has been shown to be limited in paediatric groups with CFRD compared to their normal glucose tolerance (NGT) counterparts. This association has not been investigated in adults. This study addressed this knowledge gap and investigated the effects of CF-related dysglycaemia on aerobic exercise and ventilatory function in children, adolescents and adults with mild-to-severe CF.
METHODS: Cardiopulmonary exercise testing with supramaximal verification and oral glucose tolerance testing were retrospectively analysed in 75 people with mild-to-severe CF (age: 27.0 ± 13.8 y [range: 9.3 – 66.5 y]) forced expiratory volume in 1 s [FEV1]: 70.8 ± 20.8% [range: 26.8 – 112.7%]; 60% male). These included 19 adults with CFRD, and 8 adults with impaired glucose tolerance (IGT). Seventeen children and 31 adults had NGT. Aerobic fitness and ventilatory function during exercise were determined by maximal O2 uptake (V̇O2max), ventilatory drive (ΔV̇E/ΔV̇CO2), breathing reserve (V̇E/MVV), peak ventilatory equivalents for O2 (V̇E/V̇O2peak) and CO2 (V̇E/V̇CO2peak), change in arterial O2 saturation (ΔSpO2), and peak dyspnoea.
RESULTS: V̇O2max, ΔV̇E/ΔV̇CO2, V̇E/MVV, V̇E/V̇O2peak, V̇E/V̇CO2peak and ΔSpO2 were not different between adults with NGT, IGT or CFRD (all $p > 0.05$). Sub-group analyses revealed V̇O2max, relative to body mass and as a percentage of normative values, was greater in adults who experience post-reactive hypoglycaemia vs. adults with NGT without hypoglycaemia ($p < 0.05$). Ventilatory limitation (i.e. V̇E/MVV ≥ 85%) was more frequent in adults with CFRD (84%) vs. NGT (29%), and V̇E/MVV was correlated with ΔSpO2 ($r = -0.35$, $p < 0.01$) and dyspnoea ($r = +0.40$, $p < 0.01$). Age, FEV1, body mass index, V̇E/MVV and ΔV̇E/ΔV̇CO2 were significant predictors of V̇O2max in children, adolescents and adults without CFRD (adjusted $R2 = 0.74$, $p < 0.01$), but assessments of glycaemic control did not significantly explain any additional variance (all $p > 0.05$). There were no significant associations between glycaemic control and V̇O2max in people with CF, irrespective of glycaemic status (all $p > 0.05$).
CONCLUSION: In this study, dysglycaemia in CF adults did not contribute to worsening aerobic fitness. However, more advanced dysglycaemia was associated with poorer lung function and ventilatory limitation during exercise, which may have implications for physical activity prescription in this population. The modulators of V̇O2max in this cohort, which included children, adolescents and adults with mild-to-severe CF appear to be age, lung function, nutritional status and ventilatory function during exercise.

END CRITERIA FOR REACHING MAXIMAL OXYGEN UPTAKE IN PATIENTS NEWLY DIAGNOSED WITH CANCER. BASELINE DATA FROM THE RANDOMIZED CONTROLLED TRIAL OF PHYSICAL TRAINING AND CANCER (PHYS-CAN)

BJØRKE, A.C.H.

UNIVERSITY OF AGDER

INTRODUCTION: It is well established that maximal oxygen uptake (VO2max) is lower in patients with various types of cancer before, during, and after cancer treatment, compared to healthy individuals. There is, however, limited knowledge on whether typical end criteria used for reaching VO2max in healthy populations are suitable for patients newly diagnosed with breast-, prostate- or colorectal cancer. Therefore, to ensure high test reliability within this group of patients, the aim of this study was to assess if fulfillment of typical end criteria for reaching VO2max was associated with the test-leaders' subjective evaluation whether a test was acceptable or not.
METHODS: From the Phys-Can randomized controlled trial of physical training in cancer, 537 patients newly diagnosed with breast, prostate or colorectal cancer performed an incremental walk/run exercise test on a treadmill until exhaustion. The test was conducted before start of adjuvant treatment and participation in an exercise intervention. End criteria and cut-points included were an O2 plateau (ΔVO2 ≤150 mL/min), 85% of predicted maximal heart rate (HRmax), a peak respiratory exchange ratio (RER) above 1.1 and the patients' rating of perceived exertion (RPE) of above 17 (BORG's 6-20 REP-scale) after terminated test. Each of the criteria was dichotomized into "fulfilled" and "not fulfilled" based on the given cut-points. The Odds Ratios (OR) for the test-leader to evaluate the test as acceptable or not, based on his/her subjective evaluation of the patients' effort, were found with logistic regression analyses.
RESULTS: RER>1.1 (OR = 3.65 (95% CI; 1.90, 7.01)), achieved by 77% of the patients, and RPE>17 (OR = 13.42 (95% CI; 6.89, 26.16)), achieved by 85% of the patients, were significantly associated ($p<0.001$) with test-leaders' evaluation with respect to whether the test was acceptable or not, adjusted for age, diagnosis anv VO2max. Fulfilling the criteria of O2 plateau (85% of the patients) or >85% of HRmax (92% of the patients) was not significantly associated with test-leaders' evaluation. Mean VO2max among the individuals fulfilling both the RER and the RPE criteria (n=359) were significantly ($p<0.001$) higher compared to individuals not fulfilling both criteria (n=169); 31 (95% CI; 30, 32) ml/kg/min vs. 27 (95% CI; 26, 28) ml/kg/min.
CONCLUSION: There are several possible challenges in defining the O2 plateau using different test protocols and the phenomenon is broadly discussed in the literature. Furthermore, estimating HRmax based on age is also a known challenge due to high inter-subject variability. The choice of using the test-leaders' subjective evaluation as the dependent variable, may additionally be subject for discussion. However, we conclude that when VO2max testing are performed in patients with cancer, the end criteria RER and RPE seems more important to assess, than HRmax and O2 plateau, in relation to the test-leaders' evaluation whether a test is accepted or not.

SIX WEEKS OF ENDURANCE TRAINING MODULATE MYELOID DERIVED SUPPRESSOR CELLS (MDSC) IN GASTROINTESTINAL CANCER PATIENTS

PESSOA, A.F.M., SEELAENDER, M., STONE, S.C., GALVÃO, R., RADLOFF, K., ROSA, J.C., MURARI, A.S., LEME, P., MATOS-NETO, E., ANDRADE, L., MARINHO, R., LIMA, J., SIMÕES, E., FORMIGA, F., CHIA BIN, F.

UNIVERSITY OF SÃO PAULO

INTRODUCTION: There is evidence that regular physical exercise reduces the incidence and recurrence of cancer, and also presents beneficial effects for cancer patients under treatment. Such effects are partly attributed to stimulation of the immune system by chronic exercise, but the mechanisms are not yet completely elucidated. Cancer progression and comorbidities, such as cachexia, are robustly associated with chronic systemic and local inflammation, and endurance training has been shown to exert anti-inflammatory effects (1,2). Circulating MDSCs (Myeloid Derived Suppressor Cells) and chemokines play a prominent role in determining immune/inflammatory profile, however the role they play in gastrointestinal cancer systemic consequences are unknown. Aim: To assess MDSCs, cytokine and chemokine profile in the circulation of cancer patients and to investigate the capacity of 6 weeks endurance exercise to modulate these parameters.
METHODS: Four gastrointestinal cancer patients (GCP) in cancer stage II or III were recruited into the study approved by the University of São Paulo Biomedical Sciences Institute (CEP 788/07) and University Hospital Ethics Committee (CEP 752/07, SISNEP CAAE:0031.0.198.019.07); Clinical Trial (U1111-1140-7773). Informed consent was obtained from the participants. Patients walked on a treadmill (progressively attaining higher intensity -up to 60% VO2 max, 20-40 min), 5 days a week in the preoperative phase for 6 weeks. Blood samples were collected at three time points, 1st (baseline), 3rd and 6th week of training to evaluate protein expression of TNF- α; CCL2, CCL-3 and CXCL-10 by (Multiplex Magpix®) and MDSCs (flow cytometry BD FACSCanto II). All recruited patients were able to complete the protocol.
RESULTS: the trained showed changes in the circulating MDSC phenotype, increased MDSC-INTER (CD33+/CD11b-low) and decrease MDSC-HIGH (CD33+/CD11b-high) populations. At baseline (1st week), a positive correlation between the inflammatory cytokine TNF- α (p=0.042) and MDSCs was observed, while the correlation of the number of circulating MDSCs and the concentration of the antitumoral cytokine CXCL-10 (p=0.01) was negative. Training interfered with these correlations already at week 3. Serum levels of the immune cell recruiting proteins CCL2 and CCL3 were higher, and CXCL10 concentration lower at baseline, when compared to the 3rd and 6th week of training.
CONCLUSION: The results demonstrated that the 6-week physical training protocol was able to induce changes in systemic inflammatory parameters such as MDSC phenotypes. Therefore, although the number of patients is small, we may suggest that preoperative endurance exercise is safe and elicits beneficial effects on systemic inflammation in gastrointestinal cancer patients.

COMPARATIVE ANALYSIS OF THE EFFECTS OF REGULAR EXERCISE ON IMMUNOREGULATORY AND COGNITIVE ABILITIES IN YOUNG AND ELDERLY ADULTS

BALOGH, L., MAKRA, G., DONKA, D., PUCSOK, M., BACSNE BABA, E., KISS, B., CSIKI, Z., NAGY, A., PAPP, G.

UNIVERSITY OF DEBRECEN

INTRODUCTION: Many studies prove the effect of regular exercise on health through positive psycho-physiological effects. Physical activity is related to cognitive abilities. Our review of the literature (Makra, Balogh 2018) found this connection, which includes 150 research papers. Physical activity, based on international literture datas, can significantly affect the function and function of the immune system (Robson-Ansley P et al., 2012; Kruijsen-Jaarsma M et al., 2013). Our hypothesis are those that there are no significant changes in the effects of regular exercise on the immune system (1) and cognitive abilities (2) at a young adult age, due to the little elapsed time. However, the more time it takes physically inactive, the greater the weakness of the immune system and the decline in cognitive abilities.
METHODS: In our study according to a holistic approach, we compared young adults and elderly adults with regurarly exercise and non exercise, examined the immunregulatory and cognitive abilities together. Our main goal is to prove the lifelong role of regular exercise based on the examination of two major systems that determine the quality of life, the immune system and the nervous system. We led 10 week exercise program for non-athlete young and eldery adults to examintaion the differences between immunregulation system and cognitive abilities.
The examinations were conducted with a TUKEB-approved (Hungarian Science Research Ethical Committee) ethics license and consent statement. There were 4 groups in our longitudinal research, athlete and non-athlete young adults (18-23 years of age, n=19) and athlete and non-athlete 60+ age (n=18) groups as focus group. We collected the data at the beginning and end of the research program. We used blood plasma to test the immune-regulating effect of regular exercise (lymphocyte subgroups, monoclonal antibodies, T cell activation marker, regulatory T cells and naive and memory B cells). For meausering cognitive abilities we used the Vienna Test System (VTS, COG/S8 and LVT/S2 tests).
RESULTS: None of the examined lymphocyte subgroups and cognitive abilities showed a significant difference between the athlete and non-athlete in youngs. The blood test after exercise program in the elderly adult group showed siginificant differences in several lymphocyte subgroups.Those elderly adults who regularly perform physical activity achieved better results in the two tests, the COG/S8 and the LVT/S2.
CONCLUSION: We found that the regular exercise in older age can lead to significant changes within immunregulation system after just 6 weeks (1), a difference between cognitive tests for athlete and non-athletic groups in older age (2).We did not find significant differences in the immunregulation system (3) and in cognitive tests (4) in young adults between the athlete and non-athlete group. We would like to take further examinations to provide the most accurate and comprehensive results possible. Exercise is a lifelong medicine for our two major system.

CHARACTERISTICS OF SPRINT RUNNING WITH THE HORIZONTAL RESISTED LOADS

KITANO, Y.1, MAKINO, A.1, ARAI, A.2, KUNIMASA, Y.1, SANO, K.3,4, ISHIKAWA, M.1

1: OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES, JAPAN, 2: DOSHISHA UNIVERSITY, KYOTO, JAPAN, 3: MORINOMIYA UNIVERSITY OF MEDICAL SCIENCES, OSAKA, JAPAN, 4: RITSUMEIKAN UNIVERSITY, SHIGA, JAPAN

INTRODUCTION: Improving acceleration and maximal velocity of sprint running are important for sprint runners. Resisted sprint running (RSR) with horizontal overloads are frequently used to enhance sprint ability by overloading the neuromuscular and physiological systems. Several studies reported that great resistance loads with forward body lean and long contact time could be used for the acceleration phase training and light loads for the maximal velocity phase training (1,2). However, limited researches have been undertaken on the kinematic, kinetic, and EMG changes across the different resisted loads for improving sprint running performance. Therefore, the purpose of the present study was to examine changes of muscle activation during sprint running with different resisted loads.
METHODS: Ten sprint runners participated in this study. They run at 30 km h-1 on the force-plate mounted treadmill with 4 different resisted loaded conditions (9.81, 58.86, 88.29 N and non-resisted conditions). A composite fiber cord is attached to the robotic resistance motor device (1080 Sprint, 1080 Motion, Lidingö, Sweden) and participant's waist belt. Muscle activities were measured with surface electromyography for the following muscles: gluteus maximus (GM), musculus iliopsoas (MI), tensor fasciae latae (TFL), adductor longus (ADD), semitendinous (ST), biceps femoris (BF), vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), gastrocnemius medialis (MG), gastrocnemius lateralis (LG), soleus (SOL) and tibialis anterior (TA) muscles. Kinematics of the sagittal plane were measured with high-speed camera together with ground reaction forces.
RESULTS: With increasing resisted loads, the stride frequency was increased and the stride length was decreased. In muscle activation profiles, muscle activities during the contact phase generally increased with increasing the resisted loads. In addition, the muscle activities of GM, ADD, TFL, MG, SOL and TA muscles during the swing phase increased with increasing the resisted loads. With increasing the resisted loads, the ankle joint angles shifted to the dorsiflexed position and the changes of the ankle and knee joint flexions during the braking phase were decreased.
CONCLUSION: Our results showed that even fast RSR, the horizontal high overloads can provide highly specific stimulations for improving muscle activities and movements of the maximal velocity phase of sprint running. Especially, the horizontal high RSR can be beneficial to improve the step frequency with specific muscle activations for maximal velocity training.

PERFORMANCE DETERMINANTS IN SPRINTING: EFFECTS OF FREQUENCY, JUMP AND STRENGTH ON SPEED IN ADOLESCENT TRACK AND FIELD ATHLETES

SPANCKEN, S., HOFFMANN, M., STEIN, T., KURZ, G.

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: The ability of fast running determines performance not only in sprint, but across many disciplines of track and field. Therefore, a multitude of studies examined the correlations between various parameters and sprint performance in adult athletes (1,2). However, to our knowledge there is no systematic performance diagnosis yielding a comprehensive model on specific factors influencing sprint performance in adolescence. This is critical as systematic performance diagnoses enable a tailored selection of suitable training tools for performance enhancement, training control and the prediction of sprint outcomes based on individual abilities of athletes (e.g., maximum leg strength). Therefore, we aimed to systematically investigate performance determinants in adolescent track and field athletes.
METHODS: The sample comprised 20 track and field athletes (f=12, m=8) aged 14.13±1.57 years. All subjects completed maximum sprints over 30m from starting blocks and 20m-flying sprints with a 20m acceleration phase. Starting blocks were instrumented with strain gauges (1000Hz) to record reaction forces. Time measurement was conducted using light barriers (TAG Heuer) placed on the starting line, 10m-, 20m- and 30m-mark. Furthermore, a sports-specific frequency test (with reduced step length), counter-movement-jump and drop-jump (DJ) on force plates (AMTI, 1000Hz), standing long jump (SLJ), 5-bound test and maximum isometric force assessment were performed. We applied step-wise regression analyses (method: backward) and set the alpha level to 0.05.
RESULTS: Three out of six parameters significantly predicted the 10m sprint time from starting blocks: front block maximal horizontal force (Fmaxh) (b=-0.001, p<0.01) and vertical impulse (b=-0.001, p=0.041) as well as peak isometric flexion force of the left leg (b=-0.001, p<0.01). In sum, all parameters explained 92.6% variance in 10m sprint performance from starting blocks. Three out of five parameters significantly predicted the 30m sprint time from starting blocks: front block Fmaxh (b=-0.002, p<0.01) and vertical impulse (b=0.002, p=0.02) as well as the frequency capability (0-20m) (b=-0.593, p=0.03). Aggregated, all parameters explained 91.6% variance in 30m sprint performance from starting blocks. Two out of four parameters significantly predicted the 20m-flying sprint time: SLJ performance (b=-0.971, p<0.01) and maximum force gradient at the DJ (b=-0.000383, p<0.01). Altogether, all parameters explained 80.2% variance in 20m-flying sprint performance.
CONCLUSION: Results suggest that junior training should focus on the horizontal push-off phase and jumping power, explosive power as well as frequency capability and maximum hamstrings strength. Thus, our study provides both practical training implications and a first important step for future research endeavors tackling a comprehensive sprint performance model for young athletes.

THE SEVEN STEPS APPROACH ON 110M HURDLES ENHANCE THE PERFORMANCE AFTER APPROACH PHASE

RYO, I., SUSUMU, S., HIRONARI, S.

TOKYO GAKUGEI UNIVERSITY

INTRODUCTION: The approach phase on 110m hurdles which is from start to first hurdle is important for win the race (1). Recently, many hurdlers use the seven steps approach that is one smaller than the conventional eight steps approach. However, no research focused this new approach has been reported. This study aimed to clarify the advantage of the new seven steps approach by training experiment.
METHODS: One male hurdler who usually used eight steps was participated in this study (age: 23, height:1.72 m, body mass: 63.5 kg, PB: 14.88 sec). Subject performed 60m hurdles test (60mH) with eight steps and that of inexperienced seven steps as pre-test. After that, seven steps training was carried out 45 times, and subject performed 60mH with seven steps per 15 times training. Each test was conducted 5 times. Based on the hypothesis that the change of performance will appears in approach phase due to the reduction of approach step, we recorded approach phase motion by three high-speed cameras (120fps). Approach time, 60mH time, lower limb joint angle and angular velocity on approach phase were obtained. These parameters among pre and post tests were compared by the Tukey's test ($P<0.05$)
RESULTS: Approach time of seven and eight steps were much the same, however, 60mH time on trained seven steps was shorter than that of eight steps [8.86 ± 0.03 vs 9.09 ± 0.10 sec, $P<0.05$]. This means seven steps approach heighten the performance after 1st hurdle. In comparison to the eight steps, close distance between hip and toe, which leads to shorten the braking phase during the landing, was observed in seven steps. It seems that this motion was due to more extension of hip and knee joint at the instance of landing, and consequently the running velocity just after landing of seven steps was higher than that of eight steps. To support these results, we analyzed a Japanese top hurdler's races of his seven and eight steps approach season (2). As a result, approach time of these two step types was almost same, while the running speed from 4th to 6th hurdle of the seven steps was higher than that of eight steps [8.60 ± 0.09 vs 8.47 ±0.09 m/s, $P<0.05$].
CONCLUSION: The seven steps approach did not improve the approach phase, however, made it possible for the hurdler to enhance the running speed after 1st hurdle landing and shortening the 60mH time.

DOSE-RESPONSE RELATIONSHIP BETWEEN RUNNING TRAINING AND BODY-MASS – EPIDEMIOLOGIC SURVEY OF EXPERIENCED RUNNERS AGED 30 TO 60 YEARS

RÜTHER, T.1, WITZKI, A.2, ROHDE, U.2, SCHOMAKER, R.3, LÖLLGEN, H.4, LEYK, D.1,2

1 GERMAN SPORT UNIVERSITY COLOGNE 2 BUNDESWEHR INSTITUTE OF PREVENTIVE MEDICINE 3 CENTRE OF SPORTS MEDICINE MÜNSTER 4 EFSMA

INTRODUCTION: Endurance training is associated with considerable preventive health effects (1). Reduction and control of body weight are relevant factors of prevention and frequently stated motives for exercise (2). Main topic of the current study is the examination of a potential dose-response-relationship between running training and body-mass in experienced runners.
METHODS: As one part of a nationwide survey (www.dshs-koeln.de/med-pace) of sporting activities, runners registering for one of the running events of the German-Road Races e.V. also complete an online health check (modified PAR-Q). The survey additionally collects anthropometric data (e.g. body-mass, BMI), and training specifics (e.g. volume, frequency, intensity, history) using a scaled questionnaire. We analyzed the cross-sectional data of a sub-sample of survey participants, aged 30 to 60 years, who have been actively and regularly running and training for 5 years or more. Statistics were performed using ANOVA and regression analysis.
RESULTS: Data of 41757 male (45.8±7.8 years; 80.1±9.8 kg; BMI 24.5±2.4) and 17713 female runners (44.5±7.7 years; 63.0±9.0 kg; BMI 22.3±2.7) were included. Mean training history was 13.9±8.5 (male) and 12.1±6.8 (female) years respectively. Mean weekly running distance amounted to 32.6±19.6 km (male) and 27.8±16.9 km (female) respectively ($p<0.001$). Mean Body weight and BMI are inversely correlated with mean weekly running volume (male: $r=-0.21$ and $r=-0.22$; female: $r=-0.22$ and $r=-0.23$). Body weight and BMI show finely grained reductions ($p<0.001$) with increased training volume and in groups matched by training volume (km). The regression coefficient ß of body weight per kilometer run is -0.115 kg (male) and -0.111 kg (female) respectively (each $p<0.001$). Female groups running more than 50 km per week show a stagnation of BMI.
CONCLUSION: The association between training volume and body mass indicates a systematic, mostly linear dose-response relationship. A ceiling effect can be observed in female runners with higher training volumes. Although a direct causal link cannot be ascertained due to the methodological limitations of the study design, the results strongly suggest lasting effects of running training on body mass. In view of bodymass- related risk factors as well as cardiovascular and metabolic diseases the results show the great protective potential of regular endurance training. References 1. Leyk et al. THERMOGRAPHIC IMAGES OF WARMING UP, INCREMENTAL EXERCISE TO EXHAUSTION ON A TREADMILL AND A RUNNING COOLING DOWN OF NON-PROFESSIONAL MIDDLE-AGED MALE RUNNERS

GUADALUPE GRAU, A., ESCOBAR-TOLEDO, D., RUEDA, J., CALONGE-PASCUAL, S., WANG, S., SILLERO, M., TORRES-PERALTA, R., GONZÁLEZ-GROSS, M.

FACULTY OF PHYSICAL ACTIVITY AND SPORT-INEF, UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Infrared Thermographic (IRT) is a non-invasive method to assess skin temperature (Tsk), which has been improved recently (1). The use of automatic tools of image processing seems to be critical for the acceptance of this technique in both medicine (2) and sports (3). There is a high correlation between Tsk and some chronic diseases (4). This work analyzes the expected Tsk response to a complete running exercise to exhaustion.
METHODS: 33 middle-aged recreational male runners (48±4y.; 174.8 ±4.3cm; 77.3±9.5kg; 20.3±6.6%fatmass; 4207.4±357.8ml of VO2max) were recruited in track and field clubs. They accepted to undergo an incremental ergoespirometry until exhaustion on a treadmill (IE) between two running biomechanics (RB) analysis on the same evening. The RB consisted of jogging for a distance (20mx50) at a

fixed pace and were used as warm-up and cool-down exercises. Seven Infrared Thermographic (IRT) images were taken in basal condition, prior to and after each test. Data were analyzed using one-way ANOVAs.
RESULTS: Similar Tsk tendencies were obtained on all the analyzed regions of interest (ROI) of both legs. After the warm-up, Tsk decreased significantly on both calfs, and on both posterior and anterior views of the knee ($p<0.05$). Meanwhile, the heterogeneity of the signal increased compared to baseline in all tests. Tsk returned to previous baseline Tsk before IE in all areas. After the IE, Tsk had a non-significant decrease, together with an increase in heterogeneity of Tsk in most of ROIs ($p<0.05$). During cool-down, the Tsk continued decreasing to minimum values of the testing session.
CONCLUSION: We provide reference data on the Tsk profile during the warm-up, IE and cool-down under laboratory conditions.

EVALUATION OF AN INTENSIVE VERSUS EXTENSIVE HALF-MARATHON SCHEDULE TRAINING FOR MIDDLE-AGED AMATEUR FEMALE RUNNERS

BONET, J.B., TORRELLA, J.R., MAGALHÃES, J., VISCOR, G., PAGÈS, T., JAVIERRE, C.

UNIVERSITY OF BARCELONA

INTRODUCTION: Half-marathon running is a common challenge for amateur runners, with remarkable increases in the participation of senior runners and women. Several training schedules are available, even for master sport practitioners, but most are extensive schedules (EX) involving high training volumes in km/wk. To induce a lower level of mechanical and/or physiological stress, and favour conciliation of training and daily life, we designed an intensive schedule (IN), with higher loads and lower running volumes, to be applied in female recreational master runners.
METHODS: Twenty women recreational runners (40±6 yr) followed an extensive (EX) or intensive (IN) training schedule (3 sessions/wk, 12 wk). EX group trained a mean of 31±4 km/wk at an intensity below 80% VO2max. IN group run 25±5 km/wk (80-100% VO2max) combined with uphill running and resistance training circuits. All women were evaluated at the beginning and at the end of the training schedules for running power, rhythm in the long run, ratio of perceived exertion (RPE) and with a maximal UMTT test (1) where VO2, heart rate (HR), and ventilatory parameters were monitored until 6 min of recovery. At the end of the training period, all women participated in the same half-marathon run.
RESULTS: Both EX and IN groups decreased by 3% their previous finishing times in completing a half-marathon, not registering significant differences between the groups. The developed power (w) after running 400m by IN group increased from an 190±16 to 227±19 ($p<.001$) without changes in RPE ($p=.347$). In contrast, EXT group did not showed an increase in running power after 800m (210±27 vs 211±28, $p=.878$) with an almost significant increase in RPE ($p=.068$). Neither the rhythm of the long running nor RPE significantly changed after both training schedules. The physiological registers obtained after the maximal test for the IN group from 3- to 6-min recovery showed significant reductions (ranging from 18 to 21%) in VO2 and respiratory minute volume (VE). In contrast, the 8 to 13 % decrease obtained in EX group were not significant. Moreover, IN group registered a baseline decrease in HR of 14% ($p=.001$) contrasting the not significant 6% decrease in EX group ($p=.395$).
CONCLUSION: Runners following an IN training improved running power without increasing perceived exertion, had better recovery from a maximal test and decreased their basal HR, which could improve their aerobic power. Regarding to finishing times, IN training obtained similar registers as a traditional EX schedule, investing less time and running less distance. The findings of the present study provide preliminary evidence to suggest that an intensive vs extensive training schedule may provide an alternative model for half marathon training in female recreational master runners.

VALIDATION OF SELF-PACED TRACK-TEST ALLOWING TO REACH AND TO ESTIMATE VO2MAX FROM SUBMAXIMAL SPEED

MOLINARI, C., PALACIN, F., POINSARD, L., KORALSZTEIN, J.P., BESSE, S., BILLAT, V.

UNIVERSITÉ EVRY VAL DESSONNE

INTRODUCTION: In treadmill running, $\dot{V}O2max$ is not altered by self-pacing during incremental exercise (1,2). The self-pace $\dot{V}O2max$ protocol (SPV) produces maximum oxygen consumption ($\dot{V}O2max$) values similar to those obtained in a standard graded exercise test (GXT) and may represent a more appropriate and athlete-friendly test that is more oriented toward the variable speed found in competitive sport (3). Indeed, despite a speed variation during middle distance races (800-1500m), VO2max plateaued during the entire race (4). The present study sought to ascertain whether these observations would also be apparent for running in field condition in which the runners were only aware to run at light, somewhat hard and very hard rate of perceived exertion of Borgs scale (RPE 11, 14 and 17, respectively). Therefore, the specific aim of this study was to validate a self-paced track-test allowing not only measuring VO2max but also to it from the self-pace submaximal speeds at Rating of Perceived Exertion (RPE) 11 and 14.
METHODS: On that purpose, 12 runners (8 men, 4 women, age = 43 ± 8 years, weight = 69 ± 12 kg, height = 1.74 ± 0.9 m), were asked to perform one University of Montreal Track Test (UMTT) to get $\dot{V}O2max$ and then, in random order, to perform two SPV at 4 days of interval. During the SPV, the runners ran 10 minutes at RPE 11 (Light), followed by 5 minutes at RPE 14 (Somewhat Hard) and finally 3 minutes at RPE 17 (Very hard). Exercise protocol: Three exercises tests for determination of $\dot{V}O2max$ (1 UMTT and 2 SPV), . SPV test included 3 stages lasting 10, 5, 3 min at RPE 11, 14 and 17 (Borg's 6–20 scale) with 1 min of rest was clamped. Using this design, subjects could vary their pace according to the RPE required at each stage. For all the tests, oxygen uptake with a portable gas exchange analyser (K5®, Cosmed, Roma, Italy), heart rate and speed (HRM-RUN, Garmin, Kansas, United-Sates) were recorded for the duration of the testing protocol. Heart rate and speed data was transmitted and registered by the K5 to be coupled on the breath-by-breath.
RESULTS: Results showed that Self-pace $\dot{V}O2max$ test (SPV) allow runner to reach $\dot{V}O2max$ plateau in a set of speed at RPE 17 in a reproducible way (SPV1 = 53.9 ± 6.4 and SPV2 = 56.4 ± 9.1, $p = 0.43$). Furthermore, the speeds at RPE 11, and 14 (67 ± 9 and 84 ± 8% of the average speeds of RPE 17) allowed to predict VO2max ($r = 0.57$ and 0.52, $p<0.01$).

CONCLUSION: On the field, runners self-paced their speeds allowing them to reach v̇O2max and even to estimate it from their submaximal RPE 11 and 14 speeds.

THE RELATIONSHIP OF AGE AND PERFORMANCE WITH NEUROMUSCULAR FITNESS OF RECREATIONAL RUNNERS: THE PARADIGM OF ATHENS CLASSIC MARATHON

BARBAS, A., TASSIOPOULOS, I., TORRES-LUQUE, G., KNECHTLE, B., NIKOLAIDIS, P.T.

UNIVERSITY OF STRASBOURG, FRANCE

INTRODUCTION: Most studies on marathon runners focused on physiological parameters determining performance (1, 2), whereas neuromuscular aspects, such as muscle strength and flexibility, received less attention. Thus, the aim of the present study was to examine the relationship of age and performance with muscle strength and flexibility of recreational marathon runners.
METHODS: Men marathon runners (n=130, age 44.1±8.6 years, height 176±6 cm, body mass 77±9 body mass index 24.7±2.6 kg.m-2 and race speed 10.29±1.87 km/h), separated into eight age groups (<30, 30-35, ..., 55-60, >60 years), performed sit-and-reach test (SAR), squat (SJ) and countermovement jump (CMJ), and four isometric muscle strength tests (right and left handgrip, trunk and legs) providing an index of overall muscle isometric strength in absolute (kg) and relative to body mass values (kg.kg-1 body mass). In addition, all participants in the present study finished the Athens Classic Marathon (2017) four weeks after the exercise testing session and the race speed was used as an index of performance.
RESULTS: SAR was 17.6±8.5 cm, SJ 24.3±4.2 cm, CMJ 25.8±4.8 cm, absolute strength 386±59 kg and relative strength 5.06±0.78 kg/kg of body mass. The older age groups had the lowest scores in SJ ($p<0.001$, $\eta p2=0.298$) and CMJ ($p<0.001$, $\eta p2=0.304$), whereas no age-related difference in SAR ($p=0.908$, $\eta p2=0.022$), absolute ($p=0.622$, $\eta p2=0.042$) and relative isometric strength ($p=0.435$, $\eta p2=0.055$) was shown. Race speed correlated moderately with relative isometric strength ($r=0.42$, $p<0.001$), but not with the other neuromuscular measures ($r<0.14$, $p>0.013$).
CONCLUSION: Recreational male marathon runners were characterized by low levels of flexibility and isometric muscle strength, and this might partially explain the lack of age differences for most of the parameters. Although these parameters - except relative strength - did not relate to sport performance, they were components of health-related physical fitness. Consequently, coaches and runners should include exercises focusing on flexibility and muscle strength in their weekly program.

THE APPLICATION OF WEARABLE SMART DEVICE ON THE EVALUATION OF RUNNING ECONOMICS IN DISTANCE RUNNERS

WU, C., WANG, W., CHOU, T., CHANG, Y.

1. CHENG SHIU UNIVERSITY 2. UNIVERSITY OF TAIPEI 3. NATIONAL TAIWAN SPORTS UNIVERSITY

INTRODUCTION: Smart wearable sports devices are popular In recent years, and related running technologies can be controlled and monitoring by the three-axis accelerometers such as foot stance time (FST), body vertical oscillation (vertical oscillation, BVO) and other related factors. Therefore, the purpose of this study was to investigate the difference of the SF, FST and VO and the velocity of maximum oxygen consumption (vVO2max) between elite and amateur distance runners, with GARMIN 920XT sports training device.
METHODS: we recruiting seven professional runners (VO2max:64.98±3.51ml/kg/min) and seven amateur runners (VO2max:52.49±3.80ml/kg/min) to participate in this study, all subjects had to complete two times modified Bruce treadmill running tests, 920XT had been attached on the chest of all subjects during the incremental tests to exhaustion. One way ANCOVA statistic method was used to analyze the differences between groups and relationships among upon variances.
RESULTS: Professional runners had higher BVO than amateur runners (mean ± SE: 99.95 ± 1.74, 92.51 ± 1.75, $F = 9.109$, $p < .05$), during the vVO2max stage; however, professional runners shown lower FST time than amateur runners (mean ± SE: 192.93 ± 2.62, 213.40 ± 2.67, $F = 29.99$, $p < .05$).
CONCLUSION: When sprinting with vVO2max in the second trial, professional runners showed the shorter the FST time, strengthen the foot toe off, and increasing the stride length and stride frequency to maintain the high speed, resulting in the increase of BVO. In contrast, amateur runner maybe lack of muscle strength of the lower extremity, so that in the final sprint stage, resulting in the longer FST, reducing the running efficiency. We suggested that the following study may be conducted in the lower limb muscle strength and foot push force in the future.

CP-MI05 Training and testing IV

THE RELATIVE AGE EFFECT IN HANDBALL: ITS EXISTENCE AND INFLUENCE ON PLAYING POSITION FOR YOUTH AND JUNIOR TEAMS

ALSHARJI, K.

COLLEGE OF BASIC EDUCATION

Introduction:Termed the "relative age effect" (RAE), the difference in age between athletes in the same age group has been found to be a significant determinant for success (Helsen et al., 2012). Previous literature has demonstrated that RAE exists in team handball (Rivilla-García et al., 2012), but RAE studies in Asian handball, especially at the national level, are lacking. Therefore, this study aims to determine the existence of RAE in Asian national handball teams for youth and junior levels as well as to analyze the impact of RAE on playing positions.
Method:To evaluate the prevalence of the RAE in Asian handball a dataset was obtained from the Asian handball federation (AHF). The dataset included date of birth and playing positions, as well as height, weight, and BMI for all players. The sample consisted of male (n =

446) youth (U18 = 281) and junior (U20 = 165) national players from 15 Asian countries (i.e., Bahrain, Iran, Iraq, Saudi Arabia, Syria, Lebanon, Jordan, Oman, UAE, Qatar, India, S. Korea, N. Korea, Japan, China, China Tipi, and Yamen) that participated in the 8th Asian Men's Youth Championship 2018 and the 16th Asian Men's Junior Championship 2018. In Asian Handball Championships, the cut-off date for youth and junior levels is January 1st. Thus, the players were categorized into four relative age quarters (Q) according to their birth month (i.e., Q1 = January to March; Q2 = April to June; Q3: July to September; and Q4: October to December). For playing positions, left- and right-wing players were categorized as wings and left-back, right-back, center-back players were categorized as backs due to the similarities in their characteristics and roles in the game. Statistical analyses were completed via SPSS 25.0 software (Armonk, NY). A Chi-square goodness-of-fit test (x2) was computed to evaluate whether there was a skewed birthdate distribution in selection to Asian national youth and junior handball teams, and in selection to playing positions. Statistical significance level was set at $p = 0.05$.
Results & Discussion:There was significant RAE for the Asian national handball players, as 39% of players were born in Q1; 39% of youth players were born in Q1; and 38% of junior players born in Q1.
In addition, for Asian national players, goalkeepers ($p = .03$), backs ($p < .001$), and wings ($p = .014$), were significantly affected by RAE. For youth teams, backs ($p = .001$) and wings ($p = .002$) were significantly affected by RAE. For junior goalkeepers ($p = .018$) and backs ($p = .014$) were significantly affected by RAE. The most reasonable explanation for the existence of RAE in Asian handball is the processes of selection and identification which strongly influenced by the two year band grouping system structured by local federations. Thus, most local teams, aiming to win local competitions, focus on kids who mature early and exhibit greater physical characteristics without giving attention to maturational status of those kids.

NEUROMUSCULAR ACTIVATION PATTERN OF LOWER EXTREMITY MUSCLES IN CYCLISTS WITH SINGLE AMPUTATION OF LEG DURING PEDALING AT VARIOUS WORKLOADS

WATANABE, K.1, YAMAGUCHI, Y.2, FUKUDA, W.3, NAKAZAWA, S.2, KENJO, T.4, NISHIYAMA, T.2

1 CHUKYO UNIVERSITY, 2 NIPPON SPORTS SCIENCE UNIVERSITY, 3 YOKOHAMA SPORTS MEDICAL CENTER, 4 JAPAN PARA-CYCLING FEDERATION

INTRODUCTION: Since neuromuscular coordination among lower extremity muscles would be different between pedaling movements on a bicycle by one leg and two legs, training regimen to improve pedaling performance in cyclists with one leg may not be comparable with cyclists with two legs. The present study aimed to clarify neuromuscular activation pattern of lower extremity muscles in cyclists with single amputation of leg during pedaling. We hypothesized that cyclists with single leg use additional neuromuscular activation in hip and knee flexor muscles during pulling phase for compensation of an absence of muscular forces from hip and/or knee extensor muscles in contralateral leg.
METHODS: Two cyclists with single amputation of leg (CS) and one cyclist with two legs (CT) performed pedaling exercise on a bicycle ergometer at workloads of 65%, 80%, and 95% of maximal oxygen consumption. During exercise, surface electromyography (EMG) were recorded from vastus lateralis (VL), biceps femoris (BF), medial gastrocnemius (MG), and tibialis anterior (TA) muscles and crank angle data was synchronized with them for further analysis (Watanabe et al. 2015 J Sport Sci). Also, surface EMG of rectus femoris muscle was recorded from proximal and distal regions of rectus femoris muscle (RFp and RFd), since RFp could be used to assess contribution to hip flexion joint moment (Watanabe et al. 2015 Muscle Nerve).
RESULTS: In VL, EMG amplitude increased with an increase in workload in CT and CS. Increases in EMG amplitude in BF and MG during pulling phase was demonstrated only in CS. Increases in EMG amplitude with an increase in workload were found in RFp and RFd in CT but not in CS.
CONCLUSION: These results suggest that cyclists with single amputation of leg manifest characteristic neuromuscular activation patterns during pulling phase which may contributes to knee flexion joint moments.

ISO-INERTIAL ECCENTRIC-OVERLOAD TRAINING IN YOUNG SOCCER PLAYERS: EFFECTS ON STRENGTH, SPRINT, CHANGE OF DIRECTION PERFORMANCE AND SOCCER SHOOTING PRECISION

BUONSENSO, A., FIORILLI, G., IULIANO, E., INTRIERI, M., DI CAGNO, A., CALCAGNO, G.

UNIVERSITÀ DEGLI STUDI DEL MOLISE

INTRODUCTION: The iso-inertial training method owes its efficacy to an accommodated resistance and optimal individualized eccentric overload. The aim of this study was to assess the effects on explosive and reactive strength, sprint, change of direction (COD) performance and soccer shooting precision of a 6-week iso-inertial eccentric-overload training program using a flywheel device.
METHODS: Thirty-four junior soccer players were randomly assigned to the Control Group (CG; n = 16, aged 13.36 ± 0.80), who underwent a six-week traditional soccer training program, and the Experimental Group (EG; n = 18, aged 13.21 ± 1.21) who received an additional training based on two inertial eccentric-overload training sessions per week. Pre and post intervention testing sessions were performed to assess explosive and reactive strength, sprint ability, COD ability, and soccer shooting precision.
RESULTS: EG showed significantly higher values than CG in Squat Jump height (SJ_h) ($p = 0.01$), Drop Jump height (DJ_h) ($p = 0.003$), Hopping test height (HOPP_h) ($p = 0.001$), Illinois test (ILL) ($p = 0.001$), and soccer shooting precision (SHOT) ($p = 0.019$). Finally, there were significant interactions time*groups in DJ_h ($p = 0.007$), ILL ($p = 0.0002$), YTest (YT) ($p = 0.002$), SPRINT ($p = 0.001$), and SHOT ($p = 0.003$).
CONCLUSION: These results confirmed the positive effect of iso-inertial training. The possibility of iso-inertial device to overload multidirectional movements in specific sport conditions, leads to higher performance improvements than a conventional soccer training. The absence of knowledge of the eccentric overload applied by the iso-inertial device, which is different in any exercise repetition, may have improved the coordinative skills and in particular the soccer shooting precision.

LONGITUDINAL CHANGES IN 2000-METRE ROWING PERFORMANCE OF OLYMPIC MEDALLISTS. FROM ENTRY TO ELITE LEVEL

MÄESTU, J., MIKULIC, P., MÄESTU, E., LELLE, R.
UNIVERSITY OF TARTU, UNIVERSITY OF ZAGREB

INTRODUCTION: The longitudinal changes of the physiology of the Olympic medal winners give the coaches and athletes and important information regarding long-term development of the performance and the physiological demand to be the potential medal winner at the highest level. Recently, Mikulic (2011) demonstrated 6-year changes in performance and physiology of the World Champion medal winner crew. However, there is limited information available of the specific performance of the true elites from the beginning of their career until reaching and performing at the elite level. The aim of the current study was to describe and analyse the specific 2000-metre rowing ergometer performance of Olympic medal winners during their career.
METHODS: 10 male (height 190.15.3 cm, weight 94.45.8 kg) Olympic medal winners in rowing were the participants of the current longitudinal retrospective study. The subjects were from Estonia and Croatia and were competing in the Olympics in double sculls or quadruple four. All subjects were studied for their personal best 2000-meter time on Concept II rowing ergometer annually from the age of 14 until the age 27. The results were recorded either from the results from the National championships or asked from their coaches if the subjects had missed the championships. 3 subjects missed the data from 14 and 15 years of age.
RESULTS: The 2000-metre rowing ergometer performance times increased significantly until the age of 21 and plateaued afterwards without any significant change. However, there was still a 4 second improvement by the age of 23 (from 361.77.5 to 355.47.2 sec; $p>0.05$). Our results indicate about 5% improvement in 2000 m rowing ergometer performance, which could be expected from junior age to elite level where performance should be at least in the range of 5:50 to 5:57 to have the physiological potential for winning the medals at the international championships in double or quadruple sculls.
CONCLUSION: Our results indicate the average 2000-meter rowing ergometer performance development from 10 Olympic medal winners from the start of their career until winning the medals. Those results help the coaches to detect potential talents by comparing their performance to the medal winners and predict their potential for future performance development.

INFLUENCE OF TRAJECTORIES IN PHYSIOLOGICAL PARAMETERS DURING RUNNING

REZENDE, T.M.1, BALDISSERA, V.2, MARTINS, L.E.B.1, BORIN, J.P.1
1 -UNICAMP; 2 - UFSCAR

INTRODUCTION: Collective sports modalities have specific characteristics of movements due to the players dynamic interactions with teammates and opponents. During a match these interactions result in an elevated number of changes of directions as well as in displacement in different trajectories, using straight or curved maneuvers (1). A number of studies that evaluated the changes of directions show that the speed and frequency in which they occur can directly influence the increase of effort when compared with displacements in continuous straight line (2,3). However, most part of these studies were conducted in laboratory conditions (treadmill) or in tethered circular sprints, not reflecting the real complex dynamics of a game. Therefore we aimed to evaluate the differences in physiological parameters during running at straight and curvilinear trajectories.
METHODS: Volunteers were male sports recreationists (N=10) of 25.5 ± 2.2 years old. First, we applied the shuttle run test to determine the anaerobic threshold of the volunteers. Next, they performed runs of 20 meters distance for the period of five minutes in three different trajectories: shuttle run in straight line, shuttle run in semi-circle (radius = 6.28 m) and shuttle run in circle (radius = 3.18 m). In all trajectories, it was required a change of direction of 180° from the volunteers. The blood lactate concentration (BLC) was measured before and after the tests. Heart rate (HR) and heart rate variability (HRV) were collected using the POLAR® RS800cx during all tests. Five minutes after completion of the test, we asked the volunteers to their rate perceived exertion (RPE). All data was compared between the three trajectories using paired t-test.
RESULTS: The results showed that the trajectory in circle resulted in significant higher values of peak heart rate (straight line: 177.5 ± 13.3 bpm; semicircular trajectory: 181.6 ± 9.9 bpm; circular trajectory: 1881.1 ± 10.5 bpm), blood lactate (straight line: 4.5 ± 2.2 mmol/L; semicircular trajectory: 5.2 ± 2.0 mmol/L; circular trajectory: 6.5 ± 2.1 mmol/L), rate of perceived exertion (straight line: 4.7 ± 1.0 a.u.; semicircular trajectory: 5.8 ± 1.1 a.u.; circular trajectory: 8.1 ± 1.2 a.u.), meaning a higher effort from the volunteers.
CONCLUSION: This study demonstrated that changes of directions during curved trajectories represent a significant increase in the effort of players. .Such information helps in planning, organizing and distributing the training load during the competitive season.

EFFECTS OF AIMING TRAJECTORY FEEDBACK ON AIR RIFLE SHOOTING

CHUANG, Y.H., CHUANG, K.L., CHEN, H.H.
TAITUNG UNIVERSAL

Introduction
Appropriated aiming process is one of the most important techniques for air rifle shooters. While many coaches used the optoelectronic advice as the training intervention to improve the shooting performance, few experimental evidence has been shown for its influence. The presented study aimed to examine the effects of providing instruction using aiming trajectories feedback after shootings on the performance of 10 meter air rifle athletes.
Methods
Six junior rifle athletes implemented eight sets of training within each 60 shots. They could ask for the feedback and instruction about the previous trail among the intervals of shots as they want for 8 times. A SCATT optoelectronic shooting sensor (MX02) was attached on the barrel of gun to capture the trajectories of aiming process. The coordinates of trajectories on target planes in horizontal and vertical direction were export for analysis. The parameters of outcome scores (S), direction of aiming (DA), variability of DA (VDA), Steadiness of range 10 (S_10), stable index of aiming (SI), stable error of aiming (SE) and Sample entropy of aiming direction in vertical (SampEn_V) and horizontal direction (SampEn_H) were calculated for comparisons on eight sets through one-way ANOVA with repeated measures. For the repeated measure ANOVA, the Greenhouse–Geisser method was used to correct for violations of sphericity. The significant level was set at .5 and effect size reported as partial eta squares (petasq).
Results

The results of ANOVA showed significant effect on DA ($F(2.45, 12.24) = 3.67$, $p < .05$, petasq = .42) and absolute DA ($F(1.57, 7.84) = 8.52$, $p < .05$, petasq = .63). Post hoc comparisons of Bonferroni revealed that the later sets of training were smaller than the earlier sets. In addition, the result also showed the significant effect on SampEn_V ($F(2.58, 12.91) = 5.49$, $p = .014$, petasq = .52). Post hoc comparisons revealed that the SampEn_V were increased significantly in last two sets of training. No significant effect was found in the other parameters.

Discussion

The decrease on aiming direction indicated the improvement in proper aiming process of rifle shooting and provide the evidence of positive influence for the augmented feedback we intervened on junior rifle athletes. Although most of the parameters about shooting performance reveal no significant change after training, the significant increase of sample entropy in vertical direction when aiming implied a more complex coordination in aiming technique. How the augmented feedback influent the control of rifle shooting need further investigation using more nonlinear analyses.

THE ASSOCIATION OF EYE-HAND/EYE-FOOT RESPONSE TIME AND AGILITY AMONG YOUNG MALE TENNIS ATHLETES

SHIEH, L.C.1, SEE, L.C.2,3, CHANG, S.T.4, LEE, J.S.3, HO, W.H.1, LIM, A.Y.2, PENG, W.S.2, LIU, Y.H.2,3

1: UNIVERSITY OF TAIPEI, 2: CHANG GUNG UNIVERSITY, 3: CHANG GUNG MEMORIAL HOSPITAL, 4: CHUNG YUAN CHRISTIAN UNIVERSITY

INTRODUCTION: Tennis demands quick response and high agility. However, the association between RT and agility among tennis athletes is less studied. We aimed to (1) compare the eye-hand response time (RT) and agility between elite and novice male tennis athletes, (2) investigate the association between eye-hand/eye-foot RT and agility.

METHODS: We recruited 82 male tennis athletes from junior high school (n=37), senior high school (n=29) and universities (n=16). Among the recruited athletes, 50 were elite athletes (mean age, 15.84±2.94, years of practice, 7.22±2.91) and 32 were novice athletes (mean age, 15.38±2.71, years of practice, 4.66±3.07). Elite athletes were defined as participation in national or international competitions in the past 5 years. Eye-hand RT was measured for both dominant and non-dominant hands in five conditions: simple RT at zero and shoulder distance (SRT_zero, SRT_shoulder), choice RT at zero, shoulder and random distance (CRT_zero, CRT_shoulder, CRT_random). The Spider test, a tennis-specific test for agility, was made. FITLIGHT Trainer System was used to measure eye-hand RT and agility (in milliseconds).

RESULTS: There was no significant difference in demographic characteristics, BMI, hours of exercise per week for both groups. Elite tennis athletes were significantly faster in eye-hand RT (SRT_zero, SRT_shoulder, CRT_zero, and CRT_random for dominant hands; SRT_shoulder and CRT_random for non-dominant hands) compared to novice athletes ($p<0.05$). For agility, meantime was 16.83±1.61s and 17.00±1.21s for elite and novice athletes respectively ($p=0.6$). No association was found between agility and eye-hand RT (dominant hand, $r=0.04\sim0.24$; non-dominant hand, $r=0.09\sim0.32$) as well as eye-foot RT (dominant foot, $r=0.01\sim0.19$; non-dominant foot, $r=0.01\sim0.21$).

CONCLUSION: Elite male tennis athletes demonstrated faster eye-hand RT than novice athletes. Trivial association between eye-hand/eye-foot RT and agility because agility involves strength, power, and aerobic capacity while RT involved more perceptual and decision-making ability.

CLIMBING THE SEVENTH SUMMIT: NUTRITION, BODY COMPOSITION AND PHYSICAL CAPACITY OF AN ITALIAN MOUNTAIN CLIMBER

GHIANI, G., DONEDDU, A., ROBERTO, S., MAGNANI, S., SECHI, F., PINNA, V., SANNA, I., MULLIRI, G., CRISAFULLI, A.

UNIVERSITY OF CAGLIARI

INTRODUCTION: High altitude trekking is a challenging sport characterized by some technical difficulties such as trekking across long distances, chronic hypobaric hypoxia, and low temperatures. Loss of body weight is common during exposure to high altitudes, ranging from 3 to 5.4% depending on the duration of exposure and on physical activity. Between 2014 and 2018 the Italian climber AL climbed the Seven Summits. The last peak of this challenge was Mount Vinson, in Antarctic (4892 m) which he reached in January 2018. Before expedition, he asked our nutritional counselling to have a good nutritional status since he was supposed to eat the food given by the organizers, but he would have liked to carry a small amount of supplemental food with him to be pleased his sense of taste. Moreover, we were interested in his physiological adjustments to altitude.

METHODS: The athletes body composition was measured with plicometry (P) and with bioelectrical impedance analysis (BIA). The athlete filled a semi-quantitative food-frequency questionnaire to assess his usual energy intake. On the basis of his habits, he was given some nutritional advices for the last months of training. He increased his daily intake from 2700 Kcal to 3000 Kcal. Before (BEX) and after the expedition (AEX), the athlete also performed two incremental tests on a treadmill at the constant velocity of 8 km/h, while increasing the slope every minute by 1% till exhaustion. The two tests were conducted one in normoxia and the other in normobaric hypoxia (partial pressure of oxygen 12.8%, about 4.000 m altitude). Throughout sessions, the athlete was monitored for peripheral blood O2 saturation, measured by finger pulse oxymetry, and for cerebral oxygenation, which was assessed with near infrared spectroscopy.

RESULTS: At AEX the athlete lost body mass (-1.45%) both from fat (-12% BIA; -8% P), and from fat free mass (-1.5% BIA; -0.3% P). He performed better during the hypoxic test at AEX (20% vs. 21% slope at BEX and AEX respectively). Moreover, his cerebral oxygenation was increased (+10.89% increase during hypoxia at AEX with respect to BEX).

CONCLUSION: Changes in body composition observed in the present case study could be ascribed to physiological adaptations to hypoxia after 10 days in altitude. It is in fact well known that acclimation at high altitude leads to modifications in body mass and composition. One particular aspect was the enhanced capacity to exercise at AEX. In particular, he performed longer during the incremental test and his cerebral oxygenation was improved. It was concluded that this kind of expedition can be faced without particular concerns for athletes health.

EVALUATING THE IMPORTANCE OF MISTAKES IN THE EXECUTION OF TECHNIQUE IN SUCCESSFUL FRONT CRAWL SWIMMING PERFORMANCES

KAPUS, J.1, STIBILJ, J.2, KOŠMRLJ MUHA, K.3, VIRAG, J.1

1UNIVERSITY OF LJUBLJANA, FACULTY OF SPORT; 2PRIMARY SCHOOL BRANIK, BRANIK; 3UNIVERSITY OF PRIMORSKA, FACULTY OF MANAGEMENT

INTRODUCTION

A coach's feedback to swimmers often relies on qualitative observation. It requires appropriate preparation and background knowledge such as understanding the ideal form of a movement in each phase and the importance of a particular mistake in technique execution. The correct forms of swimming techniques are well known in written, diagrammatic as well as in pictorial presentations. In contrast, it is surprising that the research of Pion and co-workers (1988) has been the only attempt of an evaluation of swimming techniques by way of mistakes assessment, so far. Therefore, the purpose of this study was twofold: 1) to mark the technical mistakes that occur during front crawl (FC) swimming and, 2) to examine the validity of their importance by using the times of the 50 meters FC swim at maximal intensity.
METHODS
For the first part of the study, sixty-two Slovenian swimming coaches were asked to mark 29 mistakes that most commonly occur at FC swimming (Maglischo, 1993). They evaluated the mistakes on a 5-point range scale, depending on the impact of the particular mistake on the FC performance. Based on median values and interquartile range of coaches' marks, a scale of importance of FC mistakes was developed. For the second part of the study, eighty-nine female swimmers had to swim 50 meters FC as fast as possible. The swim test was part of the athletic entrance examination of the candidates who applied to the study at the Faculty of sport. Therefore, the participants could be classified as average or advanced swimmers. Their swimming performances were recorded. Two swim experts identified the mistakes, which appeared during participants swimming. For each participant, mistakes were assessed by the scale of importance and scores were summed. The validity of the scale was established by correlating the amount of numerically evaluated mistakes with the time achieved at 50 meters FC swim at maximal intensity.
RESULTS
The mistakes importance scale assesses the mistakes from the smallest (denoted by score 1) to the biggest (denoted by score 5). By using Pearson's correlation coefficient, we confirmed a linear correlation between the amount of numerically evaluated mistakes which occurred during FC swimming and the results achieved by candidates at the 50 meters FC swim at maximal intensity. The correlations between variables were statistically significant ($p < 0,05$) and positive ($R=0,69$). This means that the candidates that had made less mistakes or mistakes with lower scores achieved better results in the swim test.
CONCLUSION
Taking into account the obtained results, we conclude that the scale of the importance of the FC mistakes showed a high level of validity for qualitative assessment of swimming performance of average and advanced swimmers. Therefore, the suggested scale could be a useful tool for swimming teachers and coaches.

EFFECTS OF 8-WEEK LIGHT VS. HEAVY TIRE FLIP TRAINING ON PHYSICAL FITNESS OF YOUNG ADULTS

WONY, D.P., WELDON, A., NGO, J.K.
SHENZHEN UNIVERSITY. BEIJING SPORT UNIVERSITY.

INTRODUCTION: Previous study demonstrated that 88% of strength and conditioning coaches use strongman exercises in sessions (Winwood, et al, 2014) . Tire flip is one of the most popular exercises which requires an athlete to apply anteroposterior forces to flip a flat lying tire end to end (Keogh et al. 2010). However, no literature to-date has addressed the longitudinal effects of tire flip training. Therefore, this study aimed to examine the effects of an eight-week tire flipping training intervention on physical fitness by using light versus heavy tires. The results of this study can help strength and conditioning coaches to justify the use of light or heavy tire during training.
METHODS: Twenty-nine male University PE students were grouped into light (n = 15, age = 20.64 ± 1.60 years old, body weight = 69.79 ± 7.66 kg, height = 179.91 ± 5.52 cm) and heavy (n = 14, age = 20.53 ± 1.77 years old, weight = 70.72 ± 7.14 kg, height = 178.09 ± 4.55 cm) tire flipping training groups evenly according to body weight and height. Body to tire weight ratios were 0.61 ± 0.06 for light tire (tire weight = 43 kg, diameter = 98.2 cm, thickness = 23.0 cm) and 1.51 ± 0.16 for heavy tire (tire weight = 104 kg, diameter = 131.5 cm, thickness = 51.5 cm) groups respectively. Tire flip training sessions were conducted twice per week. Before and after the 8-week intervention, subjects conducted pre- and post-tests to assess physical fitness. Effect size values of 0-0.19, 0.20-0.49, 0.50-0.79 and 0.8 and above were considered to represent trivial, small, medium and large differences.
RESULTS: After 8 weeks of light tire training, large positive improvement was observed in 6RM bench press (+7.67%, ES: 0.98), small positive improvement in 5 horizontal jump (+1.01%, ES: 0.35) and agility performance (+1.18%, ES: 0.34), RSA (+0.41-0.54%, ES: 0.24-0.26) and intermittent endurance performance (+13.6%, ES: 0.45). After 8 weeks of heavy tire training, large positive improvement was observed in 6RM bench press (+13.1%, ES: 1.10), small positive improvement in 5 horizontal jump (+0.84%, ES: 0.26), agility (+1.37%, ES: 0.41), and intermittent endurance performance (+15.0%, ES: 0.66).
CONCLUSION: To the best of the author's knowledge, this is the first study comparing the longitudinal training effects of light and heavy tire flipping. Results showed that for participants with no prior tire flip and irregular weight training experience, training with light tire had similar training effects as training with heavy tire in upper body strength, agility, and horizontal explosive power. Moreover, participants of the present study shown improvements in tire flipping efficiency, through decreasing the set duration and thus the work-to-rest ratio, therefore monitoring such parameters will enable strength and conditioning coaches to make informed decisions of when to implement progressive overload.

A FEASIBLE APPROACH FOR BLOOD FLOW RESTRICTION TRAINING: ADJUSTING A NON-ELASTIC BAND BASED ON MODERATED CUFF PRESSURE

OLIVEIRA, J., ARRIEL, R.A., BILLAUT, F., MOURÃO-JR, C.A., CAMPOS, Y., VIANNA, J.V., MAROCOLO, M.
POST-GRADUATION PROGRAM OF PHYSICAL EDUCATION AND SPORTS, FEDERAL UNIVERSITY OF JUIZ DE FORA, BRAZIL.

INTRODUCTION: Resistance exercise with blood-flow restriction (BFR) condition promotes muscle hypertrophy and strength gains in different populations, such as in elderly and athletes as well as during a recovery condition. BFR training consists in applying a cuff or a band in the proximal region of the arms or thighs, and requires low loads (i.e. 20-50% of 1RM) during the sessions and appears to be safety, regarding hemodynamics. The BFR requires the utilization of a cuff, which is expensive and not prompt available for most part of practi-

tioners. So, some studies have been testing an elastic-band compared the use of the traditional tourniquet. The band represents a feasible tool, with lower cost compared to the tourniquet, and could promote the same results when applying the BFR with the tourniquet. Thus, we compared a simple strategy to use a non-elastic band for BFR training, based on the traditional tourniquet pressure and size on superior limbs.
METHODS: Eight- one (58M/23F) healthy and recreationally trained subjects volunteered in this study. In the 1st phase the pain perception was used to equalize length reduction of non-elastic band based on cuff pain set with 150 mmHg. In the 2nd phase, the length reduction of non-elastic band obtained from 1st phase was applied and the pain perception (using the same 0-10 scale) was compared between arms. The 3rd phase was carried out to compare hemodynamic responses after a resistance training session with 5 exercises. The perceived exertion as well as hemodynamics parameters (heart rate, arterial blood pressure and rate-pressure product) during resistance training sessions was measured. A portable vascular Doppler was applied on the radial artery to verify the blood flow during all interventions to guarantee that the blood-flow was not occluded.
RESULTS: The reduction length of non-elastic band was ~9% in men, ~7% in women and ~8% in both groups. No differences in pain perception were found among groups applying the non-elastic reduction length obtained in the 1st phase as well as no differences in heart rate, arterial blood pressure, rate-pressure product and rate of perceived exertion were found in hemodynamic parameters.
CONCLUSION: Our results provide strong evidence allowing recommending the use of non-elastic band adjusted from cuff validated parameter, for blood flow restriction training in healthy and recreationally trained subjects. Since the non-elastic band provides no pressure values, during the training would be interesting checking the pain values.

CROSS EDUCATION IN A KNEE EXTENSION EXERCISE DEPENDS ON SET CONFIGURATION OF RESISTANCE TRAINING

FARIÑAS, J., GIRALDEZ-GARCÍA, M.A., MAYO, X., CARBALLERIA, E., RIAL-VÁZQUEZ, J., FERNÁNDEZ-DEL-OLMO, M., IGLESIAS-SOLER, E.

UNIVERSIDADE DA CORUÑA

INTRODUCTION: Cross education (CE) consists in strength transfer from trained to non-untrained limb after an unilateral strength training program (3). Neural adaptations are suggested as responsible of CE phenomenon (4), and it seems that characteristics of load are determinant in order to obtain significant improvements. The aim of this study was to compare the strength transfer to untrained knee extensors after two unilateral strength training programs differing in set configurations but with the same total volume and repetition-to-rest ratio.
METHODS: Thirty-five physically actives participants were randomly assigned to three groups: cluster training group (CT), traditional training group (TT) and control group (CON). The experimental groups performed 10 unilateral training sessions (two sessions per week throughout 5 weeks) using the dominant limb. TT performed 4 sets of 8 repetitions with 3 minutes of rest between sets; CT performed 32 sets of 1 repetition with 17.5 seconds of rest between each set. Before and after the intervention, one repetition maximum (1RM), 10 repetitions maximums (10RM), muscle thickness and number of repetitions in postest with 10RM pretest load (10RMr) were measured in order to test plausible training effects.
RESULTS: Regarding the trained limb, TT and CT obtained significant improvements in 1RM ($p<0.001$ in both groups) and 10RMr (TT: $p<0.001$; CT: $p=0.001$). Improvements of the non-trained limb were only observed for 1RM in TT ($p<0.001$). No structural changes were observed by ultrasound measurements.
CONCLUSION: This study concludes that equating volume and repetition-to-rest ratio, a more fatiguing set configuration (TT) causes a significant CE magnitude in comparison with a shorter set configuration (CT). Evidence exists that training the non-injured limb during an immobilization period shortens the recovery time in comparison with the traditional rehabilitation procedures which are applied when the immobilization is removed (1,2). Thus, knowing how to induce higher levels of strength transfer by using the suitable set configuration will optimize the effect of the training program. These findings highlight the importance of the set configuration as a relevant parameter for the design of unilateral strength training programs aimed to inducing a CE effect.

THE EFFECTS OF ENHANCED ABDOMINAL CORE ACTIVATION ON QUADRICEPS MUSCLE TORQUE, TIME TO PEAK TORQUE AND MUSCLE ACTIVATION AT DIFFERENT KNEE FLEXION ANGLES

YILLI, S., SAHIN, D.C., ARSLAN, D., SOGUT, B., YALKI, S., HARPUT, G.

HEALTH SCIENCES

INTRODUCTION: Enhanced abdominal core activation is a popular technique in training programs to strengthen the desired muscle with stabilized lumbo-pelvic hip complex (1). Quadriceps strengthening is the primary goal of several rehabilitation programs after lower extremity injuries (2). However, it is unclear if enhanced abdominal core activation (ECA) would change quadriceps force exertion and activation. Thus, the purpose of the present study was to investigate the effects of enhancing the activation of the abdominal core muscles on quadriceps force exertion and activation levels in open kinetic chain position.
METHODS: Eleven healthy individuals (Age: 24.6±1.9 years; BMI: 22.7±2.9 kg/m2) were included in this study. Quadriceps isometric peak torque (PT) and time to peak torque (TTPT) were measured by isokinetic dynamometer at 60 and 90 degrees of knee flexion. Surface electromyography was used to measure the activation of bilateral internal oblique/transversus abdominis (IO/TA) muscles, and rectus femoris (RF), vastus lateralis (VL), vastus medialis obliquus (VMO) muscles of the dominant leg during quadriceps isometric strength testing. The isometric testing was performed with two conditions: natural abdominal core activation (NCA) and ECA. Three trials of 5-second-isometric test were performed and one-minute-rest was given between each trials. 2- way repeated measures of ANOVA (angle by condition) was used for statistical analysis.
RESULTS: There was a significant angle by condition interaction for quadriceps PT ($F(1,10)=7.42$, $p=0.02$). When compared to NCA, quadriceps PT was lower with NCA at 60 degrees of knee flexion ($p=0.001$). A significant angle by time interaction was also seen for TTPT ($F(1,10)=18.23$, $p=0.002$). With ECA, TTPT was shorter at 60 degrees of knee flexion ($p=0.04$) but it was longer at 90 degrees of knee flexion ($p=0.04$) compared to NCA. Angle by condition interaction was not found significant for VMO, RF and VL activation levels ($p>0.05$). Main effect of condition was significant for VMO activation level ($F(1,10)=6.60$,$p=0.03$). VMO activation level was lower with ECA compared to NCA ($p=0.03$).

CONCLUSION: The results of this study indicate that quadriceps isometric contraction with ECA decrease quadriceps maximal effort but also decrease the time to maximal effort. Thus, clinicians might seek to prioritize isometric strengthening with ECA in the early phase of the rehabilitation for quadriceps muscle strains to improve rapid force development without overloading the quadriceps muscle.

ON THE IDENTIFICATION OF KEY MUSCLES TO TARGET IN FES-ROWING TRAINING

VIEIRA, T.M., CERONE, G.L., STOCCHI, C., LALLI, M., ANDREWS, B., GAZZONI, M.

POLITECNICO DI TORINO

INTRODUCTION: Notwithstanding the documented musculo-skeletal and cardiovascular benefits of combining functional electrical stimulation (FES) with indoor rowing in paraplegia [1-2], no consensus seems to exist as per which muscles to stimulate. In this study we investigate how many, when and how different leg muscles are recruited during indoor rowing.
METHODS: Twenty elite rowers participated in this study (18-30 years; 170-190 cm; 60-92 kg). After 5 min warmup, subjects were asked to row on an indoor rowing machine for 120 s, 100 s and 80 s at 18, 24 and 28 strokes/min (spm) respectively. Trials were applied at random order with five minutes break in-between. Bipolar electromyograms (EMGs, 15 mm diameter and 35 mm inter-electrode distance [3]) were collected bilaterally from: tibialis anterior, gastrocnemius medialis, soleus, vastus lateralis and medialis, rectus femoris, biceps femoris and semitendinosus. The position of the handle of the rowing machine was measured with an incremental, rotatory encoder; position data was digitised synchronously with EMGs. The onset of activation and silencing, the duration of muscle activity and how similarly the amplitude of these EMG envelopes changed bilaterally for each muscle was assessed from the amplitude of rectified and low-pass filtered EMGs. Timing and modulation of muscle activity were assessed in relation to individual rowing cycles, identified from handle position.
RESULTS: Given no effect of stroke rate on onset values was observed ($P>0.05$), onset values were averaged across the three stroke rates. Different muscles were recruited and silenced at different instants during rowing ($P<0.005$). While quadriceps, gastrocnemius and soleus were recruited just before catch, the other muscles were recruited both sooner (semitendinosus and tibialis anterior) and later (biceps femoris; $P<0.02$). Tibialis anterior was the only muscle recruited only within the recovery phase. These results apply equally to both legs.
From the onset of activation to silencing, the amplitude of EMG envelopes changed concurrently in both legs and for all muscles tested. Significantly high correlation values (Pearson $R>0.78$; $P<0.005$) were observed for all muscles. The slope of regression lines calculated from normalised envelopes did not differ from unity for all muscles tested ($P>0.24$), indicating no side differences in modulation of muscle activity were present during rowing.
CONCLUSION: While the stimulation of proximal muscles is of common concern in FES-rowing protocols, our results indicate distal leg muscles may provide substantial contribution to knee extension/flexion during rowing. From our results, we suggest stimulating vastii and soleus muscles during drive and tibialis anterior during recovery.

PATELLAR TENDON STIFFNESS AND THICKNESS IN ELITE SPRINT AND ENDURANCE TRACK CYCLISTS USING MYOTONOMETRIC AND ULTRASONOGRAPHIC MEASUREMENTS

KLICH, S., KRYMSKI, I., KAWCZYNSKI, A.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION IN WROCŁAW

INTRODUCTION: Track cyclists are required to perform short- and long-term efforts during sprint and endurance race events. It is well known, that 200m flying sprint races are one of the highest performance events (involves maximal power output and velocity generation), while 4000m pursuit cyclists demand high level of aerobic and anaerobic capacity. Thigh muscles overloadings cause often patellar tendon (PT) tendinopathy and affect knee function in track cyclists. The aim of this study was to investigate PT stiffness and thickness after 200m flying sprint and 4000m pursuit race.
METHODS: Subjects (n=20) participated in this study were elite men sprint (n=10) and endurance cyclists (n=10) specializing in 200m flying start and 4000m pursuit. The participants were assessed for PT stiffness and thickness before and after both sprint and endurance races. Both measurements were collected from dominant (right) knee. PT stiffness was measured using myotonometer. The participants were positioned in a sitting position with their knees flexed to 90°. The reference point for the PT stiffness was 3 cm below the inferior pole of the patella. PT thickness was assessed using musculoskeletal ultrasonography. The subjects were positioned in a supine position with their knees in a flexed approximately 30°. For PT thickness measure, the probe was placed in a longitudinal direction distal to patella. Four positions along the tendon were measured for thickness in millimeters (mm) at 5, 10, 15 and 20 mm lateral to the reference point of the apex patella. All points were averaged for a single measure of tendon thickness.
RESULTS: PT stiffness in sprint cyclists was 1082±175.2 and 1351.5±192.3 N/m for the measurement before and after 200m flying start. PT stiffness in endurance cyclists was 954.2±86.7 and 1181.3±109.2 N/m for the assessment before and after 4000m flying start. Significant differences were observed within-cyclists comparison in each group (sprint: $p=0.0001$ and endurance: $p=0.001$) and between groups after races ($p=0.0001$). PT thickness in sprint cyclists was 4.74±0.11 and 4.85±0.06 mm for the measurement before and after 200m flying start. PT stiffness in endurance cyclists was 4.42±0.08 and 4.53±0.11 mm for the assessment before and after 4000m flying start. Significant differences were observed within-cyclists comparison in each group (sprint: $p=0.002$ and endurance: $p=0.003$) and between groups after races ($p=0.05$).
CONCLUSION: Overall, these data suggest that a stiffer and thicker PT may limits force generation during track cycling events. Furthermore, those alterations may be related with great training experience due to adaptation process. Those results could be useful information in programming rehab workouts and recovery sessions.

EFFECTS OF SITTING POSTURE CHANGES ON ABDOMINAL MUSCLE ACTIVITY

MOTOMURA, Y., TATEUCHI, H., KOMAMURA, T., YAGI, Y., ICHIHASHI, N.

KYOTO UNIVERSITY

INTRODUCTION: Abdominal hollowing (AH) is often used in selective training of the transversus abdominis (TrA) to stabilize the trunk. However, AH may be difficult for people with low back pain or elderly people since they may be unable to voluntarily contract the TrA. Therefore, it is useful to identify if the TrA contraction can be achieved as secondary to sitting posture changes. The purpose of this study was to clarify the effects of the trunk lean and thigh elevation during sitting on abdominal muscle activity and, in particular, TrA activation specificity.
METHODS: The right TrA, internal oblique, external oblique, and rectus abdominis of 14 healthy young men were examined. The muscle stiffness measured by shear wave elastography (SuperSonic Imagine) was used as an index of muscle activity. Each muscle stiffness was measured in AH with maximal effort and in the following eight sitting postures: (1) 15° or (2) maximal posterior lean, (3) 20° or (4) maximal lateral trunk lean to the right (ipsilateral), (5) 20° or (6) maximal lateral trunk lean to the left (contralateral), and (7) right and (8) left thigh elevation of approximately 1 cm. Muscle stiffness measurements were averaged across three trials. The TrA contribution rate obtained by dividing the TrA stiffness by the sum of muscle stiffness of the four abdominal muscles was calculated as an index of specificity for the TrA. For each muscle stiffness and the TrA contribution rate, multiple comparisons by the Shaffer post hoc tests were performed for comparison between tasks.
RESULTS: The TrA stiffness was significantly higher in AH than in the five postures except for 20° and maximal contralateral trunk lean, and contralateral thigh elevation. The TrA stiffness in these three postures was significantly higher than that in maximal backward lean. The TrA contribution rate was significantly higher in AH than in the five postures except for ipsilateral lean at 20° and thigh elevation. There was no significant difference in the TrA contribution rate between contralateral lean at 20° and maximal contralateral lean.
CONCLUSION: For people who cannot effectively perform AH due to voluntary TrA contraction difficulty, contralateral lean of the trunk or elevation of the contralateral thigh could be useful to enhance the activity of the TrA, and contralateral thigh elevation could particularly be beneficial to obtain the selective TrA activity. Since there was no significant difference in the TrA contribution rate between 20° and maximal contralateral lean, it 20° may be sufficient in terms of the TrA selectivity.

EFFECTS OF ECCENTRIC EXERCISE ON TRAPEZIUS MUSCLE BIOMECHANICAL PROPERTIES ASSESSED BY ULTRASONOGRAPHY AND MYOTONOMETRY

KISILEWICZ, A., KAWCZYNSKI, A., MADELEINE, P., LARSEN, R.G.

UNIVERSITY OF PHYSICAL EDUCATION, AALBORG UNIVERSITY

INTRODUCTION: Unaccustomed eccentric muscle contractions place high strain on the muscle-tendon complex causing muscle damage resulting in delayed onset muscle soreness (1). However, little is known about the effect of eccentric exercise on biomechanical properties in muscle. Therefore, the aim of the study was to investigate effects of unaccustomed eccentric contractions on biomechanical properties of trapezius muscle by means of ultrasonography and myotonometry.
METHODS: Fourteen healthy, young participants took part in the study. An ultrasound system was used for acquiring images of the upper trapezius muscle. The probe was positioned on the right upper trapezius, parallel to the arrangement of muscle fibers for measurements of muscle elastic modulus (shear wave elastography). A handheld MyotonPro device was applied to measure upper trapezius muscle stiffness. A dynamic shoulder dynamometer was used to induce delayed onset muscle soreness over the upper trapezius muscle (2). Assessments were made before and 24 hours after unaccustomed eccentric contractions.
RESULTS: Muscle elastic modulus, assessed by shear wave elastography, decreased from before to 24 hours after eccentric contractions (from 45.8 ± 1.6 kPa to 39.4 ± 1.2, $P<0.01$). Likewise, muscle stiffness measured by MyotonPro, decreased from before to 24 hours after eccentric exercise (from 369.0 ± 7.3 N/m to 302.6 ± 6.0 N/m, $P<0.0001$).
CONCLUSION: The present study showed that biomechanical muscle properties represented by elastic modulus and muscle stiffness decreased 24 hours after unaccustomed eccentric exercise. These findings may be important for injury prevention and training load programming.

FORCE-FREQUENCY CURVE BY NMES IS ASSOCIATED WITH MUSCLE THICKNESS AND MAXIMAL VOLUNTARY CONTRACTION FOR QUADRICEPS FEMORIS

TOMITA, A., WATANABE, K.

CHUKYO UNIVERSITY

INTRODUCTION: There is individual difference in force-frequency relationship by neuromuscular electrical stimulation and it is a changeable parameter by aging or fatigue. There are muscle quantity, muscle quality and central nerves system as three important factors provided muscle function. In this study, we focused on muscle quality and muscle quantity, in order to clarify factors of the individual difference on contractile properties. The purpose of the present study was to investigate the relationship between force-frequency curve using neuromuscular electrical stimulation, which prescribing contractile properties as muscle quality, and muscle thickness, which is the simplest index of muscle quantity for quadriceps femoris muscle.
METHODS: Thirteen healthy men and women (22±3 years) participated in this study. Before knee extension task and NMES, muscle thickness was measured using ultrasonography from lateral side (Vastus lateralis; VL and Vastus intermedius; Vllat) and anterior (Rectus femoris; RF and Vlant) of thigh. Subjects performed isometric maximal voluntary contraction (MVC) for knee extensor at knee joint angle of 90°. NMES for force-frequency curve was performed. Stimulation frequencies were 10-50hz (5hz each) and stimulation intensity was set 30%MVC at 20hz of stimulation frequency. Induced torque at each frequency was normalized by peak-induced torque (%peak torque). Relationship between MVC, thickness of each muscle and %peak torque by NMES were evaluated using the Pearson product moment correlation analysis.
RESULTS: MVC was 177.8±53.3 Nm. There was significant positive correlation between MVC and %peak torque at 40hz and 50hz ($p<0.05$). Muscle thickness were as follows; VL, 23.0±3.6, Vllat, 14.8±2.8, RF, 19.9±2.6, Vlant, 14.5±3.2 (mm). There were significant negative correlations between VL thickness and %peak torque at 15hz, 30hz, RF thickness and %peak torque at 15hz, 25hz, Vlant thickness and %peak torque at 15hz, 30hz, 40hz ($p<0.05$). Furthermore, for VL thickness and Vlant thickness, significant positive correlations were shown with %peak torque at 50hz ($p<0.05$).

CONCLUSION: It was shown that the frequency evoked peak torque was different according to MVC strength and that evoked torque was different at around 45hz according to size of muscle thickness. For elderly people, the change of force-frequency relationship by aging was reported and the decrease in muscle quantity and muscle strength by aging is well known. The results of this study, the relationships with muscle thickness and MVC, may follow these previous studies, although we recruited young subjects in this study. However, the muscle thickness from cross-sectional images by ultrasonography is the simplest and just a part of information in whole muscle quantity. The investigation reflected whole muscle volume correctly is considered to be required for determination the relationship with contractile properties in detail.

SIMULATION OF THE TRAJECTORY OF SHUTTLECOCK IN BADMINTON

TAKATSUKA, R., SADO, N., FUKASHIRO, S., YOSHIOKA, S.

THE UNIVERSITY OF TOKYO

INTRODUCTION: In badminton, it is important to drop shuttlecock on the opponent's court as fast as possible. However, the optimal trajectory of shuttlecock which has a peculiar aerodynamic nature remains to be clarified. Therefore, the current study aimed to clarify the optimal trajectory for dropping to the opponent's court in the shortest time, and examine the effects of variation in initial shuttlecock conditions on their trajectories.
METHODS: We simulated two-dimensional shuttlecock trajectory, seen from the side of badminton court. From 0.8 m from the end of the court (on the long service line of doubles), height of 2.5 m, a shuttlecock was launched to the targets (T1 to T12) at 50 cm intervals in the opponent's court over the net with a height of 1.524 m. It was assumed that only aerodynamic drag force was exerted on the shuttlecock. We calculated the two-dimensional coordinates of shuttlecock using Fourth Order Runge-Kutta method. Initial velocity (Vo) and angle of projection (θ) were varied between 0 and 60 m/s, and between -45°and 65°, respectively. We calculated the trajectories from the initial conditions with all combinations of them, then determined the optimal trajectory with the shortest time from launch to landing to each target. Moreover, to simulate the effects of errors on initial parameters of the shuttlecock, for each combination of Vo and θ which realized optimal trajectories, the trajectories were calculated by varying Vo between 80% and 120%, and varying θ between θ-10° and θ+10° for each target conditions. Then we defined and calculated the reaching rate that the shuttlecocks were in the opponent's court for each target.
RESULTS: Although the optimal trajectories for T1 (0.5 m from the net) ~ T7 (3.5 m from the net) passed just above the top of the net, the optimal trajectories for T8 (4.0 m from the net) ~ T12 (6.0 m from the net) passed much above the net. The smallest θ resulted in optimal trajectories for respective conditions (T1 ~ T12). By varying Vo between 80% and 120%, the reaching rate of T1 to T7 was almost equal (about 50%), but that of T8 to T12 was sharply increased (about 100**%**). By varying θ between θ -10° and θ +10°, the reaching rate of T1 was much low (about 10**%**), and that of T1 to T7 was equal (about 50%). In addition, that of T8 to T12 was gradually increased as the distance from the net get farther.
CONCLUSION: Our results suggest that hitting shuttlecock in small angle of projection is required to drop shuttlecock on the opponent's court as fast as possible, and that the variation of initial conditions makes it easier to mistake when players hit shuttlecocks towards the front area of the court than the back area of that. Moreover, the players are likely to miss the shot towards the area close to the net (a drop shot) by the error of angle of projection rather than initial velocity.

COMPARING MUSCLE ACTIVITY OF DROP VOLLEY AND VOLLEY IN TENNIS

RYOSUKE, F.1, MILOS, D.1, KAZUYUKI, K.1

1:WASEDA UNIVERSITY

INTRODUCTION: In tennis, the technique of hitting the ball at the target location of the opponents court is important. If it is possible to hit a shot that moves the opponent back and forth, it is tactically advantageous. Among such shots, drop volley which slows the ball speed and return the ball close to the net is particularly difficult. No study has attempted to analyze the behavior of drop volley. In this study, we focus on arm muscle activities during drop volley and clarify the difference in muscle activity between drop volley and volley. The hypothesis is, "it is important to gradually relax muscles toward the time of impact of drop volley".
METHODS: Subjects were ten college students with tennis experience of more than 8 years. Telemeter devices (Trigno wireless EMG system, Delsys, USA) were used to acquire electromyogram. The telemeter devices were attached to the flexor carpi radialis, extensor carpi radialis, biceps brachii, and triceps brachii muscle of the dominant arm. Using the tennis ball machine, the ball was given straight towards the subject. The shot was considered as success one when the ball entered the singles area of the opponents court. Subjects did volley or drop volley, both with forehand or backhand, each 15 successes. Two high-speed video cameras were set on both sides of the subject, and video recordings were made at 300 fps. Rectified EMGs were averaged in the intervals from 50 ms before the impact 100 to 200ms after the impact, and the 50ms intervals were denoted as sections 1 to 6, respectively. To calculate the ratio of the speed of hitted ball in terms of the speed of projected ball was calculated.
RESULTS: The ball speed of the drop volley was significantly slower than the volley ($p<0.05$). There was the main effects of trial and sections ($p<0.05$). In addition, there was interaction between sections and trials ($p<0.05$). In all the muscles except the extensor carpi radialis, the muscle activity at the impact for both forehand and backhand shot was significantly higher than the previous sections ($p<0.05$). All muscles activities except extensor carpi radialis at the impact were significantly lower in drop volley than volley for the forehand ($p<0.05$). For the backhand, muscle activity of flexor carpi radialis in the drop volley at the impact was significantly greater, and other muscles were significantly lower than the volley ($p<0.05$).
CONCLUSION: Muscle activities of the upper limb when hitting drop volley was significantly lower than hitting volley. When players hit the drop volley, they allowed the racket to flip after the impact to decrease the returned ball speed. This would be possible with weak muscle activity that was just enough for holding the racket as observed in this study. In the backside drop volley, muscle activity of flexor carpi radialis at the impact were significantly larger than the volley. The subject might consciously pulled the racket in the opposite direction to the hitting direction at the impact.

HAS HYEON CHUNGS SERVE PERFORMANCE IMPROVED FROM JUNIOR TO PROFESSIONAL?

KIM, H.

GEORGIA STATE UNIVERSITY

INTRODUCTION: Hyeon Chung (ATP ranking 25th) made a great achievement to the semifinals of the 2018 Australian Open. Chung was the first Korean player to reach a Grand Slam semifinal. In his previous records, the best was that Chung finished the 3rd round in the 2017 French Open. High-qualified serve is important in tennis because well-performed serve provides advantages to initiate an offense and win a point. However, it is not known if Chung's improved serve performance was one of the main reasons for his success. Thus, the aim of study was to investigate whether Chung's serve performance improved from his junior level to his professional level compared to the serve specialists.
METHODS: The match of the 2013 Junior Wimbledon Quarterfinal (Borna Coric vs. Hyeon Chung) was selected to compare with Serve & Return Tracker (SRT) offered by Association of Tennis Professionals (ATP). The match (25 fps) was downloaded from the open-source website and a custom-designed program by Matlab enabled to track the displacements of tennis ball. Frames with tennis ball displacements were captured when the tennis ball landed on the service box of the court. Each service box was divided equally into three sections (T section, Mid section, & Wide section) to analyze serve performance. We chose Andy Roddick as a serve specialist and his recent records were provided by ATP.
RESULTS: In the junior match of 2013 between Chung and Coric, there were 68 times of serves performed by each player. Chung showed 29.0% ($z=-3.14$, $p<0.05$) of serve on the T section of the Advantage court and 18.9% ($z=-7.65$, $p<0.05$) of serve on the T section of the Deuce court. There was a significant difference between Chung's serve performance and the group of professional players (Advantage: $M=44.86\%$, $SD=5.05\%$, Deuce: $M=46.90\%$, $SD=3.67\%$). On the other hand, the professional Chung in 2018 made 46.8% ($z=0.39$, $p=0.71$) on the T section of the Advantage court (Mid section: 15.4%, Wide section: 37.8%) and 45.8% ($z=-0.31$, $p=0.77$) on the T section of the Deuce court (Mid section: 14.9%, Wide section: 39.3%) in entire year of 2018 according to SRT. The serve specialist Roddick served 57.0% of serve on the T section of the Advantage court (Mid section: 6.1%, Wide section: 36.9%) and 50.9% of serve on the T section of the Deuce court (Mid section: 5.5%, Wide section: 43.6%).
CONCLUSION: Results showed that junior Chung's serves in the 2013 Junior Wimbledon Quarterfinal clearly showed different distribution contrasting to professional players, the biggest discrepancy on T sections. A clear improvement in his ability to serve the ball to T sections or Wide sections were revealed and this pattern differentiated from junior Chung in 2013 and the earliest year as professional player in 2015. This comparison has revealed the difference between Junior players and Professional players in serve performance. Chung's achievement in 2018 Australian Open was not just a coincidence.

NOTHING VENTURED, NO POINT GAINED—AN ANALYSIS OF BREAKPOINT PERFORMANCE OF TENNIS PLAYERS

CUI, Y.1, LIU, H.1, SHEN, Y.1, BAO, D.1, ZHANG, S.2, ZHOU, C.2, GÓMEZ, M.Á.2

1: BEIJING SPORT UNIVERSITY; 2: TECHNICAL UNIVERSITY OF MADRID

INTRODUCTION: Playing a breakpoint could be regarded as one of the most critical moments in tennis match. In fact, previous research has suggested that breakpoint won is a key performance indicator that discriminated winning and losing players (ODonoghue, 2012). However, little is known about players' actual performance during breakpoint, and what contributed most to increase their effectiveness. Therefore, the aim of the study was to analyse the breakpoint performance of professional tennis players during matches and model the relationship between breakpoint-related variables with point outcome.
METHODS: Match data of 2,699 breakpoints played by 121 male tennis players from 2017-18 US Open were gathered from IBM SlamTracker of the official website. The statistics were organised into the following breakpoint-related independent variables: serve speed, rally number, distance covered, court-side, serve number, serve-zone, serve-depth, return of serve and net-point. The breakpoint outcome (win/lose) was the dependent variable. Crosstab Commands with Pearson's Chi-square test and independent t-test were performed to analyse the effects between breakpoint outcome and the categorical and continuous variables, respectively. A classification tree analysis with the exhaustive CHAID algorithm was run to model the relationship between breakpoint outcome and significant variables from the previous tests. Finally, a binary logistic regression was used to obtain the regression coefficients that reflects the estimated changes in breakpoint outcome due to a unit change in key performance indicators. The Odds ratios and their 95% confidence intervals were determined.
RESULTS: The results showed that except for court-side, all analysed variables were significant ($p<0.05$) with trivial to moderate effect sizes (Cramer's V: 0.14-0.37; Cohen's d: 0.10-0.61). The classification tree model revealed four significantly influencing factors to breakpoint outcome: serve number, serve width, return of serve and net-point. Apart from ace and serve winner, serving players saved more breakpoints by serving into the wide and center zones, and playing more net points. While returning players won more breakpoints via more net-points during non-depth returns or second serve-returns. The results of binary logistic regression showed a significant model ($=594.16$, $p<0.001$) with strong influence of serve number and net-point. Higher breakpoint saving effectiveness was achieved when serving players achieved first serves (OR=0.67) and played net points (OR=0.45).
CONCLUSION: Maintaining high-quality first serves, playing less rallies and more net-points seems to be key performance indicator that enable serving players to win breakpoints. Whereas, returning players are benefited to win breakpoints by playing aggressively during second serve, and more importantly, finishing the points at the net. Specific drills could be designed during training and match preparation to enhance players' breakpoint performance.

KINEMATIC MOTION ANALYSIS OF THREE DIFFERENT SERVICE TYPES IN ELITE JUNIOR TENNIS PLAYERS

VUONG, J., FETT, J., OBERSCHELP, N., FERRAUTI, A.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: The tennis serves' importance in the modern game is indisputably high [1]. However, the flat first serve from deuce court of high-performance adult players has received the most scientific attention. Comparable research targeting the different serve types in adolescents are rather scarce. Therefore, the aims of this study were to quantify and compare the kinematic data of elite young players' and different serve techniques.
METHODS: An eight camera Vicon motion capture system was used in combination with a specifically modified version of the University of Western Australia full body model comprising 90 retroreflective markers to collect full body, racket and ball kinematics of 15 male national elite junior players (age: 14.7 ± 1.8 yrs, height: 175.8 ± 15.4 cm, weight: 61.3 ± 15.7 kg). Serve velocity was measured with a Stalker radar gun. Players hit 8 flat (F) serves, 8 kick (K) serves and 8 slice serves (S) from the deuce court in a randomized order.

RESULTS: Significant differences ($p \leq 0.05$) between serve types were found for maximal trunk extension [°] (F: 42.2, K: 43.7, S: 42.5) and thorax axis rotation [°] (F: 115.4, K: 86.8, S: 103.9) as well as for angular velocities [°/s] of front knee extension (F: 454.1, K: 489.3, S: 448.2), trunk flexion (F: 481.8, K: 516.3, S: 514.2), shoulder internal rotation (F: 2050.0, K: 1789.9, S: 2091.5) and wrist flexion (F: 1111.8, K: 1315.7, S: 1257.0). At ball impact, angles [°] of thorax axis rotation (F: 25.4, K: -3.4, S: 13.9), shoulder abduction (F: 114.4, K: 116.9, S: 114.2) and external rotation (F: 79.7, K: 86.9, S: 84.7) as well as velocity vectors of the racket [m/s] laterally (F: 1.0, K: -9.7, S: -5.0), forward (F: 31.0, K: 28.2, S: 30.8) and upward (F: 5.8, K: 9.9, S: 7.8) varied just like service velocity in general [km/h] (F: 153.9, K: 125.3, S: 137.2). In addition, ball positions at impact [cm] differed laterally (F: 30.0, K: 45.9, S: 25.1) and forward (F: 52.7, K: 38.9, S: 46.6).
CONCLUSION: This study provides coaches, health practitioners and scientists with male elite junior tennis players' kinematic data of the tennis serve motion. Ball position at impact, racket velocity vec-tors and rotation of the torso appear to be critical features for characterizing the different serve types. Since the junior players' techniques differ for the serve types in the same way as adult players, there is no need to change coaching methods. Regardless, the data underline the im-portance of the ball toss for optimizing player kinematics to improve serve performance. A con-comitant monitoring and adjustment of the ball toss along the development pathway seems essential.

TRAINING EFFECT OF A 4-WEEKS ADD-ON VISUAL TRAINING PROGRAM ON COLLEGIATE TENNIS ATHLETES

CHANG, S.T.1, SEE, L.C.2,3, LEE, J.S.2, SHIEH, L.C.4, LIM, A.Y.3, CHEN, W.M.3, LIU, Y.H.2,3

1: CHUNG YUAN CHRISTIAN UNIVERSITY, 2: CHANG GUNG MEMORIAL HOSPITAL, 3: CHANG GUNG UNIVERSITY, 4: UNIVERSITY OF TAIPEI

INTRODUCTION: Tennis is a complex sport that required intermittent high-intensity efforts and acquired motor skills for accelerations, decelerations, and strokes during the game. Vision, response time and agility are abilities contribute to tennis performance. This study aims to evaluate the efficacy of an add-on visual training program in hand-eye response time (RT), agility and stroke performance among tennis athletes.
METHODS: We recruited 33 tennis athletes from a university and randomized them into 2 groups, the conventional training (CT) group (n=17, mean age, 21.59±1.53 years, female, 35.3%) and the add-on visual training group (VT) (n=16, mean age, 20.49±1.38 years, female, 25.0%). Both groups were trained 3 times a week (an hour per session) for a total of 4 weeks. The CT group received conventional tennis training and the VT group received additional 6-minutes visual training after finishing the same conventional tennis training. Hand-eye RT, agility, and stroke performance were assessed before, after and 18 weeks after the training program. Simple and choice hand-eye RT was measured at zero, shoulder and random distance. Repeated measured ANOVA was made to analyze the result for the 3 assessments.
RESULTS: Both groups had no significant difference in RT, agility and stroke performance at baseline. After the 4-weeks training program, the VT group had significant improvement in hand-eye RT, agility and stroke performance ($p<0.001$). The CT group only showed improvement in hand-eye choice RT measured at random distance. Twenty-one participants completed the 18 weeks follow up (14 from the VT group and 7 from the CT group). The VT group remained to have faster simple RT compared to before training but choice RT regressed. The CT group had similar or worse RT compared to before training. Both groups regressed in agility and stroke performance after 18 weeks of training.
CONCLUSION: The 4-weeks add on visual training program had short term effect in improving hand-eye RT, agility and stroke performance but did not sustain till 18 weeks.

A COMPARATIVE ANALYSIS OF SERVE CHARACTERISTICS IN ELITE JUNIOR TENNIS SINGLES AND DOUBLES

VOLK, N.R., FETT, J., BECKER, S., BINZ, N., FERRAUTI, A.

RUHR UNIVERSITÄT BOCHUM

INTRODUCTION: The first serve in doubles used to be slower and with a higher percentage of serves-in compered to singles (Talbert & Old, 1977). This strategy reduced the risk for offensive returns after the second serve and allowed a high percentage of serve & volley (Ferrauti, 1992). The modern game of tennis doubles has undoubtedly changed when compared to the game of previous eras with the trend to an adjustment of match characteristics to single tennis (Black & van de Braam, 2012). Therefore, the aim of this study was to compare the current singles (S) and doubles (D) game characteristics of the same players under real match conditions.
METHODS: In a cross-over design, eight elite male junior tennis players (17,7±0.5 years) participated in this study. Each player was analyzed at least once during both, single and double matches during the national indoor junior championship (hard court). In case of multiple matches per player we calculated the overall individual mean percentage for each player. Matches were video recorded and serve velocity was measured by a radar gun. Notational video analysis of technical and tactical details was completed, including quantity, quality and position of strokes. Items were included, if Cohens kappa inter-rater reliability was > 0.80.
RESULTS: Match characteristics differed significantly between single and double matches. Number of strokes per player and duration per rally were significantly ($p<0.05$) reduced in doubles (S: 5.0±0.8 vs D: 3.0±0.2 strokes; 6.5±1.1 vs 2.8±0.2 s). Distribution of stroke techniques differed between competition forms with higher rates in serve (S: 27.4±5.0 vs D: 33.6±2.9%), return (S: 15.4±2.3 vs D: 20.2±2.1%) and volley (S: 2.2±1.7% vs D: 18.8±8.1) for doubles and with reduced rates for baseline strokes (S: 53.3±5.1% vs D: 22.8±8.5%). Regarding the service, first (S: 57.5±5.1% vs D: 55.5±4.6%) and second serve accuracy (S: 89.6±4.6% vs D: 86.4±8.5%), and serve velocities (S: 158.3±7.8km/h vs D: 156.4±7.5km/h) showed no differences ($p>0.05$), while more aces were found in singles (S:5.5±3.5 vs D: 2.0±1.8). Further, the first and second serve from the deuce court side is served considerably less wide (S: 29.9±16.6% vs D: 8.4±9.2%) compared to singles. The serve and volley strategy showed a trend to be used more often in doubles (S: 3.8±8.5 vs D: 15.0±19.6%; p= 0.06).
CONCLUSION: Results of this study e.g. serve accuracy and service velocity underline that there are still differences but also a convergence in performance profiles in elite juniors between single and double matches compared to former dates. Due to a reduction of the serve & volley strategy there is an increase in baseline game and service power. Regarding ATP TOP 10 doubles players, most of them still apply serve & volley. Therefore, coaches must consider a longitudinal perspective in teaching doubles to juniors.

THE ACUTE EFFECT OF DYNAMIC STRETCHING COMBINED WITH VIBRATION ROLLING DURING WARM-UPS ON SPORTS PERFORMANCE IN BADMINTON ATHLETES

LIN, W., LEE, C., CHANGA, N.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Dynamic stretching (DS) is suggested to perform prior to the specific exercise increase the joint range of motion, muscle strength and explosive power; however, the ideal warm-up method is yet to be concluded. Vibration therapy may be an alternative method. Whole body vibration (WBV) improves sports performance (1). However, the application of WBV in the sideline sports is not practical. Recently designed vibrating foam rollers (VR) have emerged. The concept is designed by merged with self-myofascial release technique and a local vibration function for improving fascia release and muscular activation concurrently. Our previous study showed that VR significantly increased the quadriceps muscle strength and dynamic balance in the health adults (2). However, few literatures have explored that the effects of DS combined with VR (DS+VR) during warm-ups on muscle tone, flexibility, dynamic balance, power, and agility in badminton athletes. Therefore, this study aims investigate the acute effect of DS+VR as warm-ups protocol on sports performance in badminton player.
METHODS: This study was a crossover study. Forty college badminton team students (age: 21.6± 1.9y, body mass: 22.5 ± 2.5 kg/m2, weight: 64.6 ± 10.7 kg, height: 1.6 ± 0.9 m) were randomized to perform DS and DS+VR as warm-up protocols. Each participant performed two warm-up exercises on two separate occasions in a randomized order, with 48 hours of rest between each test. The main outcomes included muscle stiffness by MyotonPro, flexibility as determined by popliteus angle and Ely's test, dynamic balance by Y-Balance test (YBT), counter movement jump test, agility test using fitLight system were measured before and after warm-ups. A 2 (time: pretest vs. posttest) × 2 (condition: VR+DS vs. DS) repeated analysis of variance was performed to examine the effects of different conditions on dependent variables.
RESULTS: Our results indicated that VR attributes improved muscle performance. Compared with the preintervention, VR significantly reduced stiffness, increased flexibly, particular in hamstring, and increased dynamic balance, jump height as well as agility ability. Compared to DS, DS+VR had significantly more effective benefits in reducing muscle stiffness by 43%, enhancing dynamic balance by 14%, promoting agility ability by 11%.
CONCLUSION: This study investigation provides a new protocol to warm-up for acute effects on the sport sidelines. Additional VR with DS warm-up significantly reduced muscle stiffness without flexibility and balance decrements. Furthermore, DS+VR was significantly more effective than DS alone in increasing agility and balance. Hence, we recommend additional VR with DS warm-up regimen in badminton players to improve athletic performance.

A 10 YEARS' RETROSPECTIVE STUDY OF TOP RANKED TENNIS PLAYERS ABOUT THEIR PHYSICAL PRECONDITIONS IN YOUNG AGE

FETT, J., FÜHNER, T., VUONG, J., ULBRICHT, A., FERRAUTI, A.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: The modern game of tennis has evolved from being a primarily technique-based sport to an explosive sport, and has thus increasingly become more dynamic and faster. It is presently characterized by strength, speed, and power with higher stroke and serve velocities, that require a notably higher level of physical fitness [1]. This 10 yrs. longitudinal study investigates the sensitivity of physical performance components in young age to predict the complex tennis performance. Therefore, the aim of this study was to analyze the impact of athletic performance during youth for reaching the top class of national and international tennis.
METHODS: A total data set from 1727 (males = 1020; females = 707) elite junior squad players of the German Tennis Federation completed a biannual nationwide physical testing in the period from September 2009 to March 2018. From the tested individuals we determined those players being nationally (N) or internationally (I) ranked. Based on their ranking position the tested players are classified into one of the following categories (N: no ranking; N 500-201, N 200-101, N100-1; I: no ranking, I >500, I500-1). ANOVA was used to determine differences between the ranking classes regarding the physical performance tests.
RESULTS: Sample sizes for national ranking list were as follow: no ranking (40% males, 29% females), N500-201 (32% males, 28% females), N200-101 (15% males, 22% females) and N100-1 (14% males, 22% females). Respectively for international ranking: no ranking (80% males, 84% females) I>500 (15% males, 11% females) and I500-1 (5% males, 6% females). ANOVA indicated significant differences ($p \leq 0.05$) between the ranking classes for serve velocity and the tennis-specific endurance for both, the national and international ranking list, with better values for higher ranking classes. Further, body height was predictive for males and body weight for females. No effects ($p>0.05$) were found for tapping, standing long jump, 20m sprint, tennis specific sprint test, flexibility and push up. The prediction of later international success increased with age.
CONCLUSION: The obtained results can help coaches, parents and youth tennis players to be sensitive to a realistic career planning because the aspired international success is reserved for only few players. Regarding the athletic performance, results emphasize the importance of the serve velocity and the tennis specific endurance already under the age of 12 years as a predictor for a (later) high tennis performance and should be considered in the framework of talent identification and training prescription.
